PMULHRSW VPMULHRSW Packed Multiply High with Round and Scale Words

Multiplies each packed 16-bit signed value in the first source operand by the corresponding value in the second source operand, truncates the 32-bit product to the 18 most significant bits by right-shifting, then rounds the truncated value by adding 1 to its least-significant bit. Writes bits [16:1] of the sum to the corresponding word of the destination.

There are legacy and extended forms of the instruction:

PMULHRSW

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The first source register is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VPMULHRSW

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is either a YMM register or a 256-bit memory location. The destination is a third YMM register.

PMULUDQ Packed Multiply
VPMULUDQ Unsigned Doubleword to Quadword

Multiplies two or four pairs of 32-bit unsigned integers in the first and second source operands and writes two or four packed quadword unsigned integer products to the destination.

For the 128-bit form of the instruction, the following operations are performed:

dest is the destination register – either an XMM register or the corresponding YMM register.
src1 is the first source operand. src2 is the second source operand.

```
dest[63:0] = (src1[31:0] * src2[31:0])
dest[127:64] = (src1[95:64] * src2[95:64])
```

Additionally, for the 256-bit form of the instruction, the following operations are performed:

```
dest[191:128] = (src1[159:128] * src2[159:128])
dest[255:192] = (src1[223:192] * src2[223:192])
```

There are legacy and extended forms of the instruction:

PMULUDQ

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The first source register is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VPMULUDQ

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is either a YMM register or a 256-bit memory location. The destination is a third YMM register.

Page fault, #PF		S	X	Instruction execution caused a page fault.

X — SSE, AVX, and AVX2 exception
A — AVX, AVX2 exception
S — SSE exception

POR Packed OR
VPOR

Performs a bitwise OR of the first and second source operands and writes the result to the destination. When one or both of a pair of corresponding bits in the first and second operands are set, the corresponding bit of the destination is set; when neither source bit is set, the destination bit is cleared.

There are legacy and extended forms of the instruction:

POR

The first source operand is an XMM register and the second source operand is either an XMM register or a 128-bit memory location. The first source XMM register is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VPOR

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

The first source operand is an XMM register and the second source operand is either an XMM register or a 128-bit memory location. The destination is an XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is either a YMM register or a 256-bit memory location. The destination is a third YMM register.

Instruction Support

PSADBW VPSADBW — Packed Sum of Absolute Differences Bytes to Words

Subtracts the 16 or 32 packed 8-bit unsigned integers in the second source operand from the corresponding values in the first source operand and computes the absolute value of the differences. Computes two or four unsigned 16-bit integer sums of groups of eight absolute differences and writes the sums to specific words of the destination.

For the 128-bit form of the instruction:

- The unsigned 16-bit integer sum of absolute differences of the eight bytes [7:0] of the source operands is written to bits [15:0] of the destination; bits [63:16] are cleared.
- The unsigned 16-bit integer sum of absolute differences of the eight bytes [15:8] of the source operands is written to bits [79:64] of the destination; bits [127:80] are cleared.

Additionally, for the 256-bit form of the instruction:

- The unsigned 16-bit integer sum of absolute differences of the eight bytes [23:16] of the source operands is written to bits [143:128] of the destination; bits [191:144] are cleared.
- The unsigned 16-bit integer sum of absolute differences of the eight bytes [24:31] of the source operands is written to bits [207:192] of the destination; bits [255:208] are cleared.

There are legacy and extended forms of the instruction:

PSADBW

The first source operand is an XMM register and the second source operand is either an XMM register or a 128-bit memory location. The first source XMM register is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VPSADBW

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

The first source operand is an XMM register and the second source operand is either an XMM register or a 128-bit memory location. The destination is an XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is either a YMM register or a 256-bit memory location. The destination is a third YMM register.

Instruction Support

Form	Subset	Feature Flag
PSADBW	SSE2	CPUID Fn0000_0001_EDX[SSE2] (bit 26)
VPSADBW 128-bit	AVX	CPUID Fn0000_0001_ECX[AVX] (bit 28)
VPSADBW 256-bit	AVX2	CPUID Fn0000_0007_EBX[AVX2]_x0 (bit 5)

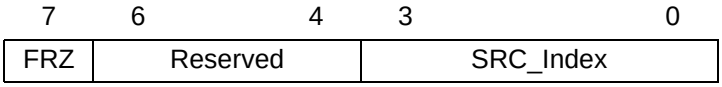
PSHUFB VPSHUFB — Packed Shuffle Byte

Copies bytes from the first source operand to the destination or clears bytes in the destination, as specified by control bytes in the second source operand.

The control bytes occupy positions in the source operand that correspond to positions in the destination. Each control byte has the following fields.



Bits	Description
[7]	Set the bit to clear the corresponding byte of the destination. Clear the bit to copy the selected source byte to the corresponding byte of the destination.
[6:4]	Reserved
[3:0]	Binary value selects the source byte.

For the 256-bit form of the instruction, the SRC_Index fields in the upper 16 bytes of the second source operand select bytes in the upper 16 bytes of the first source operand to be copied.

There are legacy and extended forms of the instruction:

PSHUFB

The first source operand is an XMM register and the second source operand is either an XMM register or a 128-bit memory location. The first source XMM register is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VPSHUFB

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

The first source operand is an XMM register and the second source operand is either an XMM register or a 128-bit memory location. The destination is an XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is either a YMM register or a 256-bit memory location. The destination is a third YMM register.

PSHUFD
VPSHUFD
Packed Shuffle Doublewords

Copies packed doubleword values from a source to a doubleword in the destination, as specified by bit fields of an immediate byte operand. A source doubleword can be copied more than once.

Source doublewords are selected by two-bit fields in the immediate-byte operand. Each field corresponds to a destination doubleword, as shown:

Destination Doubleword	Immediate-Byte Bit Field	Value of Bit Field	Source Doubleword
[31:0]	[1:0]	00	[31:0]
		01	[63:32]
		10	[95:64]
		11	[127:96]
[63:32]	[3:2]	00	[31:0]
		01	[63:32]
		10	[95:64]
		11	[127:96]
[95:64]	[5:4]	00	[31:0]
		01	[63:32]
		10	[95:64]
		11	[127:96]
[127:96]	[7:6]	00	[31:0]
		01	[63:32]
		10	[95:64]
		11	[127:96]

For the 256-bit form of the instruction, the same immediate byte selects doublewords in the upper 128-bits of the source operand to be copied to the destination.

Destination Doubleword	Immediate-Byte Bit Field	Value of Bit Field	Source Doubleword
[159:128]	[1:0]	00	[159:128]
		01	[191:160]
		10	[223:192]
		11	[225:224]
[191:160]	[3:2]	00	[159:128]
		01	[191:160]
		10	[223:192]
		11	[225:224]

Destination Doubleword	Immediate-Byte Bit Field	Value of Bit Field	Source Doubleword
[223:192]	[5:4]	00	[159:128]
		01	[191:160]
		10	[223:192]
		11	[225:224]
[255:224]	[7:6]	00	[159:128]
		01	[191:160]
		10	[223:192]
		11	[225:224]

There are legacy and extended forms of the instruction:

PSHUFD

The source operand is either an XMM register or a 128-bit memory location. The destination is an XMM register. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VPSHUFD

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

The source operand is either an XMM register or a 128-bit memory location. The destination is an XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

The source operand is either a YMM register or a 256-bit memory location. The destination is a YMM register.

Instruction Support

Form	Subset	Feature Flag
PSHUFD	SSE2	CPUID Fn0000_0001_EDX[SSE2] (bit 26)
VPSHUFD 128-bit	AVX	CPUID Fn0000_0001_ECX[AVX] (bit 28)
VPSHUFD 256-bit	AVX2	CPUID Fn0000_0007_EBX[AVX2]_x0 (bit 5)

For more on using the CPUID instruction to obtain processor feature support information, see Appendix E of Volume 3.

Instruction Encoding

Mnemonic	Opcode	Description
PSHUFD *xmm1*, *xmm2/mem128*, *imm8*	66 0F 70 /r ib	Copies packed 32-bit values from *xmm2* or *mem128* to *xmm1*, as specified by *imm8*.

PSHUFHW VPSHUFHW — Packed Shuffle High Words

Copies packed word values from the high quadword of the source operand or the upper quadwords of two halves of the source operand to a word in the high quadword of the destination or the upper quadwords of two halves of the destination, as specified by bit fields of an immediate byte operand. A source word can be copied more than once.

Source words are selected by two-bit fields in the immediate-byte operand. Each field corresponds to a destination word, as shown:

Destination Word	Immediate-Byte Bit Field	Value of Bit Field	Source Word
[79:64]	[1:0]	00	[79:64]
		01	[95:80]
		10	[111:96]
		11	[127:112]
[95:80]	[3:2]	00	[79:64]
		01	[95:80]
		10	[111:96]
		11	[127:112]
[111:96]	[5:4]	00	[79:64]
		01	[95:80]
		10	[111:96]
		11	[127:112]
[127:112]	[7:6]	00	[79:64]
		01	[95:80]
		10	[111:96]
		11	[127:112]

The least-significant quadword of the source is copied to the corresponding quadword of the destination.

For the 256-bit form of the instruction, the same immediate byte selects words in the most-significant quadword of the source operand to be copied to the destination:

Destination Word	Immediate-Byte Bit Field	Value of Bit Field	Source Word
[207:192]	[1:0]	00	[207:192]
		01	[223:208]
		10	[239:224]
		11	[255:240]

Destination Word	Immediate-Byte Bit Field	Value of Bit Field	Source Word
[223:208]	[3:2]	00	[207:192]
		01	[223:208]
		10	[239:224]
		11	[255:240]
[239:224]	[5:4]	00	[207:192]
		01	[223:208]
		10	[239:224]
		11	[255:240]
[255:240]	[7:6]	00	[207:192]
		01	[223:208]
		10	[239:224]
		11	[255:240]

The least-significant quadword of the upper 128 bits of the source is copied to the corresponding quadword of the destination.

There are legacy and extended forms of the instruction:

PSHUFHW

The source operand is either an XMM register or a 128-bit memory location. The destination is an XMM register. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VPSHUFHW

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

The source operand is either an XMM register or a 128-bit memory location. The destination is an XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

The source operand is either a YMM register or a 256-bit memory location. The destination is a YMM register.

Instruction Support

[47:32]	[5:4]	00	[15:0]
		01	[31:16]
		10	[47:32]
		11	[63:48]
[63:48]	[7:6]	00	[15:0]
		01	[31:16]
		10	[47:32]
		11	[63:48]

The most-significant quadword of the source is copied to the corresponding quadword of the destination.

For the 256-bit form of the instruction, the same immediate byte selects words in the lower quadword of the upper 128 bits of the source operand to be copied to the destination:

Destination Word	Immediate-Byte Bit Field	Value of Bit Field	Source Word
[143:128]	[1:0]	00	[143:128]
		01	[159:144]
		10	[175:160]
		11	[191:176]

Destination Word	Immediate-Byte Bit Field	Value of Bit Field	Source Word
[159:144]	[3:2]	00	[143:128]
		01	[159:144]
		10	[175:160]
		11	[191:176]
[175:160]	[5:4]	00	[143:128]
		01	[159:144]
		10	[175:160]
		11	[191:176]
[191:176]	[7:6]	00	[143:128]
		01	[159:144]
		10	[175:160]
		11	[191:176]

The most-significant quadword of the upper 128 bits of the source is copied to the corresponding quadword of the destination.

There are legacy and extended forms of the instruction:

PSHUFLW

The source operand is either an XMM register or a 128-bit memory location. The destination is an XMM register. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VPSHUFLW

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

The source operand is either an XMM register or a 128-bit memory location. The destination is an XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

The source operand is either a YMM register or a 256-bit memory location. The destination is a YMM register.

Instruction Support

Form	Subset	Feature Flag
PSHUFLW	SSE2	CPUID Fn0000_0001_EDX[SSE2] (bit 26)
VPSHUFLW 128-bit	AVX	CPUID Fn0000_0001_ECX[AVX] (bit 28)
VPSHUFLW 256-bit	AVX2	CPUID Fn0000_0007_EBX[AVX2]_x0 (bit 5)

For more on using the CPUID instruction to obtain processor feature support information, see Appendix E of Volume 3.

PSLLD VPSLLD Packed Shift Left Logical Doublewords

Left-shifts each packed 32-bit value in the source operand as specified by a shift-count operand and writes the shifted values to the destination.

The shift-count operand can be an immediate byte, a second register, or a memory location. The shift count is treated as an unsigned integer. When the shift count is provided by a register or memory location, only bits [63:0] of the value are considered.

Low-order bits emptied by shifting are cleared. When the shift count is greater than 31, the destination is cleared.

There are legacy and extended forms of the instruction:

PSLLD

There are two forms of the instruction, based on the type of count operand.

The first source operand is an XMM register. The shift count is specified by either a second XMM register or a 128-bit memory location, or by an immediate 8-bit operand. The first source XMM register is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VPSLLD

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

There are two 128-bit encodings. These differ based on the type of count operand.

The first source operand is an XMM register. The shift count is specified by either a second XMM register or a 128-bit memory location, or by an immediate 8-bit operand. The destination is an XMM register. For the immediate operand encoding, the destination is specified by VEX.vvvv. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

There are two 256-bit encodings. These differ based on the type of count operand.

The first source operand is a YMM register. The shift count is specified by either a second XMM register or a 128-bit memory location, or by an immediate 8-bit operand. The destination is a YMM register. For the immediate operand encoding, the destination is specified by VEX.vvvv.

PSLLDQ VPSLLDQ — Packed Shift Left Logical Double Quadword

Left-shifts the one or each of the two double quadword values in the source operand the number of bytes specified by an immediate byte operand and writes the shifted values to the destination.

The immediate byte operand supplies an unsigned shift count. Low-order bytes emptied by shifting are cleared. When the shift value is greater than 15, the destination is cleared. For the 256-bit form of the instruction, the shift count is applied to both the upper and the lower double quadword. Bytes shifted out of the lower 128 bits are not shifted into the upper.

There are legacy and extended forms of the instruction:

PSLLDQ

The source XMM register is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VPSLLDQ

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

The source operand is an XMM register. The destination is an XMM register specified by VEX.vvvv. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

The source operand is a YMM register. The destination is a YMM register specified by VEX.vvvv.

PSLLQ VPSLLQ Packed Shift Left Logical Quadwords

Left-shifts each packed 64-bit value in the source operand as specified by a shift-count operand and writes the shifted values to the destination.

The shift-count operand can be an immediate byte, a second register, or a memory location. The shift count is treated as an unsigned integer. When the shift count is provided by a register or memory location, only bits [63:0] of the value are considered.

Low-order bits emptied by shifting are cleared. When the shift value is greater than 63, the destination is cleared.

There are legacy and extended forms of the instruction:

PSLLQ

There are two forms of the instruction, based on the type of count operand.

The first source operand is an XMM register. The shift count is specified by either a second XMM register or a 128-bit memory location, or by an immediate 8-bit operand. The first source XMM register is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VPSLLQ

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

There are two 128-bit encodings. These differ based on the type of count operand.

The first source operand is an XMM register. The shift count is specified by either a second XMM register or a 128-bit memory location, or by an immediate 8-bit operand. The destination is an XMM register. For the immediate operand encoding, the destination is specified by VEX.vvvv. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

There are two 256-bit encodings. These differ based on the type of count operand.

The first source operand is a YMM register. The shift count is specified by either a second XMM register or a 128-bit memory location, or by an immediate 8-bit operand. The destination is a YMM register. For the immediate operand encoding, the destination is specified by VEX.vvvv.

PSLLW VPSLLW — Packed Shift Left Logical Words

Left-shifts each packed 16-bit value in the source operand as specified by a shift-count operand and writes the shifted values to the destination.

The shift-count operand can be an immediate byte, a second register, or a memory location. The shift count is treated as an unsigned integer. When the shift count is provided by a register or memory location, only bits [63:0] of the value are considered.

Low-order bits emptied by shifting are cleared. When the shift count is greater than 15, the destination is cleared.

There are legacy and extended forms of the instruction:

PSLLW

There are two forms of the instruction, based on the type of count operand.

The first source operand is an XMM register. The shift count is specified by either a second XMM register or a 128-bit memory location, or by an immediate 8-bit operand. The first source XMM register is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VPSLLW

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

There are two 128-bit encodings. These differ based on the type of count operand.

The first source operand is an XMM register. The shift count is specified by either a second XMM register or a 128-bit memory location, or by an immediate 8-bit operand. The destination is an XMM register. For the immediate operand encoding, the destination is specified by VEX.vvvv. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

There are two 256-bit encodings. These differ based on the type of count operand.

The first source operand is a YMM register. The shift count is specified by either a second XMM register or a 128-bit memory location, or by an immediate 8-bit operand. The destination is a YMM register. For the immediate operand encoding, the destination is specified by VEX.vvvv.

PSRAD VPSRAD Packed Shift Right Arithmetic Doublewords

Right-shifts each packed 32-bit value in the source operand as specified by a shift-count operand and writes the shifted values to the destination.

The shift-count operand can be an immediate byte, a second register, or a memory location. The shift count is treated as an unsigned integer. When the shift count is provided by a register or memory location, only bits [63:0] of the value are considered.

High-order bits emptied by shifting are filled with the sign bit of the initial value. When the shift value is greater than 31, each doubleword of the destination is filled with the sign bit of its initial value.

There are legacy and extended forms of the instruction:

PSRAD

There are two forms of the instruction, based on the type of count operand.

The first source operand is an XMM register. The shift count is specified by either a second XMM register or a 128-bit memory location, or by an immediate 8-bit operand. The first source XMM register is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VPSRAD

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

There are two 128-bit encodings. These differ based on the type of count operand.

The first source operand is an XMM register. The shift count is specified by either a second XMM register or a 128-bit memory location, or by an immediate 8-bit operand. The destination is an XMM register. For the immediate operand encoding, the destination is specified by VEX.vvvv. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

There are two 256-bit encodings. These differ based on the type of count operand.

The first source operand is a YMM register. The shift count is specified by either a second XMM register or a 128-bit memory location, or by an immediate 8-bit operand. The destination is a YMM register. For the immediate operand encoding, the destination is specified by VEX.vvvv.

PSRLDQ VPSRLDQ — Packed Shift Right Logical Double Quadword

Right-shifts one or each of two double quadword values in the source operand the number of bytes specified by an immediate byte operand and writes the shifted values to the destination.

The immediate byte operand supplies an unsigned shift count. High-order bytes emptied by shifting are cleared. When the shift value is greater than 15, the destination is cleared. For the 256-bit form of the instruction, the shift count is applied to both the upper and the lower double quadword. Bytes shifted out of the upper 128 bits are not shifted into the lower.

There are legacy and extended forms of the instruction:

PSRLDQ

The source XMM register is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VPSRLDQ

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

The source operand is an XMM register. The destination is an XMM register specified by VEX.vvvv. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

The source operand is a YMM register. The destination is a YMM register specified by VEX.vvvv.

PSRLQ VPSRLQ Packed Shift Right Logical Quadwords

Right-shifts each packed 64-bit value in the source operand as specified by a shift-count operand and writes the shifted values to the destination.

The shift-count operand can be an immediate byte, a second register, or a memory location. The shift count is treated as an unsigned integer. When the shift count is provided by a register or memory location, only bits [63:0] of the value are considered.

High-order bits emptied by shifting are cleared. When the shift value is greater than 63, the destination is cleared.

There are legacy and extended forms of the instruction:

PSRLQ

There are two forms of the instruction, based on the type of count operand.

The first source operand is an XMM register. The shift count is specified by either a second XMM register or a 128-bit memory location, or by an immediate 8-bit operand. The first source XMM register is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VPSRLQ

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

There are two 128-bit encodings. These differ based on the type of count operand.

The first source operand is an XMM register. The shift count is specified by either a second XMM register or a 128-bit memory location, or by an immediate 8-bit operand. The destination is an XMM register. For the immediate operand encoding, the destination is specified by VEX.vvvv. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

There are two 256-bit encodings. These differ based on the type of count operand.

The first source operand is a YMM register. The shift count is specified by either a second XMM register or a 128-bit memory location, or by an immediate 8-bit operand. The destination is a YMM register. For the immediate operand encoding, the destination is specified by VEX.vvvv.

PSRLW VPSRLW — Packed Shift Right Logical Words

Right-shifts each packed 16-bit value in the source operand as specified by a shift-count operand and writes the shifted values to the destination.

The shift-count operand can be an immediate byte, a second register, or a memory location. The shift count is treated as an unsigned integer. When the shift count is provided by a register or memory location, only bits [63:0] of the value are considered.

High-order bits emptied by shifting are cleared. When the shift value is greater than 15, the destination is cleared.

There are legacy and extended forms of the instruction:

PSRLW

There are two forms of the instruction, based on the type of count operand.

The first source operand is an XMM register. The shift count is specified by either a second XMM register or a 128-bit memory location, or by an immediate 8-bit operand. The first source XMM register is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VPSRLW

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

There are two 128-bit encodings. These differ based on the type of count operand.

The first source operand is an XMM register. The shift count is specified by either a second XMM register or a 128-bit memory location, or by an immediate 8-bit operand. The destination is an XMM register. For the immediate operand encoding, the destination is specified by VEX.vvvv. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

There are two 256-bit encodings. These differ based on the type of count operand.

The first source operand is a YMM register. The shift count is specified by either a second XMM register or a 128-bit memory location, or by an immediate 8-bit operand. The destination is a YMM register. For the immediate operand encoding, the destination is specified by VEX.vvvv.

PSUBB VPSUBB — Packed Subtract Bytes

Subtracts 16 or 32 packed 8-bit integer values in the second source operand from the corresponding values in the first source operand and writes the integer differences to the corresponding bytes of the destination.

This instruction operates on both signed and unsigned integers. When a result overflows, the carry is ignored (neither the overflow nor carry bit in rFLAGS is set), and only the low-order 8 bits of each result are written to the destination.

There are legacy and extended forms of the instruction:

PSUBB

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The first source register is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VPSUBB

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is either a YMM register or a 256-bit memory location. The destination is a third YMM register.

PSUBSW VPSUBSW Packed Subtract Signed With Saturation Words

Subtracts eight or sixteen packed 16-bit signed integer values in the second source operand from the corresponding values in the first source operand and writes the signed integer differences to the corresponding word of the destination.

Positive differences greater than 7FFFh are saturated to 7FFFh; negative differences less than 8000h are saturated to 8000h.

There are legacy and extended forms of the instruction:

PSUBSW

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The first source register is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VPSUBSW

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is either a YMM register or a 256-bit memory location. The destination is a third YMM register.

PSUBW VPSUBW — Packed Subtract Words

Subtracts eight or sixteen packed 16-bit integer values in the second source operand from the corresponding values in the first source operand and writes the integer differences to the corresponding word of the destination.

This instruction operates on both signed and unsigned integers. When a result overflows, the carry is ignored (neither the overflow nor carry bit in rFLAGS is set), and only the low-order 8 bits of each result are written to the destination.

There are legacy and extended forms of the instruction:

PSUBW

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The first source register is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VPSUBW

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is either a YMM register or a 256-bit memory location. The destination is a third YMM register.

PTEST Packed Bit Test
VPTEST

First, performs a bitwise AND of the first source operand with the second source operand. Sets rFLAGS.ZF when all bit operations = 0; else, clears ZF.

Second. performs a bitwise AND of the second source operand with the logical complement (NOT) of the first source operand. Sets rFLAGS.CF when all bit operations = 0; else, clears CF.

Neither source operand is modified.

There are legacy and extended forms of the instruction:

PTEST

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location.

VPTEST

The extended form of the instruction has both 128-bit and 256-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location.

YMM Encoding

The first source operand is a YMM register. The second source operand is a YMM register or 256-bit memory location.

Instruction Support

Form	Subset	Feature Flag

PUNPCKHBW VPUNPCKHBW — Unpack and Interleave High Bytes

Unpacks the 8 high-order bytes of each octword the first and second source operands and interleaves the bytes as they are copied to the destination. The low-order bytes of each octword of the source operands are ignored.

Bytes are interleaved in ascending order from the least-significant byte of the upper 8 bytes of each octword of the source operands with bytes from the first source operand occupying the lower byte of each pair copied to the destination.

For the 128-bit form of the instruction, the following operations are performed:

```
dest[7:0] = src1[71:64]
dest[15:8] = src2[71:64]
dest[23:16] = src1[79:72]
dest[31:24] = src2[79:72]
dest[39:32] = src1[87:80]
dest[47:40] = src2[87:80]
dest[55:48] = src1[95:88]
dest[63:56] = src2[95:88]
dest[71:64] = src1[103:96]
dest[79:72] = src2[103:96]
dest[87:80] = src1[111:104]
dest[95:88] = src2[111:104]
dest[103:96] = src1[119:112]
dest[111:104] = src2[119:112]
dest[119:112] = src1[127:120]
dest[127:120] = src2[127:120]
```

Additionally, for the 256-bit form of the instruction, the following operations are performed:

```
dest[135:128] = src1[199:192]
dest[143:136] = src2[199:192]
dest[151:144] = src1[207:200]
dest[159:152] = src2[207:200]
dest[167:160] = src1[215:208]
dest[175:168] = src2[215:208]
dest[183:176] = src1[223:216]
dest[191:184] = src2[223:216]
dest[199:192] = src1[231:224]
dest[207:200] = src2[231:224]
dest[215:208] = src1[239:232]
dest[223:216] = src2[239:232]
dest[231:224] = src1[247:240]
dest[239:232] = src2[247:240]
dest[247:240] = src1[255:248]
dest[255:248] = src2[255:248]
```

When the second source operand is all 0s, the destination effectively contains the 8 high-order bytes from the first source operand or the 8 high-order bytes from both octwords of the first source operand zero-extended to 16 bits. This operation is useful for expanding unsigned 8-bit values to unsigned 16-bit operands for subsequent processing that requires higher precision.

There are legacy and extended forms of the instruction:

PUNPCKHBW

The first source operand is an XMM register and the second source operand is either an XMM register or a 128-bit memory location. The first source operand is also the destination register. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VPUNPCKHBW

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is either a YMM register or a 256-bit memory location. The destination is a third YMM register.

Instruction Support

X — SSE, AVX, and AVX2 exception
A — AVX, AVX2 exception
S — SSE exception

PUNPCKHDQ VPUNPCKHDQ — Unpack and Interleave High Doublewords

Unpacks the two high-order doublewords of each octword of the first and second source operands and interleaves the doublewords as they are copied to the destination. The low-order doublewords of each octword of the source operands are ignored.

Doublewords are interleaved in ascending order from the least-significant doubleword of the high quadword of each octword with doublewords from the first source operand occupying the lower doubleword of each pair copied to the destination.

For the 128-bit form of the instruction, the following operations are performed:

```
dest[31:0] = src1[95:64]
dest[63:32] = src2[95:64]
dest[95:64] = src1[127:96]
dest[127:96] = src2[127:96]
```

Additionally, for the 256-bit form of the instruction, the following operations are performed:

```
dest[159:128] = src1[223:192]
dest[191:160] = src2[223:192]
dest[223:192] = src1[255:224]
dest[255:224] = src2[255:224]
```

When the second source operand is all 0s, the destination effectively receives the 2 high-order doublewords from the first source operand or the 2 high-order doublewords from both octwords of the first source operand zero-extended to 64 bits. This operation is useful for expanding unsigned 32-bit values to unsigned 64-bit operands for subsequent processing that requires higher precision.

There are legacy and extended forms of the instruction:

PUNPCKHDQ

The first source operand is an XMM register and the second source operand is an XMM register or 128-bit memory location. The first source operand is also the destination register. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VPUNPCKHDQ

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is either a YMM register or a 256-bit memory location. The destination is a third YMM register.

PUNPCKHQDQ VPUNPCKHQDQ Unpack and Interleave High Quadwords

Unpacks the high-order quadword of each octword of the first and second source operands and interleaves the quadwords as they are copied to the destination. The low-order quadword of each octword of the source operands is ignored.

Quadwords are interleaved in ascending order with the high-order quadword from the first source operand or each octword of the first source operand occupying the lower quadword of corresponding octword of the destination.

For the 128-bit form of the instruction, the following operations are performed:

```
dest[63:0] = src1[127:64]
dest[127:64] = src2[127:64]
```

Additionally, for the 256-bit form of the instruction, the following operations are performed:

```
dest[191:128] = src1[255:192]
dest[255:192] = src2[255:192]
```

When the second source operand is all 0s, the destination effectively receives the quadword from upper half of the first source operand or the high-order quadwords from each octword of the first source operand zero-extended to 128 bits. This operation is useful for expanding unsigned 64-bit values to unsigned 128-bit operands for subsequent processing that requires higher precision.

There are legacy and extended forms of the instruction:

PUNPCKHQDQ

The first source operand is an XMM register and the second source operand is an XMM register or 128-bit memory location. The first source operand is also the destination register. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VPUNPCKHQDQ

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is either a YMM register or a 256-bit memory location. The destination is a third YMM register.

PUNPCKHWD VPUNPCKHWD — Unpack and Interleave High Words

Unpacks the 4 high-order words of each octword of the first and second source operands and interleaves the words as they are copied to the destination. The low-order words of each octword of the source operands are ignored.

Words are interleaved in ascending order from the least-significant word of the high quadword of each octword with words from the first source operand occupying the lower word of each pair copied to the destination.

For the 128-bit form of the instruction, the following operations are performed:

```
dest[15:0] = src1[79:64]
dest[31:16] = src2[79:64]
dest[47:32] = src1[95:80]
dest[63:48] = src2[95:80]
dest[79:64] = src1[111:96]
dest[95:80] = src2[111:96]
dest[111:96] = src1[127:112]
dest[127:112] = src2[127:112]
```

Additionally, for the 256-bit form of the instruction, the following operations are performed:

```
dest[143:128] = src1[207:192]
dest[159:144] = src2[207:192]
dest[175:160] = src1[223:208]
dest[191:176] = src2[223:208]
dest[207:192] = src1[239:224]
dest[223:208] = src2[239:224]
dest[239:224] = src1[255:240]
dest[255:240] = src2[255:240]
```

When the second source operand is all 0s, the destination effectively receives the 4 high-order words from the first source operand or the 4 high-order words from both octwords of the first source operand and zero-extended to 32 bits. This operation is useful for expanding unsigned 16-bit values to unsigned 32-bit operands for subsequent processing that requires higher precision.

There are legacy and extended forms of the instruction:

PUNPCKHWD

The first source operand is an XMM register and the second source operand is either an XMM register or a 128-bit memory location. The first source operand is also the destination register. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VPUNPCKHWD

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is either a YMM register or a 256-bit memory location. The destination is a third YMM register.

PUNPCKLBW VPUNPCKLBW — Unpack and Interleave Low Bytes

Unpacks the 8 low-order bytes of each octword of the first and second source operands and interleaves the bytes as they are copied to the destination. The high-order bytes of each octword are ignored.

Bytes are interleaved in ascending order from the least-significant byte of source operands with bytes from the first source operand occupying the lower byte of each pair copied to the destination.

For the 128-bit form of the instruction, the following operations are performed:

```
dest[7:0] = src1[7:0]
dest[15:8] = src2[7:0]
dest[23:16] = src1[15:8]
dest[31:24] = src2[15:8]
dest[39:32] = src1[23:16]
dest[47:40] = src2[23:16]
dest[55:48] = src1[31:24]
dest[63:56] = src2[31:24]
dest[71:64] = src1[39:32]
dest[79:72] = src2[39:32]
dest[87:80] = src1[47:40]
dest[95:88] = src2[47:40]
dest[103:96] = src1[55:48]
dest[111:104] = src2[55:48]
dest[119:112] = src1[63:56]
dest[127:120] = src2[63:56]
```

Additionally, for the 256-bit form of the instruction, the following operations are performed:

```
dest[135:128] = src1[135:128]
dest[143:136] = src2[135:128]
dest[151:144] = src1[143:136]
dest[159:152] = src2[143:136]
dest[167:160] = src1[151:144]
dest[175:168] = src2[151:144]
dest[183:176] = src1[159:152]
dest[191:184] = src2[159:152]
dest[199:192] = src1[167:160]
dest[207:200] = src2[167:160]
dest[215:208] = src1[175:168]
dest[223:216] = src2[175:168]
dest[231:224] = src1[183:176]
dest[239:232] = src2[183:176]
dest[247:240] = src1[191:184]
dest[255:248] = src2[191:184]
```

When the second source operand is all 0s, the destination effectively receives the eight low-order bytes from the first source operand or the eight low-order bytes from both octwords of the first source operand zero-extended to 16 bits. This operation is useful for expanding unsigned 8-bit values to unsigned 16-bit operands for subsequent processing that requires higher precision.

There are legacy and extended forms of the instruction:

PUNPCKLBW

The first source operand is an XMM register and the second source operand is either an XMM register or a 128-bit memory location. The first source operand is also the destination register. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VPUNPCKLBW

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is either a YMM register or a 256-bit memory location. The destination is a third YMM register.

PUNPCKLDQ VPUNPCKLDQ — Unpack and Interleave Low Doublewords

Unpacks the two low-order doublewords of each octword of the first and second source operands and interleaves the doublewords as they are copied to the destination. The high-order doublewords of each octword of the source operands are ignored.

Doublewords are interleaved in ascending order from the least-significant doubleword of the sources with doublewords from the first source operand occupying the lower doubleword of each pair copied to the destination.

For the 128-bit form of the instruction, the following operations are performed:

```
dest[31:0] = src1[31:0]
dest[63:32] = src2[31:0]
dest[95:64] = src1[63:32]
dest[127:96] = src2[63:32]
```

Additionally, for the 256-bit form of the instruction, the following operations are performed:

```
dest[159:128] = src1[159:128]
dest[191:160] = src2[159:128]
dest[223:192] = src1[191:160]
dest[255:224] = src2[191:160]
```

When the second source operand is all 0s, the destination effectively receives the two low-order doublewords from the first source operand or the two low-order doublewords from both octwords of the source operand zero-extended to 64 bits. This operation is useful for expanding unsigned 32-bit values to unsigned 64-bit operands for subsequent processing that requires higher precision.

There are legacy and extended forms of the instruction:

PUNPCKLDQ

The first source operand is an XMM register and the second source operand is an XMM register or 128-bit memory location. The first source operand is also the destination register. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VPUNPCKLDQ

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is either a YMM register or a 256-bit memory location. The destination is a third YMM register.

PUNPCKLQDQ VPUNPCKLQDQ — Unpack and Interleave Low Quadwords

Unpacks the low-order quadword of each octword of the first and second source operands and interleaves the quadwords as they are copied to the destination. The high-order quadword of each octword of the source operands is ignored.

Quadwords are interleaved in ascending order from the least-significant quadword of the sources with quadwords from the first source operand occupying the lower quadword of each pair copied to the destination.

For the 128-bit form of the instruction, the following operations are performed:

```
dest[63:0] = src1[63:0]
dest[127:64] = src2[63:0]
```

Additionally, for the 256-bit form of the instruction, the following operations are performed:

```
dest[191:128] = src1[191:128]
dest[255:192] = src2[191:128]
```

When the second source operand is all 0s, the destination effectively receives the low-order quadword from the first source operand or the low-order quadword of both octwords of the first source operand zero-extended to 128 bits. This operation is useful for expanding unsigned 64-bit values to unsigned 128-bit operands for subsequent processing that requires higher precision.

There are legacy and extended forms of the instruction:

PUNPCKLQDQ

The first source operand is an XMM register and the second source operand is an XMM register or 128-bit memory location. The first source operand is also the destination register. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VPUNPCKLQDQ

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is either a YMM register or a 256-bit memory location. The destination is a third YMM register.

PUNPCKLWD VPUNPCKLWD — Unpack and Interleave Low Words

Unpacks the four low-order words of each octword of the first and second source operands and interleaves the words as they are copied to the destination. The high-order words of each octword of the source operands are ignored.

Words are interleaved in ascending order from the least-significant word of the source operands with words from the first source operand occupying the lower word of each pair copied to the destination.

For the 128-bit form of the instruction, the following operations are performed:

```
dest[15:0] = src1[15:0]
dest[31:16] = src2[15:0]
dest[47:32] = src1[31:16]
dest[63:48] = src2[31:16]
dest[79:64] = src1[47:32]
dest[95:80] = src2[47:32]
dest[111:96] = src1[63:48]
dest[127:112] = src2[63:48]
```

Additionally, for the 256-bit form of the instruction, the following operations are performed:

```
dest[143:128] = src1[143:128]
dest[159:144] = src2[143:128]
dest[175:160] = src1[159:144]
dest[191:176] = src2[159:144]
dest[207:192] = src1[175:160]
dest[223:208] = src2[175:160]
dest[239:224] = src1[191:176]
dest[255:240] = src2[191:176]
```

When the second source operand is all 0s, the destination effectively receives the 4 low-order words from the first source operand or the 4 low-order words of each octword of the first source operand zero-extended to 32 bits. This operation is useful for expanding unsigned 16-bit values to unsigned 32-bit operands for subsequent processing that requires higher precision.

There are legacy and extended forms of the instruction:

PUNPCKLWD

The first source operand is an XMM register and the second source operand is either an XMM register or a 128-bit memory location. The first source operand is also the destination register. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

PUNPCKLWD

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is either a YMM register or a 256-bit memory location. The destination is a third YMM register.

PXOR Packed Exclusive OR
VPXOR

Performs a bitwise XOR of the first and second source operands and writes the result to the destination. When either of a pair of corresponding bits in the first and second operands are set, the corresponding bit of the destination is set; when both source bits are set or when both source bits are not set, the destination bit is cleared.

There are legacy and extended forms of the instruction:

PXOR

The first source operand is an XMM register and the second source operand is either an XMM register or a 128-bit memory location. The first source XMM register is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VPXOR

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

RCPPS Reciprocal
VRCPPS Packed Single-Precision Floating-Point

Computes the approximate reciprocal of each packed single-precision floating-point value in the source operand and writes the results to the corresponding doubleword of the destination. MXCSR.RC as no effect on the result.

The maximum error is less than or equal to $1.5 * 2^{-12}$ times the true reciprocal. A source value that is ±zero or denormal returns an infinity of the source value sign. Results that underflow are changed to signed zero. For both SNaN and QNaN source operands, a QNaN is returned.

There are legacy and extended forms of the instruction:

RCPPS

Computes four reciprocals. The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The first source register is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VRCPPS

The extended form of the instruction has both 128-bit and 256-bit encodings:

XMM Encoding

Computes four reciprocals. The source operand is either an XMM register or a 128-bit memory location. The destination is an XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

Computes eight reciprocals. The source operand is either a YMM register or a 256-bit memory location. The destination is a YMM register.

Instruction Support

Form	Subset	Feature Flag
RCPPS	SSE2	CPUID Fn0000_0001_EDX[SSE2] (bit 26)
VRCPPS	AVX	CPUID Fn0000_0001_ECX[AVX] (bit 28)

RCPSS Reciprocal
VRCPSS Scalar Single-Precision Floating-Point

Computes the approximate reciprocal of the scalar single-precision floating-point value in a source operand and writes the results to the low-order doubleword of the destination. MXCSR.RC as no effect on the result.

The maximum error is less than or equal to $1.5 * 2^{-12}$ times the true reciprocal. A source value that is ±zero or denormal returns an infinity of the source value sign. Results that underflow are changed to signed zero. For both SNaN and QNaN source operands, a QNaN is returned.

There are legacy and extended forms of the instruction:

RCPSS

The source operand is either an XMM register or a 32-bit memory location. The destination is an XMM register. Bits [127:32] of the destination are not affected. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VRCPSS

The extended form of the instruction has a 128-bit encoding only.

The first source operand and the destination are XMM registers. The second source operand is either an XMM register or a 32-bit memory location. Bits [31:0] of the destination contain the reciprocal; bits [127:32] of the destination are copied from the first source register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

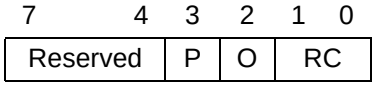
ROUNDPD Round
VROUNDPD Packed Double-Precision Floating-Point

Rounds two or four double-precision floating-point values as specified by an immediate byte operand. Source values are rounded to integral values and written to the destination as double-precision floating-point values.

SNaN source values are converted to QNaN. When DAZ =1, denormals are converted to zero before rounding.

The immediate byte operand is defined as follows.



Bits	Mnemonic	Description
[7:4]	—	Reserved
[3]	P	Precision Exception
[2]	O	Rounding Control Source
[1:0]	RC	Rounding Control

Precision exception definitions:

Value	Description
0	Normal PE exception
1	PE field is not updated. No precision exception is taken when unmasked.

Rounding control source definitions:

Value	Description
0	Use RC from immediate operand
1	Use RC from MXCSR

Rounding control definition:

Value	Description
00	Nearest
01	Downward (toward negative infinity)
10	Upward (toward positive infinity)
11	Truncated

There are legacy and extended forms of the instruction:

ROUNDPD

Rounds two source values. The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. There is a third 8-bit immediate operand. The first source register is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VROUNDPD

The extended form of the instruction has both 128-bit and 256-bit encodings:

XMM Encoding

Rounds two source values. The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. There is a third 8-bit immediate operand. The destination is a third XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

Rounds four source values. The first source operand is a YMM register and the second source operand is either a YMM register or a 256-bit memory location. There is a third 8-bit immediate operand. The destination is a third YMM register.

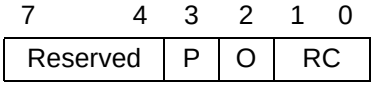
X — AVX and SSE exception *A — AVX exception* *S — SSE exception*				

ROUNDPS Round
VROUNDPS Packed Single-Precision Floating-Point

Rounds four or eight single-precision floating-point values as specified by an immediate byte operand. Source values are rounded to integral values and written to the destination as single-precision floating-point values.

SNaN source values are converted to QNaN. When DAZ =1, denormals are converted to zero before rounding.

The immediate byte operand is defined as follows.



Bits	Mnemonic	Description
[7:4]	—	Reserved
[3]	P	Precision Exception
[2]	O	Rounding Control Source
[1:0]	RC	Rounding Control

Precision exception definitions:

Value	Description
0	Normal PE exception
1	PE field is not updated. No precision exception is taken when unmasked.

Rounding control source definitions:

Value	Description
0	Use RC from immediate operand
1	Use RC from MXCSR

Rounding control definition:

Value	Description
00	Nearest
01	Downward (toward negative infinity)
10	Upward (toward positive infinity)
11	Truncated

There are legacy and extended forms of the instruction:

ROUNDPS

Rounds four source values. The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. There is a third 8-bit immediate operand. The first source register is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VROUNDPS

The extended form of the instruction has both 128-bit and 256-bit encodings:

XMM Encoding

Rounds four source values. The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. There is a third 8-bit immediate operand. The destination is a third XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

Rounds eight source values. The first source operand is a YMM register and the second source operand is either a YMM register or a 256-bit memory location. There is a third 8-bit immediate operand. The destination is a third YMM register.

Instruction Support

Form	Subset	Feature Flag
ROUNDPS	SSE4.1	CPUID Fn0000_0001_ECX[SSE41] (bit 19)
VROUNDPS	AVX	CPUID Fn0000_0001_ECX[AVX] (bit 28)

For more on using the CPUID instruction to obtain processor feature support information, see Appendix E of Volume 3.

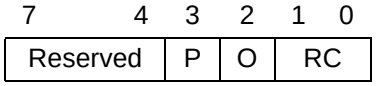
ROUNDSD Round
VROUNDSD Scalar Double-Precision

Rounds a scalar double-precision floating-point value as specified by an immediate byte operand. Source values are rounded to integral values and written to the destination as double-precision floating-point values.

SNaN source values are converted to QNaN. When DAZ =1, denormals are converted to zero before rounding.

The immediate byte operand is defined as follows.



Bits	Mnemonic	Description
[7:4]	—	Reserved
[3]	P	Precision Exception
[2]	O	Rounding Control Source
[1:0]	RC	Rounding Control

Precision exception definitions:

Value	Description
0	Normal PE exception
1	PE field is not updated. No precision exception is taken when unmasked.

Rounding control source definitions:

Value	Description
0	Use RC from immediate operand
1	Use RC from MXCSR

Rounding control definition:

Value	Description
00	Nearest
01	Downward (toward negative infinity)
10	Upward (toward positive infinity)
11	Truncated

There are legacy and extended forms of the instruction:

ROUNDSD

The source operand is either an XMM register or a 64-bit memory location. When the source is an XMM register, the value to be rounded must be in the low quadword. The destination is an XMM register. There is a third 8-bit immediate operand. Bits [127:64] of the destination are not affected. Bits [255:128] of the YMM register that corresponds to destination XMM register are not affected.

VROUNDSD

The extended form of the instruction has a 128-bit encoding only.

The first source operand is an XMM register. The second source operand is either an XMM register or a 64-bit memory location. The destination is a third XMM register. There is a fourth 8-bit immediate operand. Bits [127:64] of the destination are copied from the first source operand. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

Instruction Support

Form	Subset	Feature Flag
ROUNDSD	SSE4.1	CPUID Fn0000_0001_ECX[SSE41] (bit 19)

RSQRTPS Reciprocal Square Root
VRSQRTPS Packed Single-Precision Floating-Point

Computes the approximate reciprocal of the square root of each packed single-precision floating-point value in the source operand and writes the results to the corresponding doublewords of the destination. MXCSR.RC has no effect on the result.

The maximum error is less than or equal to $1.5 * 2^{-12}$ times the true reciprocal square root. A source value that is ±zero or denormal returns an infinity of the source value sign. Negative source values other than –zero and –denormal return a QNaN floating-point indefinite value. For both SNaN and QNaN source operands, a QNaN is returned.

There are legacy and extended forms of the instruction:

RSQRTPS

Computes four values. The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The first source register is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VRSQRTPS

The extended form of the instruction has both 128-bit and 256-bit encodings:

XMM Encoding

Computes four values. The destination is an XMM register. The source operand is either an XMM register or a 128-bit memory location. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

Computes eight values. The destination is a YMM register. The source operand is either a YMM register or a 256-bit memory location.

Instruction Support

Form	Subset	Feature Flag
RSQRTPS	SSE1	CPUID Fn0000_0001_EDX[SSE] (bit 25)
VRSQRTPS	AVX	CPUID Fn0000_0001_ECX[AVX] (bit 28)

For more on using the CPUID instruction to obtain processor feature support information, see Appendix E of Volume 3.

Instruction Encoding

Mnemonic	Opcode	Description

SHA1RNDS4 Four Rounds of SHA1

Execute 4 rounds of a SHA1 operation using the 4 double words (A, B, C, D) from the first source operand, and value E from the second operand. The lower two bits of the immediate are used to specify the function and constant appropriate for the current round of processing. The resulting (A, B, C, D) is placed in the destination register which is the same as the first source register.

The following function is performed:

```
A ← SRC1[127:96];
B ← SRC1[95:64];
C ← SRC1[63:32];
D ← SRC1[31:0];

W0E ← SRC2[127:96];
W1  ← SRC2[95:64];
W2  ← SRC2[63:32];
W3  ← SRC2[31:0];

i=imm[1:0]  which determines f_i and K_i

First Round operation:
A_1 ← f_ 0(B, C, D) + (A Rotate Left 5) +W0E +K_0;
B_1 ← A;
C_1 ← B Rotate Left 30;
D_1 ← C;
E_1 ← D;

FOR j = 1 to 3
{       A_(j +1) ← f_j(B_j, C_j, D_j) + (A_j Rotate Left 5) +Wj+ E_j +K_i;

        B_(j+1) <- A_j;

        C_(j +1) ← B_j Rotate Left 30;

        D_(j +1) ← C_j;
        E_(j +1) ← D_j;

}

DEST[127:96] ← A_4;
DEST[95:64]  ← B_4;
DEST[63:32]  ← C_4;
DEST[31:0]   ← D_4;
```

Mnemonic	Opcode	Description
SHA1RNDS4 xmm1, xmm2/m128, imm8	0F 3A CC /r ib	Executes 4 Rounds of SHA1

A - AVX, AVX2 exception
S - SSE exception

SHA1NEXTE Calculate Next E SHA1

Calculate what the next E register values should be after 4 rounds of a SHA1 operation using the 4 double words from the second source operand, and value A from the first operand. The resulting E is placed in the destination register which is the same as the first source register.

```
DEST[127:96] ← SRC2[127:96] + (SRC1[127:96] rotated left 30)
DEST[95:0]   ← SRC2[95:0];
```

Mnemonic	Opcode	Description
SHA1NEXTE xmm1,xmm2/m128	0F 38 C8 /r	Calculate Next E of SHA1

SHA256RNDS2 Two Rounds of SHA256

Performs 2 rounds of SHA256 operation with the first operand holding the initial SHA256 state (C, D, G, H), the second operand holding the initial SHA256 state (A, B, E, F), and the implicit operand xmm0 holding a pre-computed sum of the next two double word round 2 message as well as the corresponding round constants. The resulting SHA256 state (A, B, E, F) is placed in the destination register.

```
A_0 ← SRC2[127:96];
B_0 ← SRC2[95:64];
C_0 ← SRC1[127:96];
D_0 ← SRC1[95:64];
E_0 ← SRC2[63:32];
F_0 ← SRC2[31:0];
G_0 ← SRC1[63:32];
H_0 ← SRC1[31:0];
K0 ← XMM0[31: 0];
K1 ← XMM0[63: 32];

FOR i = 0 to 1
{       A_(i +1) ← Ch (E_i, F_i, G_i) + Perm1(E_i) +K_i + H_i + Ma(A_i , B_i, C_i) + Perm0(A_i);
        B_(i +1) ← A_i;

SHUFPD Shuffle
VSHUFPD Packed Double-Precision Floating-Point

Copies packed double-precision floating-point values from either of two sources to quadwords in the destination, as specified by bit fields of an immediate byte operand.

Each bit corresponds to a quadword destination. The 128-bit legacy and extended versions of the instruction use bits [1:0]; the 256-bit extended version uses bits [3:0], as shown.

Destination Quadword	Immediate-Byte Bit Field	Value of Bit Field	Source 1 Bits Copied	Source 2 Bits Copied
Used by 128-bit encoding and 256-bit encoding				
[63:0]	[0]	0	[63:0]	—
		1	[127:64]	—
[127:64]	[1]	0	—	[63:0]
		1	—	]127:64]
Used only by 256-bit encoding				
[191:128]	[2]	0	[191:128]	—
		1	[255:192]	—
[255:192]	[3]	0	—	[191:128]
		1	—	[255:192]

There are legacy and extended forms of the instruction:

SHUFPD

Selects from four source values. The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. There is a third 8-bit immediate operand. The first source register is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VSHUFPD

The extended form of the instruction has both 128-bit and 256-bit encodings:

XMM Encoding

Selects from four source values. The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The destination is a third XMM register. There is a fourth 8-bit immediate operand. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

Selects from eight source values. The first source operand is a YMM register and the second source operand is either a YMM register or a 256-bit memory location. The destination is a third YMM register. There is a fourth 8-bit immediate operand.

Instruction Support

Form	Subset	Feature Flag
SHUFPD	SSE2	CPUID Fn0000_0001_EDX[SSE2] (bit 26)
VSHUFPD	AVX	CPUID Fn0000_0001_ECX[AVX] (bit 28)

For more on using the CPUID instruction to obtain processor feature support information, see Appendix E of Volume 3.

Instruction Encoding

Mnemonic	Opcode	Description

S — SSE exception

SHUFPS Shuffle
VSHUFPS Packed Single-Precision Floating-Point

Copies packed single-precision floating-point values from either of two sources to doublewords in the destination, as specified by bit fields of an immediate byte operand.

Each bit field corresponds to a doubleword destination. The 128-bit legacy and extended versions of the instruction use a single 128-bit destination; the 256-bit extended version performs duplicate operations on bits [127:0] and bits [255:128] of the source and destination.

Destination Doubleword	Immediate-Byte Bit Field	Value of Bit Field	Source 1 Bits Copied	Source 2 Bits Copied
[31:0]	[1:0]	00	[31:0]	—
		01	[63:32]	—
		10	[95:64]	—

		01	—	[191:160]
		10	—	[223:192]
		11	—	[255:224]

There are legacy and extended forms of the instruction:

SHUFPS

Selects from eight source values. The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. There is a third 8-bit immediate operand. The first source register is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VSHUFPS

The extended form of the instruction has both 128-bit and 256-bit encodings:

XMM Encoding

Selects from eight source values. The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The destination is a third XMM register. There is a fourth 8-bit immediate operand. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

Selects from 16 source values. The first source operand is a YMM register and the second source operand is either a YMM register or a 256-bit memory location. The destination is a third YMM register. There is a fourth 8-bit immediate operand.

Instruction Support

Form	Subset	Feature Flag
SHUFPS	SSE1	CPUID Fn0000_0001_EDX[SSE] (bit 25)
VSHUFPS	AVX	CPUID Fn0000_0001_ECX[AVX] (bit 28)

For more on using the CPUID instruction to obtain processor feature support information, see Appendix E of Volume 3.

SQRTPD Square Root
VSQRTPD Packed Double-Precision Floating-Point

Computes the square root of each packed double-precision floating-point value in a source operand and writes the result to the corresponding quadword of the destination.

Performing the square root of +infinity returns +infinity.

There are legacy and extended forms of the instruction:

SQRTPD

Computes two values. The destination is an XMM register. The source operand is either an XMM register or a 128-bit memory location. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VSQRTPD

The extended form of the instruction has both 128-bit and 256-bit encodings:

XMM Encoding

Computes two values. The source operand is either an XMM register or a 128-bit memory location. The destination is an XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

Computes four values. The source operand is either a YMM register or a 256-bit memory location. The destination is a YMM register.

Instruction Support

Form	Subset	Feature Flag
SQRTPD	SSE2	CPUID Fn0000_0001_EDX[SSE2] (bit 26)
VSQRTPD	AVX	CPUID Fn0000_0001_ECX[AVX] (bit 28)

For more on using the CPUID instruction to obtain processor feature support information, see Appendix E of Volume 3.

SQRTSD Square Root
VSQRTSD Scalar Double-Precision Floating-Point

Computes the square root of a double-precision floating-point value and writes the result to the low quadword of the destination. The three-operand form of the instruction also writes a copy of the upper quadword of a second source operand to the upper quadword of the destination.

Performing the square root of +infinity returns +infinity.

There are legacy and extended forms of the instruction:

SQRTSD

The source operand is either an XMM register or a 64-bit memory location. When the source is an XMM register, the source value must be in the low quadword. The destination is an XMM register. Bits [127:64] of the destination are not affected. Bits [255:128] of the YMM register that corresponds to destination XMM register are not affected.

VSQRTSD

The extended form of the instruction has a single 128-bit encoding that requires three operands:

VSQRTSD *xmm1, xmm2, xmm3/mem64*

The first source operand is an XMM register. The second source operand is either an XMM register or a 64-bit memory location. When the second source is an XMM register, the source value must be in the low quadword. The destination is a third XMM register. The square root of the second source operand is written to bits [63:0] of the destination register. Bits [127:64] of the destination are copied from the corresponding bits of the first source operand. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

Instruction Support

SQRTSS Square Root
VSQRTSS Scalar Single-Precision Floating-Point

Computes the square root of a single-precision floating-point value and writes the result to the low doubleword of the destination. The three-operand form of the instruction also writes a copy of the three most significant doublewords of a second source operand to the upper 96 bits of the destination.

Performing the square root of +infinity returns +infinity.

There are legacy and extended forms of the instruction:

SQRTSS

The source operand is either an XMM register or a 32-bit memory location. When the source is an XMM register, the source value must be in the low doubleword. The destination is an XMM register. Bits [127:32] of the destination are not affected. Bits [255:128] of the YMM register that corresponds to destination XMM register are not affected.

VSQRTSS

The extended form has a single 128-bit encoding that requires three operands:

VSQRTSS *xmm1, xmm2, xmm3/mem64*

The first source operand is an XMM register. The second source operand is either an XMM register or a 32-bit memory location. When the second source is an XMM register, the source value must be in the low doubleword. The destination is a third XMM register. The square root of the second source operand is written to bits [31:0] of the destination register. Bits [127:32] of the destination are copied from the corresponding bits of the first source operand. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

Instruction Support

Form	Subset	Feature Flag
SQRTSS	SSE1	CPUID Fn0000_0001_EDX[SSE] (bit 25)
VSQRTSS	AVX	CPUID Fn0000_0001_ECX[AVX] (bit 28)

For more on using the CPUID instruction to obtain processor feature support information, see Appendix E of Volume 3.

Instruction Encoding

Mnemonic	Opcode	Description
SQRTSS *xmm1*, *xmm2/mem32*	F3 0F 51 /r	Computes square root of a single-precision floating-point value in *xmm1* or *mem32*. Writes the result to *xmm1*.

STMXCSR Store MXCSR
VSTMXCSR

Saves the content of the MXCSR extended control/status register to a 32-bit memory location. Reserved bits are stored as zeroes. The MXCSR is described in “Registers” in Volume 1.

For both legacy STMXCSR and extended VSTMXCSR forms of the instruction, the source operand is the MXCSR and the destination is a 32-bit memory location.

There is one encoding for each instruction form.

Instruction Support

Form	Subset	Feature Flag
STMXCSR	SSE1	CPUID Fn0000_0001_EDX[SSE] (bit 25)
VSTMXCSR	AVX	CPUID Fn0000_0001_ECX[AVX] (bit 28)

For more on using the CPUID instruction to obtain processor feature support information, see Appendix E of Volume 3.

The extended form of the instruction has both 128-bit and 256-bit encodings:

XMM Encoding

Subtracts four pairs of values. The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

Subtracts eight pairs of values. The first source operand is a YMM register and the second source operand is either a YMM register or a 256-bit memory location. The destination is a third YMM register.

Instruction Support

Form	Subset	Feature Flag
SUBPS	SSE1	CPUID Fn0000_0001_EDX[SSE] (bit 25)
VSUBPS	AVX	CPUID Fn0000_0001_ECX[AVX] (bit 28)

For more on using the CPUID instruction to obtain processor feature support information, see Appendix E of Volume 3.

Instruction Encoding

Mnemonic	Opcode	Description
SUBPS *xmm1*, *xmm2/mem128*	0F 5C /r	Subtracts packed single-precision floating-point values in *xmm2* or *mem128* from corresponding values of *xmm1*. Writes differences to *xmm1*.

Mnemonic	Encoding			
	VEX	RXB.map_select	W.vvvv.L.pp	Opcode
VSUBPS *xmm1*, *xmm2*, *xmm3/mem128*	C4	$\overline{\text{RXB}}$.00001	X.$\overline{src}$.0.00	5C /r
VSUBPS *ymm1*, *ymm2*, *ymm3/mem256*	C4	$\overline{\text{RXB}}$.00001	X.$\overline{src}$.1.00	5C /r

SUBSD Subtract
VSUBSD Scalar Double-Precision Floating-Point

Subtracts the double-precision floating-point value in the low-order quadword of the second source operand from the corresponding value in the first source operand and writes the result to the low-order quadword of the destination

There are legacy and extended forms of the instruction:

SUBSD

The first source operand is an XMM register and the second source operand is either an XMM register or a 64-bit memory location. The first source register is also the destination register. Bits [127:64] of the destination and bits [255:128] of the corresponding YMM register are not affected.

VSUBSD

The extended form of the instruction has a 128-bit encoding only.

The first source operand is an XMM register and the second source operand is either an XMM register or a 64-bit memory location. The destination is a third XMM register. Bits [127:64] of the first source operand are copied to bits [127:64] of the destination. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

Instruction Support

Form	Subset	Feature Flag
SUBSD	SSE2	CPUID Fn0000_0001_EDX[SSE2] (bit 26)
VSUBSD	AVX	CPUID Fn0000_0001_ECX[AVX] (bit 28)

For more on using the CPUID instruction to obtain processor feature support information, see Appendix E of Volume 3.

Instruction Encoding

Mnemonic	Opcode	Description

UCOMISD Unordered Compare
VUCOMISD Scalar Double-Precision Floating-Point

Performs an unordered comparison of a double-precision floating-point value in the low-order 64 bits of an XMM register with a double-precision floating-point value in the low-order 64 bits of an XMM register or a 64-bit memory location.

The ZF, PF, and CF bits in the rFLAGS register reflect the result of the compare as follows.

Result of Compare	ZF	PF	CF
Unordered	1	1	1
Greater Than	0	0	0
Less Than	0	0	1
Equal	1	0	0

The OF, AF, and SF bits in rFLAGS are cleared. If the instruction causes an unmasked SIMD floating-point exception (#XF), the rFLAGS bits are not updated.

The result is unordered when one or both of the operand values is a NaN. UCOMISD signals a SIMD floating-point invalid operation exception (#I) only when a source operand is an SNaN.

The legacy and extended forms of the instruction operate in the same way.

Instruction Support

Form	Subset	Feature Flag
UCOMISD	SSE2	CPUID Fn0000_0001_EDX[SSE2] (bit 26)
VUCOMISD	AVX	CPUID Fn0000_0001_ECX[AVX] (bit 28)

For more on using the CPUID instruction to obtain processor feature support information, see Appendix E of Volume 3.

Instruction Encoding

Mnemonic	Opcode	Description
UCOMISD *xmm1*, *xmm2/mem64*	66 0F 2E /r	Compares scalar double-precision floating-point values in *xmm1* and *xmm2* or *mem64*. Sets rFLAGS.

UNPCKHPD Unpack High
VUNPCKHPD Double-Precision Floating-Point

Unpacks the high-order double-precision floating-point values of the first and second source operands and interleaves the values into the destination. Bits [63:0] of the source operands are ignored.

Values are interleaved in ascending order from the lsb of the sources and the destination. Bits [127:64] of the first source are written to bits [63:0] of the destination; bits [127:64] of the second source are written to bits [127:64] of the destination. For the 256-bit encoding, the process is repeated for bits [255:192] of the sources and bits [255:128] of the destination.

There are legacy and extended forms of the instruction:

UNPCKHPD

Interleaves one pair of values. The first source operand is an XMM register and the second source operand is either an XMM register or a 128-bit memory location. The first source register is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VUNPCKHPD

The extended form of the instruction has both 128-bit and 256-bit encodings:

XMM Encoding

Interleaves one pair of values. The first source operand is an XMM register and the second source operand is either an XMM register or a 128-bit memory location. The destination is an XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

Interleaves two pairs of values. The first source operand is a YMM register and the second source operand is either a YMM register or a 256-bit memory location. The destination is a third YMM register.

Instruction Support

Form	Subset	Feature Flag
UNPCKHPD	SSE2	CPUID Fn0000_0001_EDX[SSE2] (bit 26)
VUNPCKHPD	AVX	CPUID Fn0000_0001_ECX[AVX] (bit 28)

For more on using the CPUID instruction to obtain processor feature support information, see Appendix E of Volume 3.

Instruction Encoding

Mnemonic	Opcode	Description
UNPCKHPD *xmm1*, *xmm2/mem128*	66 0F 15 /r	Unpacks the high-order double-precision floating-point values in *xmm1* and *xmm2* or *mem128* and interleaves them into *xmm1*

UNPCKHPS Unpack High
VUNPCKHPS Single-Precision Floating-Point

Unpacks the high-order single-precision floating-point values of the first and second source operands and interleaves the values into the destination. Bits [63:0] of the source operands are ignored.

Values are interleaved in ascending order from the lsb of the sources and the destination. Bits [95:64] of the first source are written to bits [31:0] of the destination; bits [95:64] of the second source are written to bits [63:32] of the destination and so on, ending with bits [127:96] of the second source in bits [127:96] of the destination. For the 256-bit encoding, the process continues for bits [255:192] of the sources and bits [255:128] of the destination.

There are legacy and extended forms of the instruction:

UNPCKHPS

Interleaves two pairs of values. The first source operand is an XMM register and the second source operand is either an XMM register or a 128-bit memory location. The first source register is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VUNPCKHPS

The extended form of the instruction has both 128-bit and 256-bit encodings:

XMM Encoding

Interleaves two pairs of values. The first source operand is an XMM register and the second source operand is either an XMM register or a 128-bit memory location. The destination is an XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

Interleaves four pairs of values. The first source operand is a YMM register and the second source operand is either a YMM register or a 256-bit memory location. The destination is a third YMM register.

Instruction Support

Form	Subset	Feature Flag
UNPCKHPS	SSE1	CPUID Fn0000_0001_EDX[SSE] (bit 25)
VUNPCKHPS	AVX	CPUID Fn0000_0001_ECX[AVX] (bit 28)

For more on using the CPUID instruction to obtain processor feature support information, see Appendix E of Volume 3.

Instruction Encoding

Mnemonic	Opcode	Description
UNPCKHPS *xmm1*, *xmm2*/*mem128*	0F 15 /r	Unpacks the high-order single-precision floating-point values in *xmm1* and *xmm2* or *mem128* and interleaves them into *xmm1*

UNPCKLPD Unpack Low
VUNPCKLPD Double-Precision Floating-Point

Unpacks the low-order double-precision floating-point values of the first and second source operands and interleaves the values into the destination. Bits [127:64] of the source operands are ignored.

Values are interleaved in ascending order from the lsb of the sources and the destination. Bits [63:0] of the first source are written to bits [63:0] of the destination; bits [63:0] of the second source are written to bits [127:64] of the destination. For the 256-bit encoding, the process is repeated for bits [191:128] of the sources and bits [255:128] of the destination.

There are legacy and extended forms of the instruction:

UNPCKLPD

Interleaves one pair of values. The first source operand is an XMM register and the second source operand is either an XMM register or a 128-bit memory location. The first source register is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VUNPCKLPD

The extended form of the instruction has both 128-bit and 256-bit encodings:

XMM Encoding

Interleaves one pair of values. The first source operand is an XMM register and the second source operand is either an XMM register or a 128-bit memory location. The destination is an XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

Interleaves two pairs of values. The first source operand is a YMM register and the second source operand is either a YMM register or a 256-bit memory location. The destination is a third YMM register.

Instruction Support

Form	Subset	Feature Flag
UNPCKLPD	SSE2	CPUID Fn0000_0001_EDX[SSE2] (bit 26)
VUNPCKLPD	AVX	CPUID Fn0000_0001_ECX[AVX] (bit 28)

For more on using the CPUID instruction to obtain processor feature support information, see Appendix E of Volume 3.

Instruction Encoding

UNPCKLPS Unpack Low
VUNPCKLPS Single-Precision Floating-Point

Unpacks the low-order single-precision floating-point values of the first and second source operands and interleaves the values into the destination. Bits [127:64] of the source operands are ignored.

Values are interleaved in ascending order from the lsb of the sources and the destination. Bits [31:0] of the first source are written to bits [31:0] of the destination; bits [31:0] of the second source are written to bits [63:32] of the destination and so on, ending with bits [63:32] of the second source in bits [127:96] of the destination. For the 256-bit encoding, the process continues for bits [191:128] of the sources and bits [255:128] of the destination.

There are legacy and extended forms of the instruction:

UNPCKLPS

Interleaves two pairs of values. The first source operand is an XMM register and the second source operand is either an XMM register or a 128-bit memory location. The first source register is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VUNPCKLPS

The extended form of the instruction has both 128-bit and 256-bit encodings:

XMM Encoding

Interleaves two pairs of values. The first source operand is an XMM register and the second source operand is either an XMM register or a 128-bit memory location. The destination is an XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

Interleaves four pairs of values. The first source operand is a YMM register and the second source operand is either a YMM register or a 256-bit memory location. The destination is a third YMM register.

Instruction Support

VBROADCASTI128 Load With Broadcast Integer From 128-bit Memory Location

Loads data from a 128-bit memory location and writes it to the two 128-bit elements of a YMM register

There is a single form of this instruction:

VBROADCASTI128 *dest, mem128*

There is a single VEX.L = 1 encoding of this instruction.

The source operand is a 128-bit memory location. The destination is a YMM register.

VBROADCASTSS Load With Broadcast Scalar Single

Loads a single-precision floating-point value from a register or memory and writes it to all 4 or 8 doublewords of an XMM or YMM register.

This extended-form instruction has both 128-bit and 256-bit encodings:

XMM Encoding

Copies the source operand to all four 32-bit elements of the destination.

The source operand is the least-significant 32 bits of an XMM register or a 32-bit memory location. The destination is an XMM register.

YMM Encoding

Copies the source operand to all eight 32-bit elements of the destination.

The source operand is the least-significant 32 bits of an XMM register or a 32-bit memory location. The destination is a YMM register.

Instruction Support

Form	Subset	Feature Flag
VBROADCASTSS *mem32*	AVX	CPUID Fn0000_0001_ECX[AVX] (bit 28)

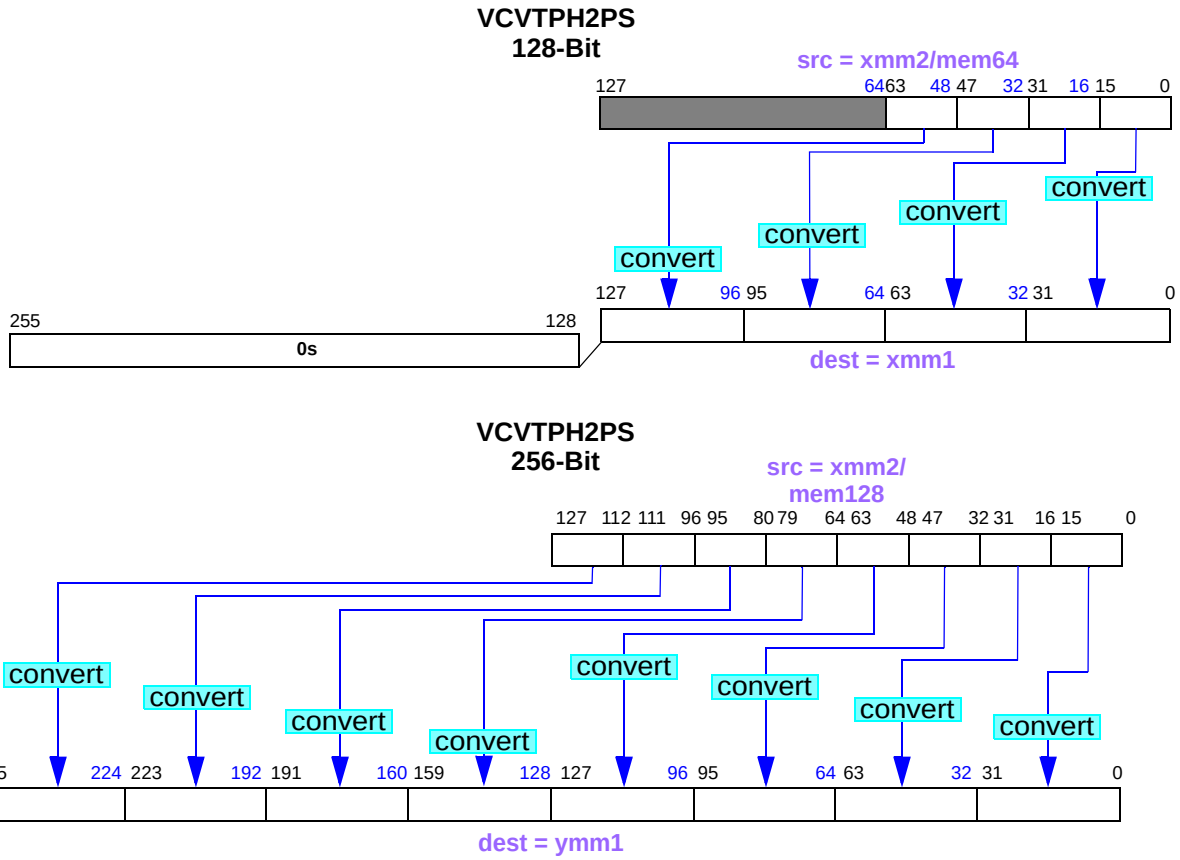
VCVTPH2PS Convert Packed 16-Bit Floating-Point to Single-Precision Floating-Point

Converts packed 16-bit floating point values to single-precision floating point values.

A denormal source operand is converted to a normal result in the destination register. MXCSR.DAZ is ignored and no MXCSR denormal exception is reported.

Because the full range of 16-bit floating-point encodings, including denormal encodings, can be represented exactly in single-precision format, rounding, inexact results, and denormalized results are not applicable.

The operation of this instruction is illustrated in the following diagram.



This extended-form instruction has both 128-bit and 256-bit encodings:

XMM Encoding

Converts four packed 16-bit floating-point values in the low-order 64 bits of an XMM register or in a 64-bit memory location to four packed single-precision floating-point values and writes the converted values to an XMM destination register. When the result operand is written to the destination register, the upper 128 bits of the corresponding YMM register are zeroed.

YMM Encoding

Converts eight packed 16-bit floating-point values in the low-order 128 bits of a YMM register or in a 128-bit memory location to eight packed single-precision floating-point values and writes the converted values to a YMM destination register.

Instruction Support

Form	Subset	Feature Flag
VCVTPH2PS	F16C	CPUID Fn0000_0001_ECX[F16C] (bit 29)

For more on using the CPUID instruction to obtain processor feature support information, see Appendix E of Volume 3.

SIMD Floating-Point Exceptions				
Invalid-operation exception (IE)			F	A source operand was an SNaN value.
			F	Undefined operation.
Denormalized-operand exception (DE)			F	A source operand was a denormal value.
Overflow exception (OE)			F	Rounded result too large to fit into the format of the destination operand.
Underflow exception (UE)			F	Rounded result too small to fit into the format of the destination operand.
Precision exception (PE)			F	A result could not be represented exactly in the destination format.

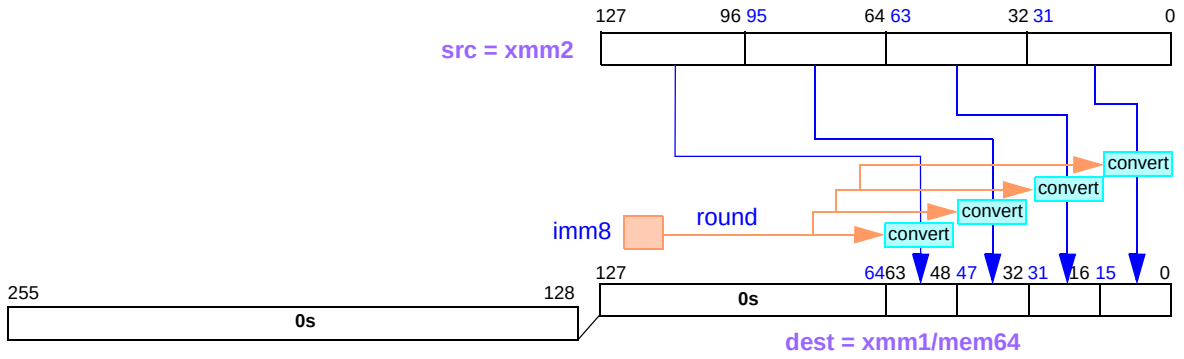
F — F16C exception.

VCVTPS2PH Convert Packed Single-Precision Floating-Point to 16-Bit Floating-Point

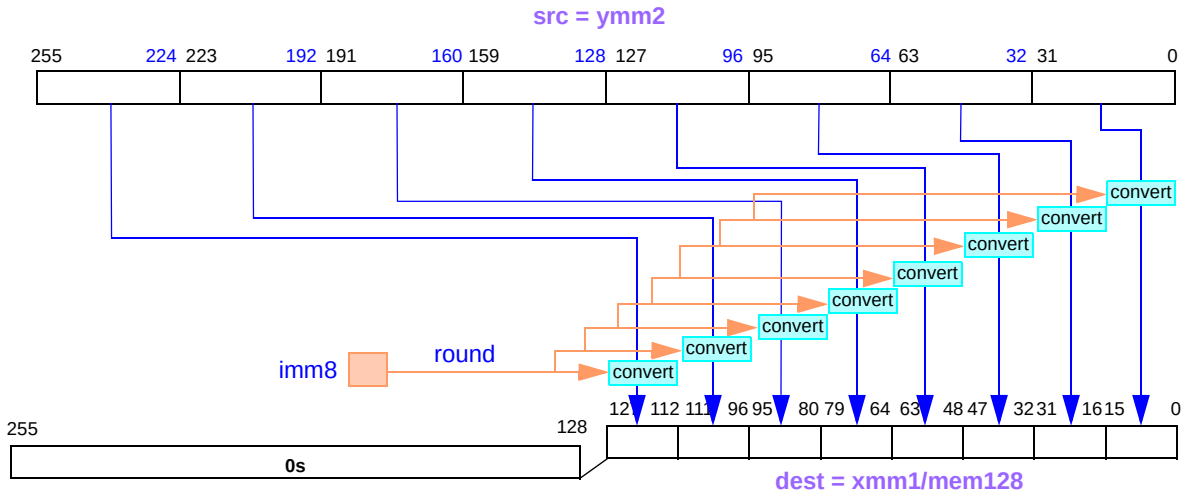
Converts packed single-precision floating-point values to packed 16-bit floating-point values and writes the converted values to the destination register or to memory. An 8-bit immediate operand provides dynamic control of rounding.

The operation of this instruction is illustrated in the following diagram.

VCVTPS2PH
128-Bit



VCVTPS2PH
256-Bit



The handling of rounding is controlled by fields in the immediate byte, as shown in the following table.

Rounding Control with Immediate Byte Operand

Mnemonic	Rounding Source (RS)	Rounding Control (RC)			
Bit	**2**	**1**	**0**	**Description**	**Notes**
Value	0	0	0	Nearest	Ignore MXCSR.RC.
		0	1	Down	
		1	0	Up	
		1	1	Truncate	
	1	X	X	Use MXCSR.RC for rounding.	

MXCSR[FTZ] has no effect on this instruction. Values within the half-precision denormal range are unconditionally converted to denormals.

This extended-form instruction has both 128-bit and 256-bit encodings:

XMM Encoding

Converts four packed single-precision floating-point values in an XMM register to four packed 16-bit floating-point values and writes the converted values to the low-order 64 bits of the destination XMM register or to a 64-bit memory location. When the result is written to the destination XMM register, the high-order 64 bits in the destination XMM register and the upper 128 bits of the corresponding YMM register are cleared to 0s.

YMM Encoding

Converts eight packed single-precision floating-point values in a YMM register to eight packed 16-bit floating-point values and writes the converted values to the low-order 128 bits of a YMM register or to a 128-bit memory location. When the result is written to the destination YMM register, the high-order 128 bits in the register are cleared to 0s.

Instruction Support

Form	Subset	Feature Flag
VCVTPH2PH	F16C	CPUID Fn0000_0001_ECX[F16C] (bit 29)

Invalid-operation exception (IE)			F	A source operand was an SNaN value.
			F	Undefined operation.
Denormalized-operand exception (DE)			F	A source operand was a denormal value.
Overflow exception (OE)			F	Rounded result too large to fit into the format of the destination operand.
Underflow exception (UE)			F	Rounded result too small to fit into the format of the destination operand.
Precision exception (PE)			F	A result could not be represented exactly in the destination format.
F — F16C exception.				

VEXTRACTF128 Extract Packed Floating-Point Values

Extracts 128 bits of packed data from a YMM register as specified by an immediate byte operand, and writes it to either an XMM register or a 128-bit memory location.

Only bit [0] of the immediate operand is used. Operation is as follows.

- When imm8[0] = 0, copy bits [127:0] of the source to the destination.
- When imm8[0] = 1, copy bits [255:128] of the source to the destination.

This extended-form instruction has a single 256-bit encoding.

The source operand is a YMM register and the destination is either an XMM register or a 128-bit memory location. There is a third immediate byte operand.

Instruction Support

Form	Subset	Feature Flag
VEXTRACTF128	AVX	CPUID Fn0000_0001_ECX[AVX] (bit 28)

For more on using the CPUID instruction to obtain processor feature support information, see Appendix E of Volume 3.

VEXTRACTI128 Extract 128-bit Integer

Writes a selected 128-bit half of a YMM register to an XMM register or a 128-bit memory location based on the value of bit 0 of an immediate byte.

There is a single form of this instruction:

VEXTRACTI128 *dest, src, imm8*

If imm8[0] = 0, the lower half of the source YMM register is selected; if imm8[0] = 1, the upper half of the source register is selected.

There is a single VEX.L = 1 encoding of this instruction.

The source operand is a YMM register. The destination is either an XMM register or a 128-bit memory location. When the destination is a register, bits [255:128] of the YMM register that corresponds to the destination are cleared.

Instruction Support

VFMADDPD VFMADD132PD VFMADD213PD VFMADD231PD — Multiply and Add Packed Double-Precision Floating-Point

Multiplies together two double-precision floating-point vectors and adds the unrounded product to a third double-precision floating-point vector producing a precise result which is then rounded to double-precision based on the mode specified by the MXCSR[RC] field. The rounded sum is written to the destination register. The role of each of the source operands specified by the assembly language prototypes given below is reflected in the vector equation in the comment on the right.

There are two four-operand forms:

```
VFMADDPD dest, src1, src2/mem, src3     // dest = (src1* src2/mem) + src3
VFMADDPD dest, src1, src2, src3/mem     // dest = (src1* src2) + src3/mem
```

and three three-operand forms:

```
VFMADD132PD src1, src2, src3/mem        // src1 = (src1* src3/mem) + src2
VFMADD213PD src1, src2, src3/mem        // src1 = (src2* src1) + src3/mem
VFMADD231PD src1, src2, src3/mem        // src1 = (src2* src3/mem) + src1
```

When VEX.L = 0, the vector size is 128 bits (two double-precision elements per vector) and register-based source operands are held in XMM registers.

When VEX.L = 1, the vector size is 256 bits (four double-precision elements per vector) and register-based source operands are held in YMM registers.

For the four-operand forms, VEX.W determines operand configuration.

- When VEX.W = 0, the second source is either a register or a memory location and the third source is a register.
- When VEX.W = 1, the second source is a register and the third source is either a register or a memory location.

For the three-operand forms, VEX.W is 1. The first and second operands are registers and the third operand is either a register or a memory location.

The destination is either an XMM register or a YMM register, as determined by VEX.L. When the destination is an XMM register (L = 0), bits [255:128] of the corresponding YMM register are cleared.

Instruction Support

Form	Subset	Feature Flag
VFMADDPD	FMA4	CPUID Fn8000_0001_ECX[FMA4] (bit 16)
VFMADD*nnn*PD	FMA	CPUID Fn0000_0001_ECX[FMA] (bit 12)

For more on using the CPUID instruction to obtain processor feature support information, see Appendix E of Volume 3.

Multiply and Add Packed Single-Precision Floating-Point

Multiplies together two single-precision floating-point vectors and adds the unrounded product to a third single-precision floating-point vector producing a precise result which is then rounded to single-precision based on the mode specified by the MXCSR[RC] field. The rounded sum is written to the destination register. The role of each of the source operands specified by the assembly language prototypes given below is reflected in the vector equation in the comment on the right.

There are two four-operand forms:

```
VFMADDPS dest, src1, src2/mem, src3     // dest = (src1* src2/mem) + src3
VFMADDPS dest, src1, src2, src3/mem     // dest = (src1* src2) + src3/mem
```

and three three-operand forms:

```
VFMADD132PS src1, src2, src3/mem        // src1 = (src1* src3/mem) + src2
VFMADD213PS src1, src2, src3/mem        // src1 = (src2* src1) + src3/mem
VFMADD231PS src1, src2, src3/mem        // src1 = (src2* src3/mem) + src1
```

When VEX.L = 0, the vector size is 128 bits (four single-precision elements per vector) and register-based source operands are held in XMM registers.

When VEX.L = 1, the vector size is 256 bits (eight single-precision elements per vector) and register-based source operands are held in YMM registers.

For the four-operand forms, VEX.W determines operand configuration.

- When VEX.W = 0, the second source is either a register or a memory location and the third source is a register.
- When VEX.W = 1, the second source is a register and the third source is either a register or a memory location.

For the three-operand forms, VEX.W is 0. The first and second operands are registers and the third operand is either a register or a memory location.

The destination is either an XMM register or a YMM register, as determined by VEX.L. When the destination is an XMM register (L = 0), bits [255:128] of the corresponding YMM register are cleared.

VFMADDSD VFMADD132SD VFMADD213SD VFMADD231SD — Multiply and Add Scalar Double-Precision Floating-Point

Multiplies together two double-precision floating-point values and adds the unrounded product to a third double-precision floating-point value producing a precise result which is then rounded to double-precision based on the mode specified by the MXCSR[RC] field. The rounded sum is written to the destination register. The role of each of the source operands specified by the assembly language prototypes given below is reflected in the equation in the comment on the right.

There are two four-operand forms:

```
VFMADDSD dest, src1, src2/mem64, src3     // dest = (src1* src2/mem64) + src3
VFMADDSD dest, src1, src2, src3/mem64     // dest = (src1* src2) + src3/mem64
```

and three three-operand forms:

```
VFMADD132SD src1, src2, src3/mem64        // src1 = (src1* src3/mem64) + src2
VFMADD213SD src1, src2, src3/mem64        // src1 = (src2* src1) + src3/mem64
VFMADD231SD src1, src2, src3/mem64        // src1 = (src2* src3/mem64) + src1
```

All 64-bit double-precision floating-point register-based operands are held in the lower quadword of XMM registers. The result is written to the lower quadword of the destination register. For those instructions that use a memory-based operand, one of the source operands is a 64-bit value read from memory.

For the four-operand forms, VEX.W determines operand configuration.

- When VEX.W = 0, the second source is either a register or a 64-bit memory location and the third source is a register.
- When VEX.W = 1, the second source is a register and the third source is either a register or a 64-bit memory location.

For the three-operand forms, VEX.W is 1. The first and second operands are registers and the third operand is either a register or a 64-bit memory location.

The destination is an XMM register. When the result is written to the destination XMM register, bits [127:64] of the destination and bits [255:128] of the corresponding YMM register are cleared.

Instruction Support

Form	Subset	Feature Flag

Underflow, UE			F	Rounded result too small to fit into the format of the destination operand.
Precision, PE			F	A result could not be represented exactly in the destination format.
F — FMA, FMA4 exception				

VFMADDSS Multiply and Add
VFMADD132SS Scalar Single-Precision Floating-Point
VFMADD213SS
VFMADD231SS

Multiplies together two single-precision floating-point values and adds the unrounded product to a third single-precision floating-point value producing a precise result which is then rounded to single-precision based on the mode specified by the MXCSR[RC] field. The rounded sum is written to the destination register. The role of each of the source operands specified by the assembly language prototypes given below is reflected in the equation in the comment on the right.

There are two four-operand forms:

```
VFMADDSS dest, src1, src2/mem32, src3     // dest = (src1* src2/mem32) + src3
VFMADDSS dest, src1, src2, src3/mem32     // dest = (src1* src2) + src3/mem32
```

and three three-operand forms:

```
VFMADD132SS src1, src2, src3/mem32        // src1 = (src1* src3/mem32) + src2
VFMADD213SS src1, src2, src3/mem32        // src1 = (src2* src1) + src3/mem32
VFMADD231SS src1, src2, src3/mem32        // src1 = (src2* src3/mem32) + src1
```

All 32-bit single-precision floating-point register-based operands are held in the lower doubleword of XMM registers. The result is written to the low doubleword of the destination register. For those instructions that use a memory-based operand, one of the source operands is a 32-bit value read from memory.

For the four-operand forms, VEX.W determines operand configuration.

- When VEX.W = 0, the second source is either a register or a 32-bit memory location and the third source is a register.
- When VEX.W = 1, the second source is a a register and the third source is either a register or a 32-bit memory location.

For the three-operand forms, VEX.W is 0. The first and second operands are registers and the third operand is either a register or a 32-bit memory location.

The destination is an XMM register. When the result is written to the destination XMM register, bits [127:32] of the destination and bits [255:128] of the corresponding YMM register are cleared.

Instruction Support

Form	Subset	Feature Flag
VFMADDSS	FMA4	CPUID Fn8000_0001_ECX[FMA4] (bit 16)
VFMADD*nnn*SS	FMA	CPUID Fn0000_0001_ECX[FMA] (bit 12)

For more on using the CPUID instruction to obtain processor feature support information, see Appendix E of Volume 3.

F — FMA, FMA4 exception				

VFMADDSUBPD VFMADDSUB132PD VFMADDSUB213PD VFMADDSUB231PD — Multiply with Alternating Add/Subtract Packed Double-Precision Floating-Point

Multiplies together two double-precision floating-point vectors, adds odd elements of the unrounded product to odd elements of a third double-precision floating-point vector, and subtracts even elements of the third floating point vector from even elements of unrounded product. The precise result of each addition or subtraction is then rounded to double-precision based on the mode specified by the MXCSR[RC] field and written to the corresponding element of the destination.

The role of each of the source operands specified by the assembly language prototypes given below is reflected in the equation in the comment on the right.

There are two four-operand forms:

VFMADDSUBPD *dest, src1, src2/mem, src3*	// $dest_{odd} = (src1_{odd} * src2_{odd}/mem_{odd}) + src3_{odd}$ // $dest_{even} = (src1_{even} * src2_{even}/mem_{even}) - src3_{even}$
VFMADDSUBPD *dest, src1, src2, src3/mem*	// $dest_{odd} = (src1_{odd} * src2_{odd}) + src3_{odd}/mem_{odd}$ // $dest_{even} = (src1_{even} * src2_{even}) - src3_{even}/mem_{even}$

and three three-operand forms:

VFMADDSUB132PD *src1, src2, src3/mem*	// $src1_{odd} = (src1_{odd} * src3_{odd}/mem_{odd}) + src2_{odd}$ // $src1_{even} = (src1_{even} * src3_{even}/mem_{even}) - src2_{even}$
VFMADDSUB213PD *src1, src2, src3/mem*	// $src1_{odd} = (src2_{odd} * src1_{odd}) + src3_{odd}/mem_{odd}$ // $src1_{even} = (src2_{even} * src1_{even}) - src3_{even}/mem_{even}$
VFMADDSUB231PD *src1, src2, src3/mem*	// $src1_{odd} = (src2_{odd} * src3_{odd}/mem_{odd}) + src1_{odd}$ // $src1_{even} = (src2_{even} * src3_{even}/mem_{even}) - src1_{even}$

When VEX.L = 0, the vector size is 128 bits (two double-precision elements per vector) and register-based source operands are held in XMM registers.

When VEX.L = 1, the vector size is 256 bits (four double-precision elements per vector) and register-based source operands are held in YMM registers.

For the four-operand forms, VEX.W determines operand configuration.

- When VEX.W = 0, the second source is either a register or a memory location and the third source is a register.
- When VEX.W = 1, the second source is a register and the third source is either a register or a memory location.

For the three-operand forms, VEX.W is 1. The first and second operands are registers and the third operand is either a register or a memory location.

The destination is either an XMM register or a YMM register, as determined by VEX.L. When the destination is an XMM register (L = 0), bits [255:128] of the corresponding YMM register are cleared.

Instruction Support

VFMADDSUBPS VFMADDSUB132PS VFMADDSUB213PS VFMADDSUB231PS — Multiply with Alternating Add/Subtract Packed Single-Precision Floating-Point

Multiplies together two single-precision floating-point vectors, adds odd elements of the unrounded product to odd elements of a third single-precision floating-point vector, and subtracts even elements of the third floating point vector from even elements of unrounded product. The precise result of each addition or subtraction is then rounded to single-precision based on the mode specified by the MXCSR[RC] field and written to the corresponding element of the destination.

The role of each of the source operands specified by the assembly language prototypes given below is reflected in the equation in the comment on the right.

There are two four-operand forms:

VFMADDSUBPS *dest, src1, src2/mem, src3*	// $dest_{odd} = (src1_{odd} * src2_{odd}/mem_{odd}) + src3_{odd}$ // $dest_{even} = (src1_{even} * src2_{even}/mem_{even}) - src3_{even}$
VFMADDSUBPS *dest, src1, src2, src3/mem*	// $dest_{odd} = (src1_{odd} * src2_{odd}) + src3_{odd}/mem_{odd}$ // $dest_{even} = (src1_{even} * src2_{even}) - src3_{even}/mem_{even}$

and three three-operand forms:

VFMADDSUB132PS *src1, src2, src3/mem*	// $src1_{odd} = (src1_{odd} * src3_{odd}/mem_{odd}) + src2_{odd}$ // $src1_{even} = (src1_{even} * src3_{even}/mem_{even}) - src2_{even}$
VFMADDSUB213PS *src1, src2, src3/mem*	// $src1_{odd} = (src2_{odd} * src1_{odd}) + src3_{odd}/mem_{odd}$ // $src1_{even} = (src2_{even} * src1_{even}) - src3_{even}/mem_{even}$
VFMADDSUB231PS *src1, src2, src3/mem*	// $src1_{odd} = (src2_{odd} * src3_{odd}/mem_{odd}) + src1_{odd}$ // $src1_{even} = (src2_{even} * src3_{even}/mem_{even}) - src1_{even}$

When VEX.L = 0, the vector size is 128 bits (four single-precision elements per vector) and register-based source operands are held in XMM registers.

When VEX.L = 1, the vector size is 256 bits (eight single-precision elements per vector) and register-based source operands are held in YMM registers.

For the four-operand forms, VEX.W determines operand configuration.

- When VEX.W = 0, the second source is either a register or a memory location and the third source is a register.
- When VEX.W = 1, the second source is a register and the third source is either a register or a memory location.

For the three-operand forms, VEX.W is 0. The first and second operands are registers and the third operand is either a register or a memory location.

The destination is either an XMM register or a YMM register, as determined by VEX.L. When the destination is an XMM register (L = 0), bits [255:128] of the corresponding YMM register are cleared.

VFMSUBADDPD VFMSUBADD132PD VFMSUBADD213PD VFMSUBADD231PD — Multiply with Alternating Subtract/Add Packed Double-Precision Floating-Point

Multiplies together two double-precision floating-point vectors, adds even elements of the unrounded product to even elements of a third double-precision floating-point vector, and subtracts odd elements of the third floating point vector from odd elements of unrounded product. The precise result of each addition or subtraction is then rounded to double-precision based on the mode specified by the MXCSR[RC] field and written to the corresponding element of the destination.

The role of each of the source operands specified by the assembly language prototypes given below is reflected in the equation in the comment on the right.

There are two four-operand forms:

VFMSUBADDPD *dest, src1, src2/mem, src3*	// $dest_{odd} = (src1_{odd} * src2_{odd}/mem_{odd}) - src3_{odd}$ // $dest_{even} = (src1_{even} * src2_{even}/mem_{even}) + src3_{even}$
VFMSUBADDPD *dest, src1, src2, src3/mem*	// $dest_{odd} = (src1_{odd} * src2_{odd}) - src3_{odd}/mem_{odd}$ // $dest_{even} = (src1_{even} * src2_{even}) + src3_{even}/mem_{even}$

and three three-operand forms:

VFMSUBADD132PD *src1, src2, src3/mem*	// $src1_{odd} = (src1_{odd} * src3_{odd}/mem_{odd}) - src2_{odd}$ // $src1_{even} = (src1_{even} * src3_{even}/mem_{even}) + src2_{even}$
VFMSUBADD213PD *src1, src2, src3/mem*	// $src1_{odd} = (src2_{odd} * src1_{odd}) - src3_{odd}/mem_{odd}$ // $src1_{even} = (src2_{even} * src1_{even}) + src3_{even}/mem_{even}$
VFMSUBADD231PD *src1, src2, src3/mem*	// $src1_{odd} = (src2_{odd} * src3_{odd}/mem_{odd}) - src1_{odd}$ // $src1_{even} = (src2_{even} * src3_{even}/mem_{even}) + src1_{even}$

For VEX.L = 0, vector size is 128 bits and register-based operands are held in XMM registers. For VEX.L = 1, vector size is 256 bits and register-based operands are held in YMM registers.

For the four-operand forms, VEX.W determines operand configuration.

- When VEX.W = 0, the second source is either a register or a memory location and the third source is a register.
- When VEX.W = 1, the second source is a register and the third source operand is either a register or a memory location.

For the three-operand forms, VEX.W is 1. The first and second operands are registers and the third operand is either a register or a memory location.

The destination is either an XMM register or a YMM register, as determined by VEX.L. When the destination is an XMM register (L = 0), bits [255:128] of the corresponding YMM register are cleared.

Instruction Support

Form	Subset	Feature Flag

Denormalized operand, DE			F	A source operand was a denormal value.
Overflow, OE			F	Rounded result too large to fit into the format of the destination operand.
Underflow, UE			F	Rounded result too small to fit into the format of the destination operand.
Precision, PE			F	A result could not be represented exactly in the destination format.
F — FMA, FMA4 exception				

VFMSUBADDPS VFMSUBADD132PS VFMSUBADD213PS VFMSUBADD231PS — Multiply with Alternating Subtract/Add Packed Single-Precision Floating-Point

Multiplies together two single-precision floating-point vectors, adds even elements of the unrounded product to even elements of a third single-precision floating-point vector, and subtracts odd elements of the third floating point vector from odd elements of unrounded product. The precise result of each addition or subtraction is then rounded to single-precision based on the mode specified by the MXCSR[RC] field and written to the corresponding element of the destination.

The role of each of the source operands specified by the assembly language prototypes given below is reflected in the equation in the comment on the right.

There are two four-operand forms:

VFMSUBADDPS *dest, src1, src2/mem, src3*	// $dest_{odd} = (src1_{odd} * src2_{odd}/mem_{odd}) - src3_{odd}$ // $dest_{even} = (src1_{even} * src2_{even}/mem_{even}) + src3_{even}$
VFMSUBADDPS *dest, src1, src2, src3/mem*	// $dest_{odd} = (src1_{odd} * src2_{odd}) - src3_{odd}/mem_{odd}$ // $dest_{even} = (src1_{even} * src2_{even}) + src3_{even}/mem_{even}$

and three three-operand forms:

VFMSUBADD132PS *src1, src2, src3/mem*	// $src1_{odd} = (src1_{odd} * src3_{odd}/mem_{odd}) - src2_{odd}$ // $src1_{even} = (src1_{even} * src3_{even}/mem_{even}) + src2_{even}$
VFMSUBADD213PS *src1, src2, src3/mem*	// $src1_{odd} = (src2_{odd} * src1_{odd}) - src3_{odd}/mem_{odd}$ // $src1_{even} = (src2_{even} * src1_{even}) + src3_{even}/mem_{even}$
VFMSUBADD231PS *src1, src2, src3/mem*	// $src1_{odd} = (src2_{odd} * src3_{odd}/mem_{odd}) - src1_{odd}$ // $src1_{even} = (src2_{even} * src3_{even}/mem_{even}) + src1_{even}$

When VEX.L = 0, the vector size is 128 bits (four single-precision elements per vector) and register-based source operands are held in XMM registers.

When VEX.L = 1, the vector size is 256 bits (eight single-precision elements per vector) and register-based source operands are held in YMM registers.

For the four-operand forms, VEX.W determines operand configuration.

- When VEX.W = 0, the second source is either a register or a memory location and the third source is a register.
- When VEX.W = 1, the second source is a register and the third source is either a register or a memory location.

For the three-operand forms, VEX.W is 0. The first and second operands are registers and the third operand is either a register or a memory location.

The destination is either an XMM register or a YMM register, as determined by VEX.L. When the destination is an XMM register (L = 0), bits [255:128] of the corresponding YMM register are cleared.

VFMSUBPD VFMSUB132PD VFMSUB213PD VFMSUB231PD — Multiply and Subtract Packed Double-Precision Floating-Point

Multiplies together two double-precision floating-point vectors and subtracts a third double-precision floating-point vector from the unrounded product to produce a precise intermediate result. The intermediate result is then rounded to double-precision based on the mode specified by the MXCSR[RC] field and written to the destination register. The role of each of the source operands specified by the assembly language prototypes given below is reflected in the vector equation in the comment on the right.

There are two four-operand forms:

```
VFMSUBPD dest, src1, src2/mem, src3     // dest = (src1* src2/mem) − src3
VFMSUBPD dest, src1, src2, src3/mem     // dest = (src1* src2) − src3/mem
```

and three three-operand forms:

```
VFMSUB132PD src1, src2, src3/mem        // src1 = (src1* src3/mem) − src2
VFMSUB213PD src1, src2, src3/mem        // src1 = (src2* src1) − src3/mem
VFMSUB231PD src1, src2, src3/mem        // src1 = (src2* src3/mem) − src1
```

For VEX.L = 0, vector size is 128 bits and register-based operands are held in XMM registers. For VEX.L = 1, vector size is 256 bits and register-based operands are held in YMM registers.

For the four-operand forms, VEX.W determines operand configuration.

- When VEX.W = 0, the second source is either a register or a memory location and the third source is a register.
- When VEX.W = 1, the second source is a register and the third source is either a register or a memory location.

For the three-operand forms, VEX.W is 1. The first and second operands are registers and the third operand is either a register or a memory location.

The destination is either an XMM register or a YMM register, as determined by VEX.L. When the destination is an XMM register (L = 0), bits [255:128] of the corresponding YMM register are cleared.

VFMSUBSD VFMSUB132SD VFMSUB213SD VFMSUB231SD — Multiply and Subtract Scalar Double-Precision Floating-Point

Multiplies together two double-precision floating-point values and subtracts a third double-precision floating-point value from the unrounded product to produce a precise intermediate result. The intermediate result is then rounded to double-precision based on the mode specified by the MXCSR[RC] field and written to the destination register. The role of each of the source operands specified by the assembly language prototypes given below is reflected in the vector equation in the comment on the right.

There are two four-operand forms:

```
VFMSUBSD dest, src1, src2/mem, src3     // dest = (src1* src2/mem) − src3
VFMSUBSD dest, src1, src2, src3/mem     // dest = (src1* src2) − src3/mem
```

and three three-operand forms:

```
VFMSUB132SD src1, src2, src3/mem        // src1 = (src1* src3/mem) − src2
VFMSUB213SD src1, src2, src3/mem        // src1 = (src2* src1) − src3/mem
VFMSUB231SD src1, src2, src3/mem        // src1 = (src2* src3/mem) − src1
```

For the four-operand forms, VEX.W determines operand configuration.

- When VEX.W = 0, the second source is either a register or 64-bit memory location and the third source is a register.
- When VEX.W = 1, the second source is a register and the third source is a register or 64-bit memory location.

For the three-operand forms, VEX.W is 1. The first and second operands are registers and the third operand is either a register or a memory location.

The destination is an XMM register. When the result is written to the destination XMM register, bits [127:64] of the destination and bits [255:128] of the corresponding YMM register are cleared.

			F	Lock prefix (F0h) preceding opcode.
			F	Unmasked SIMD floating-point exception while CR4.OSXMMEXCPT = 0, see *SIMD Floating-Point Exceptions* below for details.
Device not available, #NM			F	CR0.TS = 1.
Stack, #SS			F	Memory address exceeding stack segment limit or non-canonical.
General protection, #GP			F	Memory address exceeding data segment limit or non-canonical.
			F	Null data segment used to reference memory.
Page fault, #PF			F	Instruction execution caused a page fault.
Alignment check, #AC			F	Non-aligned memory reference when alignment checking enabled.
SIMD floating-point, #XF			F	Unmasked SIMD floating-point exception while CR4.OSXMMEXCPT = 1, see *SIMD Floating-Point Exceptions* below for details.
SIMD Floating-Point Exceptions				
Invalid operation, IE			F	A source operand was an SNaN value.
			F	Undefined operation.
Denormalized operand, DE			F	A source operand was a denormal value.
Overflow, OE			F	Rounded result too large to fit into the format of the destination operand.
Underflow, UE			F	Rounded result too small to fit into the format of the destination operand.
Precision, PE			F	A result could not be represented exactly in the destination format.
F — FMA, FMA4 exception				

VFMSUBSS VFMSUB132SS VFMSUB213SS VFMSUB231SS — Multiply and Subtract Scalar Single-Precision Floating-Point

Multiplies together two single-precision floating-point values and subtracts a third single-precision floating-point value from the unrounded product to produce a precise intermediate result. The intermediate result is then rounded to single-precision based on the mode specified by the MXCSR[RC] field and written to the destination register. The role of each of the source operands specified by the assembly language prototypes given below is reflected in the vector equation in the comment on the right.

There are two four-operand forms:

```
VFMSUBSS dest, src1, src2/mem, src3     // dest = (src1* src2/mem) − src3
VFMSUBSS dest, src1, src2, src3/mem     // dest = (src1* src2) − src3/mem
```

and three three-operand forms:

```
VFMSUB132SS src1, src2, src3/mem        // src1 = (src1* src3/mem) − src2
VFMSUB213SS src1, src2, src3/mem        // src1 = (src2* src1) − src3/mem
VFMSUB231SS src1, src2, src3/mem        // src1 = (src2* src3/mem) − src1
```

For the four-operand forms, VEX.W determines operand configuration.

- When VEX.W = 0, the second source is either a register or 32-bit memory location and the third source is a register.
- When VEX.W = 1, the second source is a register and the third source is a register or 32-bit memory location.

For the three-operand forms, VEX.W is 0. The first and second operands are registers and the third operand is either a register or a memory location.

The destination is an XMM register. When the result is written to the destination XMM register, bits [127:32] of the XMM register and bits [255:128] of the corresponding YMM register are cleared.

VFNMADDPD VFNMADD132PD VFNMADD213PD VFNMADD231PD — Negative Multiply and Add Packed Double-Precision Floating-Point

Multiplies together two double-precision floating-point vectors, negates the unrounded product, and adds it to a third double-precision floating-point vector. The precise result is then rounded to double-precision based on the mode specified by the MXCSR[RC] field and written to the destination register. The role of each of the source operands specified by the assembly language prototypes given below is reflected in the vector equation in the comment on the right.

There are two four-operand forms:

```
VFNMADDPD dest, src1, src2/mem, src3    // dest = −(src1* src2/mem) + src3
VFNMADDPD dest, src1, src2, src3/mem    // dest = −(src1* src2) + src3/mem
```

and three three-operand forms:

```
VFNMADD132PD src1, src2, src3/mem    // src1 = −(src1* src3/mem) + src2
VFNMADD213PD src1, src2, src3/mem    // src1 = −(src2* src1) + src3/mem
VFNMADD231PD src1, src2, src3/mem    // src1 = −(src2* src3/mem) + src1
```

When VEX.L = 0, the vector size is 128 bits (two double-precision elements per vector) and register-based source operands are held in XMM registers.

When VEX.L = 1, the vector size is 256 bits (four double-precision elements per vector) and register-based source operands are held in YMM registers.

For the four-operand forms, VEX.W determines operand configuration.

- When VEX.W = 0, the second source is either a register or a memory location and the third source is a register.
- When VEX.W = 1, the second source is a register and the third source is either a register or a memory location.

For the three-operand forms, VEX.W is 1. The first and second operands are registers and the third operand is either a register or a memory location.

The destination is either an XMM register or a YMM register, as determined by VEX.L. When the destination is an XMM register (L = 0), bits [255:128] of the corresponding YMM register are cleared.

Negative Multiply and Add Packed Single-Precision Floating-Point

Multiplies together two single-precision floating-point vectors, negates the unrounded product, and adds it to a third single-precision floating-point vector. The precise result is then rounded to single-precision based on the mode specified by the MXCSR[RC] field and written to the destination register. The role of each of the source operands specified by the assembly language prototypes given below is reflected in the vector equation in the comment on the right.

There are two four-operand forms:

```
VFNMADDPS dest, src1, src2/mem, src3      // dest = −(src1* src2/mem) + src3
VFNMADDPS dest, src1, src2, src3/mem      // dest = −(src1* src2) + src3/mem
```

and three three-operand forms:

```
VFNMADD132PS src1, src2, src3/mem         // src1 = −(src1* src3/mem) + src2
VFNMADD213PS src1, src2, src3/mem         // src1 = −(src2* src1) + src3/mem
VFNMADD231PS src1, src2, src3/mem         // src1 = −(src2* src3/mem) + src1
```

When VEX.L = 0, the vector size is 128 bits (four single-precision elements per vector) and register-based source operands are held in XMM registers.

When VEX.L = 1, the vector size is 256 bits (eight single-precision elements per vector) and register-based source operands are held in YMM registers.

For the four-operand forms, VEX.W determines operand configuration.

- When VEX.W = 0, the second source is either a register or a memory location and the third source is a register.
- When VEX.W = 1, the second source is a register and the third source is either a register or a memory location.

For the three-operand forms, VEX.W is 0. The first and second operands are registers and the third operand is either a register or a memory location.

The destination is either an XMM register or a YMM register, as determined by VEX.L. When the destination is an XMM register (L = 0), bits [255:128] of the corresponding YMM register are cleared.

VFNMADDSD VFNMADD132SD VFNMADD213SD VFNMADD231SD — Negative Multiply and Add Scalar Double-Precision Floating-Point

Multiplies together two double-precision floating-point values, negates the unrounded product, and adds it to a third double-precision floating-point value. The precise result is then rounded to double-precision based on the mode specified by the MXCSR[RC] field and written to the destination register. The role of each of the source operands specified by the assembly language prototypes given below is reflected in the equation in the comment on the right.

There are two four-operand forms:

```
VFNMADDSD dest, src1, src2/mem, src3     // dest = −(src1* src2/mem) + src3
VFNMADDSD dest, src1, src2, src3/mem     // dest = −(src1* src2) + src3/mem
```

and three three-operand forms:

```
VFNMADD132SD src1, src2, src3/mem        // src1 = −(src1* src3/mem) + src2
VFNMADD213SD src1, src2, src3/mem        // src1 = −(src2* src1) + src3/mem
VFNMADD231SD src1, src2, src3/mem        // src1 = −(src2* src3/mem) + src1
```

For the four-operand forms, VEX.W determines operand configuration.

- When VEX.W = 0, the second source is either a register or 64-bit memory location and the third source is a register.
- When VEX.W = 1, the second source is a register and the third source is a register or 64-bit memory location.

For the three-operand forms, VEX.W is 1. The first and second operands are registers and the third operand is either a register or a 64-bit memory location.

The destination is an XMM register. When the result is written to the destination, bits [127:64] of the XMM register and bits [255:128] of the corresponding YMM register are cleared.

			F	Null data segment used to reference memory.
Page fault, #PF			F	Instruction execution caused a page fault.
Alignment check, #AC			F	Non-aligned memory reference when alignment checking enabled.
SIMD floating-point, #XF			F	Unmasked SIMD floating-point exception while CR4.OSXMMEXCPT = 1, see *SIMD Floating-Point Exceptions* below for details.
SIMD Floating-Point Exceptions				
Invalid operation, IE			F	A source operand was an SNaN value.
			F	Undefined operation.
Denormalized operand, DE			F	A source operand was a denormal value.
Overflow, OE			F	Rounded result too large to fit into the format of the destination operand.
Underflow, UE			F	Rounded result too small to fit into the format of the destination operand.
Precision, PE			F	A result could not be represented exactly in the destination format.
F — FMA, FMA4 exception				

VFNMADDSS VFNMADD132SS VFNMADD213SS VFNMADD231SS — Negative Multiply and Add Scalar Single-Precision Floating-Point

Multiplies together two single-precision floating-point values, negates the unrounded product, and adds it to a third single-precision floating-point value. The precise result is then rounded to single-precision based on the mode specified by the MXCSR[RC] field and written to the destination register. The role of each of the source operands specified by the assembly language prototypes given below is reflected in the equation in the comment on the right.

There are two four-operand forms:

```
VFNMADDSS dest, src1, src2/mem, src3     // dest = −(src1* src2/mem) + src3
VFNMADDSS dest, src1, src2, src3/mem     // dest = −(src1* src2) + src3/mem
```

and three three-operand forms:

```
VFNMADD132SS src1, src2, src3/mem        // src1 = −(src1* src3/mem) + src2
VFNMADD213SS src1, src2, src3/mem        // src1 = −(src2* src1) + src3/mem
VFNMADD231SS src1, src2, src3/mem        // src1 = −(src2* src3/mem) + src1
```

For the four-operand forms, VEX.W determines operand configuration.

- When VEX.W = 0, the second source is either a register or 32-bit memory location and the third source is a register.
- When VEX.W = 1, the second source is a register and the third source is a register or 32-bit memory location.

For the three-operand forms, VEX.W is 0. The first and second operands are registers and the third operand is either a register or a 32-bit memory location.

The destination is an XMM register. When the result is written to the destination, bits [127:32] of the XMM register and bits [255:128] of the corresponding YMM register are cleared.

Instruction Support

Form	Subset	Feature Flag
VFNMADDSS	FMA4	CPUID Fn8000_0001_ECX[FMA4] (bit 16)
VFNMADD*nnn*SS	FMA	CPUID Fn0000_0001_ECX[FMA] (bit 12)

For more on using the CPUID instruction to obtain processor feature support information, see Appendix E of Volume 3.

Instruction Encoding

Mnemonic	Encoding			
	VEX	RXB.map_select	W.vvvv.L.pp	Opcode

F — FMA, FMA4 exception				

VFNMSUBPD VFNMSUB132PD VFNMSUB213PD VFNMSUB231PD — Negative Multiply and Subtract Packed Double-Precision Floating-Point

Multiplies together two double-precision floating-point vectors, negates the unrounded product, and subtracts a third double-precision floating-point vector from it. The precise result is then rounded to double-precision based on the mode specified by the MXCSR[RC] field and written to the destination register. The role of each of the source operands specified by the assembly language prototypes given below is reflected in the vector equation in the comment on the right.

There are two four-operand forms:

```
VFNMSUBPD dest, src1, src2/mem, src3    // dest = −(src1* src2/mem) − src3
VFNMSUBPD dest, src1, src2, src3/mem    // dest = −(src1* src2) − src3/mem
```

and three three-operand forms:

```
VFNMSUB132PD src1, src2, src3/mem    // src1 = −(src1* src3/mem) − src2
VFNMSUB213PD src1, src2, src3/mem    // src1 = −(src2* src1) − src3/mem
VFNMSUB231PD src1, src2, src3/mem    // src1 = −(src2* src3/mem) − src1
```

When VEX.L = 0, the vector size is 128 bits (two double-precision elements per vector) and register-based source operands are held in XMM registers.

When VEX.L = 1, the vector size is 256 bits (four double-precision elements per vector) and register-based source operands are held in YMM registers.

For the four-operand forms, VEX.W determines operand configuration.

- When VEX.W = 0, the second source is either a register or a memory location and the third source is a register.
- When VEX.W = 1, the second source is a register and the third source is either a register or a memory location.

For the three-operand forms, VEX.W is 1. The first and second operands are registers and the third operand is either a register or a memory location.

The destination is either an XMM register or a YMM register, as determined by VEX.L. When the destination is an XMM register (L = 0), bits [255:128] of the corresponding YMM register are cleared.

Negative Multiply and Subtract Packed Single-Precision Floating-Point

Multiplies together two single-precision floating-point vectors, negates the unrounded product, and subtracts a third single-precision floating-point vector from it. The precise result is then rounded to single-precision based on the mode specified by the MXCSR[RC] field and written to the destination register. The role of each of the source operands specified by the assembly language prototypes given below is reflected in the vector equation in the comment on the right.

There are two four-operand forms:

```
VFNMADDPS dest, src1, src2/mem, src3      // dest = −(src1* src2/mem) − src3
VFNMADDPS dest, src1, src2, src3/mem      // dest = −(src1* src2) − src3/mem
```

and three three-operand forms:

```
VFNMADD132PS src1, src2, src3/mem         // src1 = −(src1* src3/mem) − src2
VFNMADD213PS src1, src2, src3/mem         // src1 = −(src2* src1) − src3/mem
VFNMADD231PS src1, src2, src3/mem         // src1 = −(src2* src3/mem) − src1
```

When VEX.L = 0, the vector size is 128 bits (four single-precision elements per vector) and register-based source operands are held in XMM registers.

When VEX.L = 1, the vector size is 256 bits (eight single-precision elements per vector) and register-based source operands are held in YMM registers.

For the four-operand forms, VEX.W determines operand configuration.

- When VEX.W = 0, the second source is either a register or a memory location and the third source is a register.
- When VEX.W = 1, the second source is a register and the third source is either a register or a memory location.

For the three-operand forms, VEX.W is 0. The first and second operands are registers and the third operand is either a register or a memory location.

The destination is either an XMM register or a YMM register, as determined by VEX.L. When the destination is an XMM register (L = 0), bits [255:128] of the corresponding YMM register are cleared.

There are two four-operand forms:

```
VFNMSUBSS dest, src1, src2/mem, src3    // dest = −(src1* src2/mem) − src3
VFNMSUBSS dest, src1, src2, src3/mem    // dest = −(src1* src2) − src3/mem
```

and three three-operand forms:

```
VFNMSUB132SS src1, src2, src3/mem    // src1 = −(src1* src3/mem) − src2
VFNMSUB213SS src1, src2, src3/mem    // src1 = −(src2* src1) − src3/mem
VFNMSUB231SS src1, src2, src3/mem    // src1 = −(src2* src3/mem) − src1
```

For the four-operand forms, VEX.W determines operand configuration.

- When VEX.W = 0, the second source is either a register or a 32-bit memory location and the third source is a register.
- When VEX.W = 1, the second source is a register and the third source is either a register or a 32-bit memory location.

For the three-operand forms, VEX.W is 0. The first and second operands are registers and the third operand is either a register or a 32-bit memory location.

The destination is an XMM register. Bits[127:32] of the destination XMM register and bits [255:128] of the corresponding YMM register are cleared.

SIMD Floating-Point Exceptions				
Invalid operation, IE			F	A source operand was an SNaN value.
			F	Undefined operation.
Denormalized operand, DE			F	A source operand was a denormal value.
Overflow, OE			F	Rounded result too large to fit into the format of the destination operand.
Underflow, UE			F	Rounded result too small to fit into the format of the destination operand.
Precision, PE			F	A result could not be represented exactly in the destination format.
F — FMA, FMA4 exception				

VFRCZPD Extract Fraction Packed Double-Precision Floating-Point

Extracts the fractional portion of each double-precision floating-point value of either a source register or a memory location and writes the resulting values to the corresponding elements of the destination. The fractional results are precise.

- When XOP.L = 0, the source is either an XMM register or a 128-bit memory location.
- When XOP.L = 1, the source is a YMM register or 256-bit memory location.

When the destination is an XMM register, bits [255:128] of the corresponding YMM register are cleared.

Exception conditions are the same as for other arithmetic instructions, except with respect to the sign of a zero result. A zero is returned in the following cases:

- When the operand is a zero.
- When the operand is a normal integer.
- When the operand is a denormal value and is coerced to zero by MXCSR.DAZ.
- When the operand is a denormal value that is not coerced to zero by MXCSR.DAZ.

In the first three cases, when MXCSR.RC = 01b (round toward – ∞) the sign of the zero result is negative, and is otherwise positive.

In the fourth case, the operand is its own fractional part, which results in underflow, and the result is forced to zero by MXCSR.FZ; the result has the same sign as the operand.

VGATHERDPD Conditionally Gather Double-Precision Floating-Point Values, Doubleword Indices

Conditionally loads double-precision (64-bit) values from memory using VSIB addressing with doubleword indices.

The instruction is of the form:

VGATHERDPD *dest, mem64[vm32x], mask*

Loading of each element of the destination register is conditional based on the value of the corresponding element of the mask operand. If the most-significant bit of the *i*th element of the mask is set, the *i*th element of the destination is loaded from memory using the *i*th address of the array of effective addresses calculated using VSIB addressing.

The index register is treated as an array of signed 32-bit values. Quadword elements of the destination for which the corresponding mask element is zero are not affected by the operation. If no exceptions occur, the mask register is set to zero.

Execution of the instruction can be suspended by an exception if the exception is triggered by an element other than the rightmost element loaded. When this happens, the destination register and the mask operand may be observed as partially updated. Elements that have been loaded will have their mask elements set to zero. If any traps or faults are pending from elements that have been loaded, they will be delivered in lieu of the exception; in this case, the RF flag is set so that an instruction breakpoint is not re-triggered when the instruction execution is resumed.

See Section 1.3, “VSIB Addressing,” on page 6 for a discussion of the VSIB addressing mode.

There are 128-bit and 256-bit forms of this instruction.

XMM Encoding

The destination is an XMM register. The first source operand is up to two 64-bit values located in memory. The second source operand (the mask) is an XMM register. The index vector is the two low-order doublewords of an XMM register; the two high-order doublewords of the index register are not used. Bits [255:128] of the YMM register that corresponds to the destination and bits [255:128] of the YMM register that corresponds to the second source (mask) operand are cleared.

YMM Encoding

The destination is a YMM register. The first source operand is up to four 64-bit values located in memory. The second source operand (the mask) is a YMM register. The index vector is the four doublewords of an XMM register.

Instruction Support

VGATHERDPS Conditionally Gather Single-Precision Floating-Point Values, Doubleword Indices

Conditionally loads single-precision (32-bit) values from memory using VSIB addressing with doubleword indices.

The instruction is of the form:

VGATHERDPS *dest, mem32[vm32x/y], mask*

Loading of each element of the destination register is conditional based on the value of the corresponding element of the mask operand. If the most-significant bit of the *i*th element of the mask is set, the *i*th element of the destination is loaded from memory using the *i*th address of the array of effective addresses calculated using VSIB addressing.

The index register is treated as an array of signed 32-bit values. Doubleword elements of the destination for which the corresponding mask element is zero are not affected by the operation. If no exceptions occur, the mask register is set to zero.

Execution of the instruction can be suspended by an exception if the exception is triggered by an element other than the rightmost element loaded. When this happens, the destination register and the mask operand may be observed as partially updated. Elements that have been loaded will have their mask elements set to zero. If any traps or faults are pending from elements that have been loaded, they will be delivered in lieu of the exception; in this case, the RF flag is set so that an instruction breakpoint is not re-triggered when the instruction execution is resumed.

See Section 1.3, “VSIB Addressing,” on page 6 for a discussion of the VSIB addressing mode.

There are 128-bit and 256-bit forms of this instruction.

XMM Encoding

The destination is an XMM register. The first source operand is up to four 32-bit values located in memory. The second source operand (the mask) is an XMM register. The index vector is the four doublewords of an XMM register. Bits [255:128] of the YMM register that corresponds to the destination and bits [255:128] of the YMM register that corresponds to the second source (mask) operand are cleared.

YMM Encoding

The destination is a YMM register. The first source operand is up to eight 32-bit values located in memory. The second source operand (the mask) is a YMM register. The index vector is the eight doublewords of a YMM register.

Instruction Support

VGATHERQPD Conditionally Gather Double-Precision Floating-Point Values, Quadword Indices

Conditionally loads double-precision (64-bit) values from memory using VSIB addressing with quadword indices.

The instruction is of the form:

VGATHERQPD *dest, mem64[vm64x/y], mask*

Loading of each element of the destination register is conditional based on the value of the corresponding element of the mask operand. If the most-significant bit of the *i*th element of the mask is set, the *i*th element of the destination is loaded from memory using the *i*th address of the array of effective addresses calculated using VSIB addressing.

The index register is treated as an array of signed 64-bit values. Quadword elements of the destination for which the corresponding mask element is zero are not affected by the operation. If no exceptions occur, the mask register is set to zero.

Execution of the instruction can be suspended by an exception if the exception is triggered by an element other than the rightmost element loaded. When this happens, the destination register and the mask operand may be observed as partially updated. Elements that have been loaded will have their mask elements set to zero. If any traps or faults are pending from elements that have been loaded, they will be delivered in lieu of the exception; in this case, the RF flag is set so that an instruction breakpoint is not re-triggered when the instruction execution is resumed.

See Section 1.3, “VSIB Addressing,” on page 6 for a discussion of the VSIB addressing mode.

There are 128-bit and 256-bit forms of this instruction.

XMM Encoding

The destination is an XMM register. The first source operand is up to two 64-bit values located in memory. The second source operand (the mask) is an XMM register. The index vector is the two quadwords of an XMM register. Bits [255:128] of the YMM register that corresponds to the destination and bits [255:128] of the YMM register that corresponds to the second source (mask) operand are cleared.

YMM Encoding

The destination is a YMM register. The first source operand is up to four 64-bit values located in memory. The second source operand (the mask) is a YMM register. The index vector is the four quadwords of a YMM register.

A — AVX2 exception				

VGATHERQPS Conditionally Gather Single-Precision Floating-Point Values, Quadword Indices

Conditionally loads single-precision (32-bit) values from memory using VSIB addressing with quadword indices.

The instruction is of the form:

VGATHERQPS *dest, mem32[vm64x/y], mask*

Loading of each element of the destination register is conditional based on the value of the corresponding element of the mask operand. If the most-significant bit of the *i*th element of the mask is set, the *i*th element of the destination is loaded from memory using the *i*th address of the array of effective addresses calculated using VSIB addressing.

The index register is treated as an array of signed 64-bit values. Doubleword elements of the destination for which the corresponding mask element is zero are not affected by the operation. The upper half of the destination is zeroed. If no exceptions occur, the mask register is set to zero.

Execution of the instruction can be suspended by an exception if the exception is triggered by an element other than the rightmost element loaded. When this happens, the destination register and the mask operand may be observed as partially updated. Elements that have been loaded will have their mask elements set to zero. If any traps or faults are pending from elements that have been loaded, they will be delivered in lieu of the exception; in this case, the RF flag is set so that an instruction breakpoint is not re-triggered when the instruction execution is resumed.

See Section 1.3, “VSIB Addressing,” on page 6 for a discussion of the VSIB addressing mode.

There are 128-bit and 256-bit forms of this instruction.

XMM Encoding

The destination is an XMM register. The first source operand is up to two 32-bit values located in memory. The second source operand (the mask) is an XMM register. Only the lower half of the mask is used. The index vector is the two quadwords of an XMM register. Bits [255:64] of the YMM register that corresponds to the destination and bits [255:64] of the YMM register that corresponds to the second source (mask) operand are cleared.

YMM Encoding

The destination is an XMM register. The first source operand is up to four 32-bit values located in memory. The second source operand (the mask) is an XMM register. The index vector is the four quadwords of a YMM register. Bits [255:128] of the YMM register that corresponds to the destination and bits [255:128] of the YMM register that corresponds to the second source (mask) operand are cleared.

VINSERTF128 Insert Packed Floating-Point Values 128-bit

Combines 128 bits of data from a YMM register with 128-bit packed-value data from an XMM register or a 128-bit memory location, as specified by an immediate byte operand, and writes the combined data to the destination.

Only bit [0] of the immediate operand is used. Operation is as follows.

- When imm8[0] = 0, copy bits [255:128] of the first source to bits [255:128] of the destination and copy bits [127:0] of the second source to bits [127:0] of the destination.
- When imm8[0] = 1, copy bits [127:0] of the first source to bits [127:0] of the destination and copy bits [127:0] of the second source to bits [255:128] of the destination.

This extended-form instruction has a single 256-bit encoding.

The first source operand is a YMM register. The second source operand is either an XMM register or a 128-bit memory location. The destination is a YMM register. There is a third immediate byte operand.

VINSERTI128 Insert Packed Integer Values 128-bit

Combines 128 bits of data from a YMM register with 128-bit packed-value data from an XMM register or a 128-bit memory location, as specified by an immediate byte operand, and writes the combined data to the destination.

Bit [0] of the immediate operand controls how the 128-bit values from the source operands are merged into the destination. The operation is as follows.

- When imm8[0] = 0, copy bits [255:128] of the first source to bits [255:128] of the destination and copy bits [127:0] of the second source to bits [127:0] of the destination.
- When imm8[0] = 1, copy bits [127:0] of the first source to bits [127:0] of the destination and copy bits [127:0] of the second source to bits [255:128] of the destination.

This instruction has a single 256-bit encoding.

The first source operand is a YMM register. The second source operand is either an XMM register or a 128-bit memory location. The destination is a YMM register. The immediate byte is encoded in the instruction.

VMASKMOVPD Masked Move Packed Double-Precision

Moves packed double-precision data elements from a source element to a destination element, as specified by mask bits in a source operand. There are load and store versions of the instruction.

For loads, the data elements are in a source memory location; for stores the data elements are in a source register. The mask bits are the most-significant bit of the corresponding data element of a source register.

- For loads, when a mask bit = 1, the corresponding data element is copied from the source to the same element of the destination; when a mask bit = 0, the corresponding element of the destination is cleared.
- For stores, when a mask bit = 1, the corresponding data element is copied from the source to the same element of the destination; when a mask bit = 0, the corresponding element of the destination is not affected.

Exception and trap behavior for elements not selected for loading or storing from/to memory is implementation dependent. For instance, a given implementation may signal a data breakpoint or a page fault for quadwords that are zero-masked and not actually written.

XMM Encoding

There are load and store encodings.

- For loads, there are two 64-bit source data elements in a 128-bit memory location, the mask operand is an XMM register, and the destination is an XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.
- For stores, there are two 64-bit source data elements in an XMM register, the mask operand is an XMM register, and the destination is a 128-bit memory location.

YMM Encoding

There are load and store encodings.

- For loads, there are four 64-bit source data elements in a 256-bit memory location, the mask operand is a YMM register, and the destination is a YMM register.
- For stores, there are four 64-bit source data elements in a YMM register, the mask operand is a YMM register, and the destination is a 128-bit memory location.

VMASKMOVPS Masked Move Packed Single-Precision

Moves packed single-precision data elements from a source element to a destination element, as specified by mask bits in a source operand. There are load and store versions of the instruction.

For loads, the data elements are in a source memory location; for stores the data elements are in a source register. The mask bits are the most-significant bits of the corresponding data element of a source register.

- For loads, when a mask bit = 1, the corresponding data element is copied from the source to the same element of the destination; when a mask bit = 0, the corresponding element of the destination is cleared.
- For stores, when a mask bit = 1, the corresponding data element is copied from the source to the same element of the destination; when a mask bit = 0, the corresponding element of the destination is not affected.

Exception and trap behavior for elements not selected for loading or storing from/to memory is implementation dependent. For instance, a given implementation may signal a data breakpoint or a page fault for doublewords that are zero-masked and not actually written.

XMM Encoding

There are load and store encodings.

- For loads, there are four 32-bit source data elements in a 128-bit memory location, the mask operand is an XMM register, and the destination is an XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.
- For stores, there are four 32-bit source data elements in an XMM register, the mask operand is an XMM register, and the destination is a 128-bit memory location.

YMM Encoding

There are load and store encodings.

- For loads, there are eight 32-bit source data elements in a 256-bit memory location, the mask operand is a YMM register, and the destination is a YMM register.
- For stores, there are eight 32-bit source data elements in a YMM register, the mask operand is a YMM register, and the destination is a 128-bit memory location.

VPBLENDD — Blend Packed Doublewords

Copies packed doublewords from either of two sources to a destination, as specified by an immediate 8-bit mask operand.

Each bit of the mask selects a doubleword from one of the source operands to be copied to the destination. The least-significant bit controls the selection of the doubleword to be copied to the lowest doubleword of the destination. For each doubleword *i* of the destination:

- When mask bit [*i*] = 0, doubleword *i* of the first source operand is copied to the corresponding doubleword of the destination.
- When mask bit [*i*] = 1, doubleword *i* of the second source operand is copied to the corresponding doubleword of the destination.

VPBLENDD

The instruction has 128-bit and 256-bit encodings.

XMM Encoding

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is either a YMM register or a 256-bit memory location. The destination is a third YMM register.

VPBROADCASTB Broadcast Packed Byte

Loads a byte from a register or memory and writes it to all 16 or 32 bytes of an XMM or YMM register.

This instruction has both 128-bit and 256-bit encodings:

XMM Encoding

Copies the source operand to all 16 bytes of the destination.

The source operand is the least-significant 8 bits of an XMM register or an 8-bit memory location. The destination is an XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

Copies the source operand to all 32 bytes of the destination.

The source operand is the least-significant 8 bits of an XMM register or an 8-bit memory location. The destination is a YMM register.

Instruction Support

VPBROADCASTD Broadcast Packed Doubleword

Loads a doubleword from a register or memory and writes it to all 4 or 8 doublewords of an XMM or YMM register.

This instruction has both 128-bit and 256-bit encodings:

XMM Encoding

Copies the source operand to all 4 doublewords of the destination.

The source operand is the least-significant 32 bits of an XMM register or a 32-bit memory location. The destination is an XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

Copies the source operand to all 8 doublewords of the destination.

The source operand is the least-significant 32 bits of an XMM register or a 32-bit memory location. The destination is a YMM register.

Instruction Support

Form	Subset	Feature Flag
VPBROADCASTD	AVX2	CPUID Fn0000_0007_EBX[AVX2]_x0 (bit 5)

For more on using the CPUID instruction to obtain processor feature support information, see Appendix E of Volume 3.

A — AVX exception.				

VPBROADCASTQ Broadcast Packed Quadword

Loads a quadword from a register or memory and writes it to all 2 or 4 quadwords of an XMM or YMM register.

This instruction has both 128-bit and 256-bit encodings:

XMM Encoding

Copies the source operand to both quadwords of the destination.

The source operand is the least-significant 64 bits of an XMM register or a 64-bit memory location. The destination is an XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

Copies the source operand to all 4 quadwords of the destination.

The source operand is the least-significant 64 bits of an XMM register or a 64-bit memory location. The destination is a YMM register.

Instruction Support

Form	Subset	Feature Flag
VPBROADCASTQ	AVX2	CPUID Fn0000_0007_EBX[AVX2]_x0 (bit 5)

VPBROADCASTW Broadcast Packed Word

Loads a word from a register or memory and writes it to all 8 or 16 words of an XMM or YMM register.

This instruction has both 128-bit and 256-bit encodings:

XMM Encoding

Copies the source operand to all 8 words of the destination.

The source operand is the least-significant 16 bits of an XMM register or a 16-bit memory location. The destination is an XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

Copies the source operand to all 16 words of the destination.

The source operand is the least-significant 16 bits of an XMM register or a 16-bit memory location. The destination is a YMM register.

VPCMOV Vector Conditional Move

Moves bits of either the first source or the second source to the corresponding positions in the destination, depending on the value of the corresponding bit of a third source.

When a bit of the third source = 1, the corresponding bit of the first source is moved to the destination; when a bit of the third source = 0, the corresponding bit of the second source is moved to the destination.

This instruction directly implements the C-language ternary "?" operation on each source bit.

Arbitrary bit-granular predicates can be constructed by any number of methods, or loaded as constants from memory. This instruction may use the results of any SSE instructions as the predicate in the selector. VPCMPEQB (VPCMPGTB), VPCMPEQW (VPCMPGTW), VPCMPEQD (VPCMPGTD) and VPCMPEQQ (VPCMPGTQ) compare bytes, words, doublewords, quadwords and integers, respectively, and set the predicate in the destination to masks of 1s and 0s accordingly. VCMPPS (VCMPSS) and VCMPPD (VCMPSD) compare word and doubleword floating-point source values, respectively, and provide the predicate for the floating-point instructions.

There are four operands: VPCMOV *dest, src1, src2, src3.*

The first source (*src1*) is an XMM or YMM register specified by XOP.vvvv.

XOP.W and bits [7:4] of an immediate byte (*imm8*) configure *src2* and *src3*:

- When XOP.W = 0, *src2* is either a register or a memory location specified by ModRM.r/m and *src3* is a register specified by *imm8[7:4]*.
- When XOP.W = 1, s*rc2* is a register specified by *imm8[7:4]* and *src3* is either a register or a memory location specified by ModRM.r/m.

The destination (*dest*) is either an XMM or a YMM register, as determined by XOP.L. When the destination is an XMM register, bits [255:128] of the corresponding YMM register are cleared.

Instruction Support

Form	Subset	Feature Flag
VPCMOV	XOP	CPUID Fn8000_0001_ECX[XOP] (bit 11)

VPCOMB — Compare Vector Signed Bytes

Compares corresponding packed signed bytes in the first and second sources and writes the result of each comparison in the corresponding byte of the destination. The result of each comparison is an 8-bit value of all 1s (TRUE) or all 0s (FALSE).

There are four operands: VPCOMB *dest*, *src1*, *src2*, *imm8*

The destination (*dest*) is an XMM registers specified by ModRM.reg. When the comparison results are written to the destination XMM register, bits [255:128] of the corresponding YMM register are cleared.

The first source (*src1*) is an XMM register specified by the XOP.vvvv field and the second source (*src2*) is either an XMM register or a 128-bit memory location specified by the ModRM.r/m field.

The comparison type is specified by bits [2:0] of the immediate-byte operand (*imm8*). Each type has an alias mnemonic to facilitate coding.

VPCOMUW — Compare Vector Unsigned Words

Compares corresponding packed unsigned words in the first and second sources and writes the result of each comparison to the corresponding word of the destination. The result of each comparison is a 16-bit value of all 1s (TRUE) or all 0s (FALSE).

There are four operands: VPCOMUW *dest, src1, src2, imm8*

The destination (*dest*) is an XMM register specified by ModRM.reg. When the results are written to the destination XMM register, bits [255:128] of the corresponding YMM register are cleared.

The first source (src1) is an XMM register specified by the XOP.vvvv field and the second source (src2) is either an XMM register or a 128-bit memory location specified by the ModRM.r/m field.

The comparison type is specified by bits [2:0] of an immediate-byte operand (*imm8)*. Each type has an alias mnemonic to facilitate coding.

VPERM2F128 Permute Floating-Point 128-bit

Copies 128 bits of floating-point data from a selected octword of two 256-bit source operands or zero to each octword of a 256-bit destination, as specified by an immediate byte operand.

The immediate operand is encoded as follows.

Destination	Immediate-Byte Bit Field	Value of Bit Field	Source 1 Bits Copied	Source 2 Bits Copied
[127:0]	[1:0]	00	[127:0]	—
		01	[255:128]	—
		10	—	[127:0]
		11	—	[255:128]
Setting *imm8* [3] clears bits [127:0] of the destination; i*mm8* [2] is ignored.				
[255:128]	[5:4]	00	[127:0]	—
		01	[255:128]	—
		10	—	[127:0]
		11	—	[255:128]
Setting *imm8* [7] clears bits [255:128] of the destination; i*mm8* [6] is ignored.				

This is a 256-bit extended-form instruction:

The first source operand is a YMM register and the second source operand is either a YMM register or a 256-bit memory location. The destination is a third YMM register.

Instruction Support

Form	Subset	Feature Flag

VPERM2I128 Permute Integer 128-bit

Copies 128 bits of integer data from a selected octword of two 256-bit source operands or zero to each octword of a 256-bit destination, as specified by an immediate byte operand.

The immediate operand is encoded as follows.

Destination	Immediate-Byte Bit Field	Value of Bit Field	Source 1 Bits Copied	Source 2 Bits Copied
[127:0]	[1:0]	00	[127:0]	—
		01	[255:128]	—
		10	—	[127:0]
		11	—	[255:128]
Setting *imm8* [3] clears bits [127:0] of the destination; *imm8* [2] is ignored.				
[255:128]	[5:4]	00	[127:0]	—
		01	[255:128]	—
		10	—	[127:0]
		11	—	[255:128]
Setting *imm8* [7] clears bits [255:128] of the destination; *imm8* [6] is ignored.				

This is a 256-bit extended-form instruction:

The first source operand is a YMM register and the second source operand is either a YMM register or a 256-bit memory location. The destination is a third YMM register. Bits 2 and 6 of the immediate byte are ignored.

VPERMD Packed Permute Doubleword

Copies selected doublewords from a 256-bit value located either in memory or a YMM register to specific doublewords of the destination YMM register. For each doubleword of the destination, selection of which doubleword to copy from the source is specified by a selector field in the corresponding doubleword of a YMM register.

There is a single form of this instruction:

VPERMD *dest, src1, src2*

The first source operand provides eight 3-bit selectors, each selector occupying the least-significant bits of a doubleword. Each selector specifies the index of the doubleword of the second source operand to be copied to the destination. The doubleword in the destination that each selector controls is based on its position within the first source operand.

The index value may be the same in multiple selectors. This results in multiple copies of the same source doubleword being copied to the destination.

There is no 128-bit form of this instruction.

YMM Encoding

The destination is a YMM register. The first source operand is a YMM register and the second source operand is either a YMM register or a 256-bit memory location.

VPERMIL2PD Permute Two-Source Double-Precision Floating-Point

Copies a selected quadword from one of two source operands to a selected quadword of the destination or clears the selected quadword of the destination. Values in a third source operand and an immediate two-bit operand control the operation.

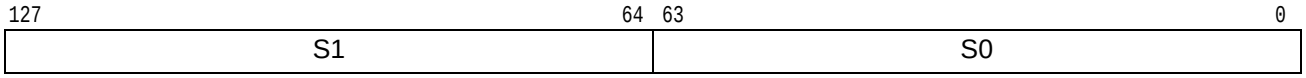
There are 128-bit and 256-bit versions of this instruction. Both versions have five operands:

VPERMIL2PD *dest, src1, src2, src3, m2z.*

The first four operands are either 128 bits or 256 bits wide, as determined by VEX.L. When the destination is an XMM register, bits [255:128] of the corresponding YMM register are cleared.

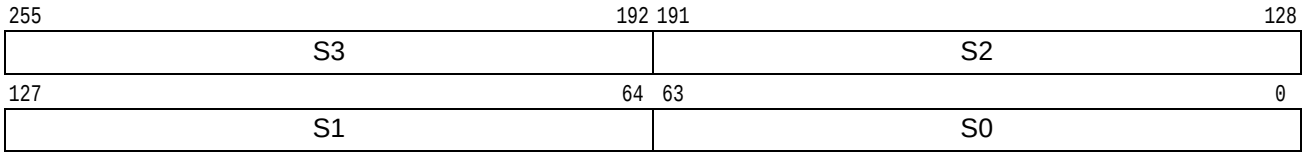
The third source operand is a selector that specifies how quadwords are copied or cleared in the destination. The selector contains one selector element for each quadword of the destination register.

Selector for 128-bit Instruction Form



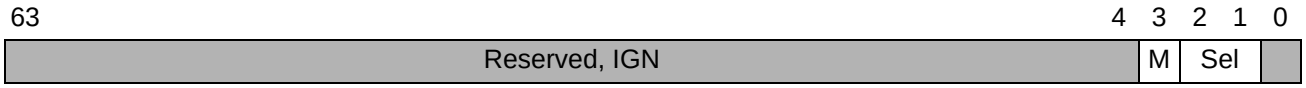
The selector for the 128-bit instruction form is an octword composed of two quadword selector elements S0 and S1. S0 (the lower quadword) controls the value written to destination quadword 0 (bits [63:0]) and S1 (the upper quadword) controls the destination quadword 1 (bits [127:64]).

Selector for 256-bit Instruction Form



The selector for the 256-bit instruction form is a double octword and adds two more selector elements S2 and S3. S0 controls the value written to the destination quadword 0 (bits [63:0]), S1 controls the destination quadword 1 (bits [127:64]), S2 controls the destination quadword 2 (bits [191:128]), and S3 controls the destination quadword 3 (bits [255:192]).

The layout of each selector element is as follows:



Bits	Mnemonic	Description
[63:4]	—	Reserved, IGN
[3]	M	Match
[2:1]	Sel	Select
[0]	—	Reserved, IGN

The fields are defined as follows:

- Sel — Select. Selects the source quadword to copy into the corresponding quadword of the destination:

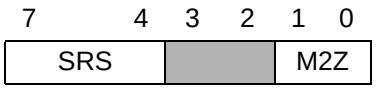
Sel Value	Source Selected for Destination Quadwords 0 and 1 (both forms)	Source Selected for Destination Quadwords 2 and 3 (256-bit form)
00b	*src1*[63:0]	*src1*[191:128]
01b	*src1*[127:64]	*src1*[255:192]
10b	*src2*[63:0]	*src2*[191:128]
11b	*src2*[127:64]	*src2*[255:192]

- M — Match bit. The combination of the Match bit in each selector element and the value of the M2Z field determines if the Select field is overridden. This is described below.

m2z immediate operand

The fifth operand is *m2z*. The assembler uses this 2-bit value to encode the M2Z field in the instruction. M2Z occupies bits [1:0] of an immediate byte. Bits [7:4] of the same byte are used to select one of 16 YMM/XMM registers. This dual use of the immediate byte is indicated in the instruction synopsis by the symbol “is5”.

The immediate byte is defined as follows.



Bits	Mnemonic	Description
[7:4]	SRS	Source Register Select
[3:2]	—	Reserved, IGN
[1:0]	M2Z	Match to Zero

Fields are defined as follows:

- SRS — Source Register Select. As with many other extended instructions, bits in the immediate byte are used to select a source operand register. This field is set by the assembler based on the operands listed in the instruction. See discussion in “*src2* and *src3* Operand Addressing” below.
- M2Z — Match to Zero. This field, combined with the M bit of the selector element, controls the function of the Sel field as follows:

M2Z Field	Selector M Bit	Value Loaded into Destination Quadword
0Xb	X	Source quadword selected by selector element Sel field.
10b	0	Source quadword selected by selector element Sel field.
10b	1	Zero
11b	0	Zero
11b	1	Source quadword selected by selector element Sel field.

src2 and *src3* Operand Addressing

In 64-bit mode, VEX.W and bits [7:4] of the immediate byte specify *src2* and *src3*:

- When VEX.W = 0, *src2* is either a register or a memory location specified by ModRM.r/m and *src3* is a register specified by bits [7:4] of the immediate byte.
- When VEX.W = 1, s*rc2* is a register specified by bits [7:4] of the immediate byte and *src3* is either a register or a memory location specified by ModRM.r/m.

In non-64-bit mode, bit 7 is ignored.

Instruction Support

Form	Subset	Feature Flag
VPERMIL2PD	XOP	CPUID Fn8000_0001_ECX[XOP] (bit 11)

For more on using the CPUID instruction to obtain processor feature support information, see Appendix E of Volume 3.

VPERMIL2PS Permute Two-Source Single-Precision Floating-Point

Copies a selected doubleword from one of two source operands to a selected doubleword of the destination or clears the selected doubleword of the destination. Values in a third source operand and an immediate two-bit operand control operation.

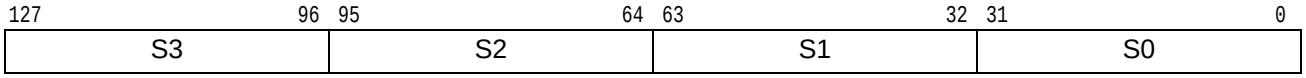
There are 128-bit and 256-bit versions of this instruction. Both versions have five operands:

VPERMIL2PS *dest, src1, src2, src3, m2z*

The first four operands are either 128 bits or 256 bits wide, as determined by VEX.L. When the destination is an XMM register, bits [255:128] of the corresponding YMM register are cleared.

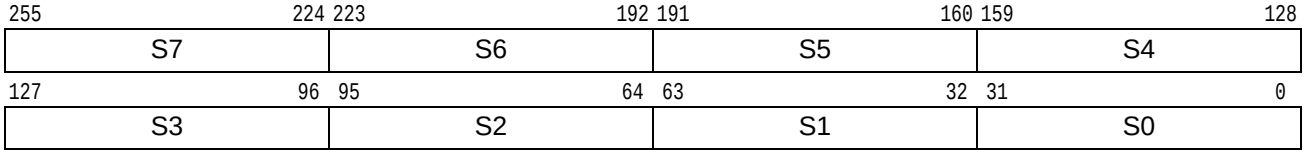
The third source operand is a selector that specifies how doublewords are copied or cleared in the destination. The selector contains one selector element for each doubleword of the destination register.

Selector for 128-bit Instruction Form



The selector for the 128-bit instruction form is an octword containing four selector elements S0–S3. S0 controls the value written to the destination doubleword 0 (bits [31:0]), S1 controls the destination doubleword 1 (bits [63:32]), S2 controls the destination doubleword 2 (bits [95:64]), and S3 controls the destination doubleword 3 (bits [127:96]).

Selector for 256-bit Instruction Form



The selector for the 256-bit instruction form is a double octword and adds four more selector elements S4–S7. S4 controls the value written to the destination doubleword 4 (bits [159:128]), S5 controls the destination doubleword 5 (bits [191:160]), S6 controls the destination doubleword 6 (bits [223:192]), and S7 controls the destination doubleword 7 (bits [255:224]).

The layout of each selector element is as follows.

Bits	Mnemonic	Description
[31:4]	—	Reserved, IGN
[3]	M	Match
[2:0]	Sel	Select

The fields are defined as follows:

- Sel — Select. Selects the source doubleword to copy into the corresponding doubleword of the destination:

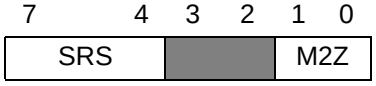
Sel Value	Source Selected for Destination Doublewords 0, 1, 2 and 3 (both forms)	Source Selected for Destination Doublewords 4, 5, 6 and 7 (256-bit form)
000b	*src1*[31:0]	*src1*[159:128]
001b	*src1*[63:32]	*src1*[191:160]
010b	*src1*[95:64]	*src1*[223:192]
011b	*src1*[127:96]	*src1*[255:224]
100b	*src2*[31:0]	*src2*[159:128]
101b	*src2*[63:32]	*src2*[191:160]
110b	*src2*[95:64]	*src2*[223:192]
111b	*src2*[127:96]	*src2*[255:224]

- M — Match. The combination of the M bit in each selector element and the value of the M2Z field determines if the Sel field is overridden. This is described below.

m2z immediate operand

The fifth operand is *m2z*. The assembler uses this 2-bit value to encode the M2Z field in the instruction. M2Z occupies bits [1:0] of an immediate byte. Bits [7:4] of the same byte are used to select one of 16 YMM/XMM registers. This dual use of the immediate byte is indicated in the instruction synopsis by the symbol “is5”.

The immediate byte is defined as follows.



Bits	Mnemonic	Description
[7:4]	SRS	Source Register Select
[3:2]	—	Reserved, IGN
[1:0]	M2Z	Match to Zero

Fields are defined as follows:

- SRS — Source Register Select. As with many other extended instructions, bits in the immediate byte are used to select a source operand register. This field is set by the assembler based on the operands listed in the instruction. See discussion in “*src2* and *src3* Operand Addressing” below.
- M2Z — Match to Zero. This field, combined with the M bit of the selector element, controls the function of the Sel field as follows:

M2Z Field	Selector M Bit	Value Loaded into Destination Doubleword
0Xb	X	Source doubleword selected by Sel field.
10b	0	Source doubleword selected by Sel field.

M2Z Field	Selector M Bit	Value Loaded into Destination Doubleword
10b	1	Zero
11b	0	Zero
11b	1	Source doubleword selected by Sel field.

src2 and *src3* Operand Addressing

In 64-bit mode, VEX.W and bits [7:4] of the immediate byte specify *src2* and *src3*:

- When VEX.W = 0, *src2* is either a register or a memory location specified by ModRM.r/m and *src3* is a register specified by bits [7:4] of the immediate byte.
- When VEX.W = 1, s*rc2* is a register specified by bits [7:4] of the immediate byte and *src3* is either a register or a memory location specified by ModRM.r/m.

In non-64-bit mode, bit 7 is ignored.

Instruction Support

Form	Subset	Feature Flag
VPERMIL2PS	XOP	CPUID Fn8000_0001_ECX[XOP] (bit 11)

For more on using the CPUID instruction to obtain processor feature support information, see Appendix E of Volume 3.

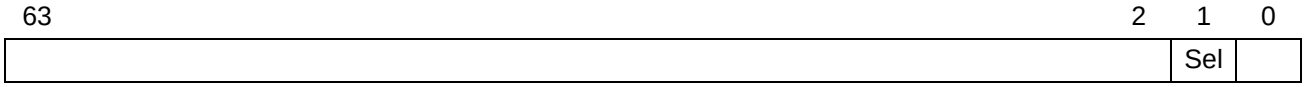
VPERMILPD Permute Double-Precision

Copies double-precision floating-point values from a source to a destination. Source and destination can be selected in two ways. There are different encodings for each selection method.

Selection by bits in a source register or memory location:

Each quadword of the operand is defined as follows.



A bit selects source and destination. Only bit [1] is used; bits [63:2} and bit [0] are ignored. Setting the bit selects the corresponding quadword element of the source and the destination.

Selection by bits in an immediate byte:

Each bit corresponds to a destination quadword. Only bits [3:2] and bits [1:0] are used; bits [7:4] are ignored. Selections are defined as follows.

Destination Quadword	Immediate-Byte Bit Field	Value of Bit Field	Source 1 Bits Copied
Used by 128-bit encoding and 256-bit encoding			
[63:0]	[0]	0	[63:0]
		1	[127:64]
[127:64]	[1]	0	[63:0]
		1	[127:64]
Used only by 256-bit encoding			
[191:128]	[2]	0	[191:128]
		1	[255:192]
[255:192]	[3]	0	[191:128]
		1	[255:192]

This extended-form instruction has both 128-bit and 256-bit encoding.

XMM Encoding

There are two encodings, one for each selection method:

- The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.
- The first source operand is either an XMM register or a 128-bit memory location. The destination is an XMM register. There is a third, immediate byte operand. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

There are two encodings, one for each selection method:

- The first source operand is a YMM register. The second source operand is either a YMM register or a 256-bit memory location. The destination is a third YMM register.
- The first source operand is either a YMM register or a 256-bit memory location. The destination is a YMM register. There is a third, immediate byte operand.

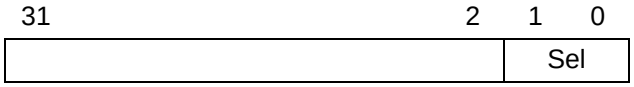
A — AVX exception.				

VPERMILPS Permute Single-Precision

Copies single-precision floating-point values from a source to a destination. Source and destination can be selected in two ways. There are different encodings for each selection method.

Selection by bit fields in a source register or memory location:

Each doubleword of the operand is defined as follows.



Each bit field corresponds to a destination doubleword. Bit values select a source doubleword. Only bits [1:0] of each word are used; bits [31:2} are ignored. The 128-bit encoding uses four two-bit fields; the 256-bit version uses eight two-bit fields. Field encoding is as follows.

Destination Doubleword	Immediate Operand Bit Field	Value of Bit Field	Source Bits Copied
[31:0]	[1:0]	00	[31:0]
		01	[63:32]
		10	[95:64]
		11	[127:96]
[63:32]	[33:32]	00	[31:0]
		01	[63:32]
		10	[95:64]
		11	[127:96]
[95:64]	[65:64]	00	[31:0]
		01	[63:32]
		10	[95:64]
		11	[127:96]
[127:96]	[97:96]	00	[31:0]
		01	[63:32]
		10	[95:64]
		11	[127:96]

Destination Doubleword	Immediate Operand Bit Field	Value of Bit Field	Source Bits Copied
Upper 128 bits of 256-bit source and destination used by 256-bit encoding			
[159:128]	[129:128]	00	[159:128]
		01	[191:160]
		10	[223:192]
		11	[255:224]
[191:160]	[161:160]	00	[159:128]
		01	[191:160]
		10	[223:192]
		11	[255:224]
[223:192]	[193:192]	00	[159:128]
		01	[191:160]
		10	[223:192]
		11	[255:224]

		01	[191:160]
		10	[223:192]
		11	[255:224]

Selection by bit fields in an immediate byte:

Each bit field corresponds to a destination doubleword. For the 256-bit encoding, the fields specify sources and destinations in both the upper and lower 128 bits of the register. Selections are defined as follows.

Destination Doubleword	Bit Field	Value of Bit Field	Source Bits Copied
[31:0]	[1:0]	00	[31:0]
		01	[63:32]
		10	[95:64]
		11	[127:96]
[63:32]	[3:2]	00	[31:0]
		01	[63:32]
		10	[95:64]
		11	[127:96]
[95:64]	[5:4]	00	[31:0]
		01	[63:32]
		10	[95:64]
		11	[127:96]
[127:96]	[7:6]	00	[31:0]
		01	[63:32]
		10	[95:64]
		11	[127:96]

Destination Doubleword	Bit Field	Value of Bit Field	Source Bits Copied
Upper 128 bits of 256-bit source and destination used by 256-bit encoding			
[159:128]	[1:0]	00	[159:128]
		01	[191:160]
		10	[223:192]
		11	[255:224]
[191:160]	[3:2]	00	[159:128]
		01	[191:160]
		10	[223:192]
		11	[255:224]
[223:192]	[5:4]	00	[159:128]
		01	[191:160]
		10	[223:192]
		11	[255:224]
[255:224]	[7:6]	00	[159:128]
		01	[191:160]
		10	[223:192]
		11	[255:224]

This extended-form instruction has both 128-bit and 256-bit encodings:

XMM Encoding

There are two encodings, one for each selection method:

- The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.
- The first source operand is either an XMM register or a 128-bit memory location. The destination is an XMM register. There is a third, immediate byte operand. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

There are two encodings, one for each selection method:

- The first source operand is a YMM register. The second source operand is either a YMM register or a 256-bit memory location. The destination is a third YMM register.
- The first source operand is either a YMM register or a 256-bit memory location. The destination is a YMM register. There is a third, immediate byte operand.

VPERMPD Packed Permute Double-Precision Floating-Point

Copies selected quadwords from a 256-bit value located either in memory or a YMM register to specific quadwords of the destination. For each quadword of the destination, selection of which quadword to copy from the source is specified by a 2 bit selector field in an immediate byte.

There is a single form of this instruction:

VPERMPD *dest, src, imm8*

The selection of which quadword of the source operand to copy to each quadword of the destination is specified by four 2-bit selector fields in the immediate byte. Bits [1:0] specify the index of the quadword to be copied to the destination quadword 0. Bits [3:2] select the quadword to be copied to quadword 1, bits [5:4] select the quadword to be copied to quadword 2, and bits [7:6] select the quadword to be copied to quadword 3.

The index value may be the same in multiple selectors. This results in multiple copies of the same source quadword being copied to the destination.

There is no 128-bit form of this instruction.

YMM Encoding

The destination is a YMM register. The source operand is a YMM register or a 256-bit memory location.

Instruction Support

Form	Subset	Feature Flag
VPERMPD	AVX2	Fn0000_00007_EBX[AVX2]_x0 (bit 5)

VPERMPS Packed Permute Single-Precision Floating-Point

Copies selected doublewords from a 256-bit value located either in memory or a YMM register to specific doublewords of the destination YMM register. For each doubleword of the destination, selection of which doubleword to copy from the source is specified by a selector field in the corresponding doubleword of a YMM register.

There is a single form of this instruction:

VPERMPS *dest, src1, src2*

The first source operand provides eight 3-bit selectors, each selector occupying the least-significant bits of a doubleword. Each selector specifies the index of the doubleword of the second source operand to be copied to the destination. The doubleword in the destination that each selector controls is based on its position within the first source operand.

The index value may be the same in multiple selectors. This results in multiple copies of the same source doubleword being copied to the destination.

There is no 128-bit form of this instruction.

YMM Encoding

The destination is a YMM register. The first source operand is a YMM register and the second source operand is either a YMM register or a 256-bit memory location.

Instruction Support

Form	Subset	Feature Flag
VPERMPS	AVX2	Fn0000_00007_EBX[AVX2]_x0 (bit 5)

VPERMQ Packed Permute Quadword

Copies selected quadwords from a 256-bit value located either in memory or a YMM register to specific quadwords of the destination. For each quadword of the destination, selection of which quadword to copy from the source is specified by a 2 bit selector field in an immediate byte.

There is a single form of this instruction:

VPERMQ *dest, src, imm8*

The selection of which quadword of the source operand to copy to each quadword of the destination is specified by four 2-bit selector fields in the immediate byte. Bits [1:0] specify the index of the quadword to be copied to the destination quadword 0. Bits [3:2] select the quadword to be copied to quadword 1, bits [5:4] select the quadword to be copied to quadword 2, and bits [7:6] select the quadword to be copied to quadword 3.

The index value may be the same in multiple selectors. This results in multiple copies of the same source quadword being copied to the destination.

There is no 128-bit form of this instruction.

YMM Encoding

The destination is a YMM register. The source operand is a YMM register or a 256-bit memory location.

VPGATHERDD Conditionally Gather Doublewords, Doubleword Indices

Conditionally loads doubleword values from memory using VSIB addressing with doubleword indices.

The instruction is of the form:

VPGATHERDD *dest, mem32[vm32x/y], mask*

The loading of each element of the destination register is conditional based on the value of the corresponding element of the mask (second source operand). If the most-significant bit of the *i*th element of the mask is set, the *i*th element of the destination is loaded from memory using the *i*th address of the array of effective addresses calculated using VSIB addressing.

The index register is treated as an array of signed 32-bit values. Doubleword elements of the destination for which the corresponding mask element is zero are not affected by the operation. If no exceptions occur, the mask register is set to zero.

Execution of the instruction can be suspended by an exception if the exception is triggered by an element other than the rightmost element loaded. When this happens, the destination register and the mask operand may be observed as partially updated. Elements that have been loaded will have their mask elements set to zero. If any traps or faults are pending from elements that have been loaded, they will be delivered in lieu of the exception; in this case, the RF flag is set so that an instruction breakpoint is not re-triggered when the instruction execution is resumed.

See Section 1.3, “VSIB Addressing,” on page 6 for a discussion of the VSIB addressing mode.

There are 128-bit and 256-bit forms of this instruction.

XMM Encoding

The destination is an XMM register. The first source operand is up to four 32-bit values located in memory. The second source operand (the mask) is an XMM register. The index vector is the four doublewords of an XMM register. Bits [255:128] of the YMM register that corresponds to the destination and bits [255:128] of the YMM register that corresponds to the second source (mask) operand are cleared.

YMM Encoding

The destination is a YMM register. The first source operand is up to eight 32-bit values located in memory. The second source operand (the mask) is a YMM register. The index vector is the eight doublewords of a YMM register.

Instruction Support

Form	Subset	Feature Flag
VPGATHERDD	AVX2	Fn0000_00007_EBX[AVX2]_x0 (bit 5)

VPGATHERDQ Conditionally Gather Quadwords, Doubleword Indices

Conditionally loads quadword values from memory using VSIB addressing with doubleword indices.

The instruction is of the form:

VPGATHERDQ *dest, mem64[vm32x], mask*

The loading of each element of the destination register is conditional based on the value of the corresponding element of the mask (second source operand). If the most-significant bit of the *i*th element of the mask is set, the *i*th element of the destination is loaded from memory using the *i*th address of the array of effective addresses calculated using VSIB addressing.

The index register is treated as an array of signed 32-bit values. Quadword elements of the destination for which the corresponding mask element is zero are not affected by the operation. If no exceptions occur, the mask register is set to zero.

Execution of the instruction can be suspended by an exception if the exception is triggered by an element other than the rightmost element loaded. When this happens, the destination register and the mask operand may be observed as partially updated. Elements that have been loaded will have their mask elements set to zero. If any traps or faults are pending from elements that have been loaded, they will be delivered in lieu of the exception; in this case, the RF flag is set so that an instruction breakpoint is not re-triggered when the instruction execution is resumed.

See Section 1.3, “VSIB Addressing,” on page 6 for a discussion of the VSIB addressing mode.

There are 128-bit and 256-bit forms of this instruction.

XMM Encoding

The destination is an XMM register. The first source operand is up to two 64-bit values located in memory. The second source operand (the mask) is an XMM register. The index vector is the two low-order doublewords of an XMM register; the two high-order doublewords of the index register are not used. Bits [255:128] of the YMM register that corresponds to the destination and bits [255:128] of the YMM register that corresponds to the second source (mask) operand are cleared.

YMM Encoding

The destination is a YMM register. The first source operand is up to four 64-bit values located in memory. The second source operand (the mask) is a YMM register. The index vector is the four doublewords of an XMM register.

VPGATHERQD Conditionally Gather Doublewords, Quadword Indices

Conditionally loads doubleword values from memory using VSIB addressing with quadword indices.

The instruction is of the form:

VPGATHERQD *dest, mem32[vm64x/y], mask*

The loading of each element of the destination register is conditional based on the value of the corresponding element of the mask (second source operand). If the most-significant bit of the *i*th element of the mask is set, the *i*th element of the destination is loaded from memory using the *i*th address of the array of effective addresses calculated using VSIB addressing.

The index register is treated as an array of signed 64-bit values. Doubleword elements of the destination for which the corresponding mask element is zero are not affected by the operation. If no exceptions occur, the mask register is set to zero.

Execution of the instruction can be suspended by an exception if the exception is triggered by an element other than the rightmost element loaded. When this happens, the destination register and the mask operand may be observed as partially updated. Elements that have been loaded will have their mask elements set to zero. If any traps or faults are pending from elements that have been loaded, they will be delivered in lieu of the exception; in this case, the RF flag is set so that an instruction breakpoint is not re-triggered when the instruction execution is resumed.

See Section 1.3, “VSIB Addressing,” on page 6 for a discussion of the VSIB addressing mode.

There are 128-bit and 256-bit forms of this instruction.

XMM Encoding

The destination is an XMM register. The first source operand is up to two 32-bit values located in memory. The second source operand (the mask) is an XMM register. The index vector is the two quadwords of an XMM register. The upper half of the destination register and the mask register are cleared. Bits [255:128] of the YMM register that corresponds to the destination and bits [255:128] of the YMM register that corresponds to the mask register are cleared.

YMM Encoding

The destination is an XMM register. The first source operand is up to four 32-bit values located in memory. The second source operand (the mask) is an XMM register. The index vector is the four quadwords of a YMM register. Bits [255:128] of the YMM register that corresponds to the destination and bits [255:128] of the YMM register that corresponds to the mask register are cleared.

VPGATHERQQ Conditionally Gather Quadwords, Quadword Indices

Conditionally loads quadword values from memory using VSIB addressing with quadword indices.

The instruction is of the form:

VPGATHERQQ *dest, mem64[vm64x/y], mask*

The loading of each element of the destination register is conditional based on the value of the corresponding element of the mask (second source operand). If the most-significant bit of the *i*th element of the mask is set, the *i*th element of the destination is loaded from memory using the *i*th address of the array of effective addresses calculated using VSIB addressing.

The index register is treated as an array of signed 64-bit values. Quadword elements of the destination for which the corresponding mask element is zero are not affected by the operation. If no exceptions occur, the mask register is set to zero.

Execution of the instruction can be suspended by an exception if the exception is triggered by an element other than the rightmost element loaded. When this happens, the destination register and the mask operand may be observed as partially updated. Elements that have been loaded will have their mask elements set to zero. If any traps or faults are pending from elements that have been loaded, they will be delivered in lieu of the exception; in this case, the RF flag is set so that an instruction breakpoint is not re-triggered when the instruction execution is resumed.

See Section 1.3, “VSIB Addressing,” on page 6 for a discussion of the VSIB addressing mode.

There are 128-bit and 256-bit forms of this instruction.

XMM Encoding

The destination is an XMM register. The first source operand is up to two 64-bit values located in memory. The second source operand (the mask) is an XMM register. The index vector is the two quadwords of an XMM register. Bits [255:128] of the YMM register that corresponds to the destination and bits [255:128] of the YMM register that corresponds to the second source (mask) operand are cleared.

YMM Encoding

The destination is a YMM register. The first source operand is up to four 64-bit values located in memory. The second source operand (the mask) is a YMM register. The index vector is the four quadwords of a YMM register.

VPMACSDD Packed Multiply Accumulate Signed Doubleword to Signed Doubleword

Multiplies each packed 32-bit signed integer value of the first source by the corresponding value of the second source, adds the corresponding value of the third source to the 64-bit signed integer product, and writes four 32-bit sums to the destination.

No saturation is performed on the sum. When the result of the multiplication causes non-zero values to be set in the upper 32 bits of the 64-bit product, they are ignored. When the result of the add overflows, the carry is ignored (neither the overflow nor carry bit in rFLAGS is set). In both cases, only the signed low-order 32 bits of the result are written to the destination.

There are four operands: VPMACSDD *dest, src1, src2, src3* *dest = src1* src2 + src3*

The destination (*dest*) is an XMM register specified by ModRM.reg. When the destination is written, bits [255:128] of the corresponding YMM register are cleared.

The first source (*src1*) is an XMM register specified by XOP.vvvv; the second source (*src2*) is either an XMM register or a 128-bit memory location specified by the ModRM.r/m field; and the third source (*src3*) is an XMM register specified by bits [7:4] of an immediate byte operand.

When the third source designates the same XMM register as the destination, the XMM register behaves as an accumulator.

Instruction Support

VPMACSDQH Packed Multiply Accumulate Signed High Doubleword to Signed Quadword

Multiplies the second 32-bit signed integer value of the first source by the corresponding value of the second source, then adds the low-order 64-bit signed integer value of the third source to the 64-bit signed integer product. Simultaneously, multiplies the fourth 32-bit signed integer value of the first source by the fourth 32-bit signed integer value of the second source, then adds the high-order 64-bit signed integer value of the third source to the 64-bit signed integer product. Writes two 64-bit sums to the destination.

No saturation is performed on the sum. When the result of the add overflows, the carry is ignored (neither the overflow nor carry bit in rFLAGS is set).

There are four operands: VPMACSDQH *dest, src1, src2, src3* *dest = src1* src2 + src3*

The destination (*dest*) is an XMM register specified by ModRM.reg. When the destination is written, bits [255:128] of the corresponding YMM register are cleared.

The first source (*src1*) is an XMM register specified by the XOP.vvvv field; the second source (*src2*) is either an XMM register or a 128-bit memory location specified by the ModRM.r/m field; and the third source (*src3*) is an XMM register specified by bits [7:4] of an immediate byte operand.

When the third source designates the same XMM register as the destination, the XMM register behaves as an accumulator.

VPMACSSDD Packed Multiply Accumulate with Saturation Signed Doubleword to Signed Doubleword

Multiplies each packed 32-bit signed integer value of the first source by the corresponding value of the second source, then adds the corresponding packed 32-bit signed integer value of the third source to each 64-bit signed integer product. Writes four saturated 32-bit sums to the destination.

Out of range results of the addition are saturated to fit into a signed 32-bit integer. For each packed value of the destination, when the value is larger than the largest signed 32-bit integer, it is saturated to 7FFF_FFFFh, and when the value is smaller than the smallest signed 32-bit integer, it is saturated to 8000_0000h.

There are four operands: VPMACSSDD *dest, src1, src2, src3* *dest = src1* src2 + src3*

The destination (*dest*) is an XMM register specified by ModRM.reg. When the destination is written, bits [255:128] of the corresponding YMM register are cleared.

The first source (*src1*) is an XMM register specified by XOP.vvvv; the second source (*src2*) is either an XMM register or a 128-bit memory location specified by the ModRM.r/m field; and the third source (*src3*) is an XMM register specified by bits [7:4] of an immediate byte operand.

When *src3* designates the same XMM register as the *dest* register, the XMM register behaves as an accumulator.

VPMACSSDQH Packed Multiply Accumulate with Saturation Signed High Doubleword to Signed Quadword

Multiplies the second 32-bit signed integer value of the first source by the corresponding value of the second source, then adds the low-order 64-bit signed integer value of the third source to the 64-bit signed integer product. Simultaneously, multiplies the fourth 32-bit signed integer value of the first source by the corresponding value of the second source, then adds the high-order 64-bit signed integer value of the third source to the 64-bit signed integer product. Writes two saturated sums to the destination.

Out of range results of the addition are saturated to fit into a signed 64-bit integer. For each packed value of the destination, when the value is larger than the largest signed 64-bit integer, it is saturated to 7FFF_FFFF_FFFF_FFFFh, and when the value is smaller than the smallest signed 64-bit integer, it is saturated to 8000_0000_0000_0000h.

There are four operands: VPMACSSDQH *dest, src1, src2, src3* *dest = src1* src2 + src3*

The destination (*dest*) is an XMM register specified by ModRM.reg. When the destination XMM register is written, bits [255:128] of the corresponding YMM register are cleared.

The first source (*src1*) is an XMM register specified by XOP.vvvv; the second source (*src2*) is either an XMM register or a 128-bit memory location specified by the ModRM.r/m field; and the third source (*src3*) is an XMM register specified by bits [7:4] of an immediate byte operand.

When *src3* designates the same XMM register as the *dest* register, the XMM register behaves as an accumulator.

VPMACSSWW Packed Multiply Accumulate with Saturation Signed Word to Signed Word

Multiplies each packed 16-bit signed integer value of the first source by the corresponding packed 16-bit signed integer value of the second source, then adds the corresponding packed 16-bit signed integer value of the third source to the 32-bit signed integer products. Writes eight saturated sums to the destination.

Out of range results of the addition are saturated to fit into a signed 16-bit integer. For each packed value of the destination, when the value is larger than the largest signed 16-bit integer, it is saturated to 7FFFh, and when the value is smaller than the smallest signed 16-bit integer, it is saturated to 8000h.

There are four operands:

VPMACSSWW *dest, src1, src2, src3* *dest = src1* src2 + src3*

The destination is an XMM register specified by ModRM.reg. When the destination is written, bits [255:128] of the corresponding YMM register are cleared.

The first source (*src1*) is an XMM register specified by XOP.vvvv; the second source (*src2*) is either an XMM register or a 128-bit memory location specified by the ModRM.r/m field; and the third source (*src3*) is an XMM register specified by bits [7:4] of an immediate byte.

When *src3* and *dest* designate the same XMM register, this register behaves as an accumulator.

VPMACSWD Packed Multiply Accumulate Signed Word to Signed Doubleword

Multiplies each odd-numbered packed 16-bit signed integer value of the first source by the corresponding value of the second source, then adds the corresponding packed 32-bit signed integer value of the third source to the 32-bit signed integer products. Writes four 32-bit results to the destination.

When the result of the add overflows, the carry is ignored (neither the overflow nor carry bit in rFLAGS is set). Only the low-order 32 bits of the result are written to the destination.

There are four operands: VPMACSWD *dest, src1, src2, src3* *dest = src1* src2 + src3*

The destination (*dest*) register is an XMM register specified by ModRM.reg. When the destination XMM register is written, bits [255:128] of the corresponding YMM register are cleared.

The first source (*src1*) is an XMM register specified by XOP.vvvv; the second source (*src2*) is either an XMM register or a 128-bit memory location specified by the ModRM.r/m field; and the third source (*src3*) is an XMM register specified by bits [7:4] of an immediate byte operand.

When *src3* designates the same XMM register as the *dest* register, the XMM register behaves as an accumulator.

VPMACSWW Packed Multiply Accumulate Signed Word to Signed Word

Multiplies each packed 16-bit signed integer value of the first source by the corresponding value of the second source, then adds the corresponding packed 16-bit signed integer value of the third source to each 32-bit signed integer product. Writes eight 16-bit results to the destination.

No saturation is performed on the sum. When the result of the multiplication causes non-zero values to be set in the upper 16 bits of the 32 bit result, they are ignored. When the result of the add overflows, the carry is ignored (neither the overflow nor carry bit in rFLAGS is set). In both cases, only the signed low-order 16 bits of the result are written to the destination.

There are four operands: VPMACSWW *dest, src1, src2, src3* *dest = src1* src2 + src3*

The destination (*dest*) is an XMM register specified by ModRM.reg. When the destination XMM register is written, bits [255:128] of the corresponding YMM register are cleared.

The first source (*src1*) is an XMM register specified by XOP.vvvv; the second source (*src2*) is either an XMM register or a 128-bit memory location specified by the ModRM.r/m field; and the third source (*src3*) is an XMM register specified by bits [7:4] of an immediate byte operand.

When *src3* designates the same XMM register as the *dest* register, the XMM register behaves as an accumulator.

VPMADCSSWD Packed Multiply Add Accumulate with Saturation Signed Word to Signed Doubleword

Multiplies each packed 16-bit signed integer value of the first source by the corresponding value of the second source, then adds the 32-bit signed integer products of the even-odd adjacent words. Each resulting sum is then added to the corresponding packed 32-bit signed integer value of the third source. Writes four 32-bit signed-integer results to the destination.

Out of range results of the addition are saturated to fit into a signed 32-bit integer. For each packed value of the destination, when the value is larger than the largest signed 32-bit integer, it is saturated to 7FFF_FFFFh, and when the value is smaller than the smallest signed 32-bit integer, it is saturated to 8000_0000h.

There are four operands: VPMADCSSWD *dest, src1, src2, src3* *dest = src1* src2 + src3*

The destination is an XMM register specified by ModRM.reg. When the destination is written, bits [255:128] of the corresponding YMM register are cleared.

The first source is an XMM register specified by XOP.vvvv; the second source is either an XMM register or a 128-bit memory location specified by the ModRM.r/m field; and the third source is an XMM register specified by bits [7:4] of an immediate byte operand.

When *src3* designates the same XMM register as the *dest* register, the XMM register behaves as an accumulator.

VPMADCSWD Packed Multiply Add Accumulate Signed Word to Signed Doubleword

Multiplies each packed 16-bit signed integer value of the first source by the corresponding value of the second source, then adds the 32-bit signed integer products of the even-odd adjacent words together and adds the sums to the corresponding packed 32-bit signed integer values of the third source. Writes four 32-bit sums to the destination.

No saturation is performed on the sum. When the result of the addition overflows, the carry is ignored (neither the overflow nor carry bit in rFLAGS is set). Only the signed 32-bits of the result are written to the destination.

There are four operands: VPMADCSWD *dest, src1, src2, src3* *dest = src1* src2 + src3*

The destination is an XMM register specified by ModRM.reg. When the destination is written, bits [255:128] of the corresponding YMM register are cleared.

The first source is an XMM register specified by XOP.vvvv, the second source is either an XMM register or a 128-bit memory location specified by the ModRM.r/m field; and the third source is an XMM register specified by bits [7:4] of an immediate byte operand.

When *src3* designates the same XMM register as the *dest* register, the XMM register behaves as an accumulator.

VPMASKMOVD — Masked Move Packed Doubleword

Moves packed doublewords from a second source operand to a destination, as specified by mask bits in a first source operand. There are load and store versions of the instruction.

The mask bits are the most-significant bit of each doubleword in the first source operand (mask).

- For loads, when a mask bit = 1, the corresponding doubleword is copied from the source to the same element of the destination; when a mask bit = 0, the corresponding element of the destination is cleared.
- For stores, when a mask bit = 1, the corresponding doubleword is copied from the source to the same element of the destination; when a mask bit = 0, the corresponding element of the destination is not affected.

Exception and trap behavior for elements not selected for loading or storing from/to memory is implementation dependent. For instance, a given implementation may signal a data breakpoint or a page fault for doublewords that are zero-masked and not actually written.

This instruction provides no non-temporal access hint.

This instruction has both 128-bit and 256-bit forms:

XMM Encoding

There are load and store encodings.

- For loads, the four doublewords that make up the source operand are located in a 128-bit memory location, the mask operand is an XMM register, and the destination is an XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.
- For stores, the four doublewords that make up the source operand are located in an XMM register, the mask operand is an XMM register, and the destination is a 128-bit memory location.

YMM Encoding

There are load and store encodings.

- For loads, the eight doublewords that make up the source operand are located in a 256-bit memory location, the mask operand is a YMM register, and the destination is a YMM register.
- For stores, the eight doublewords that make up the source operand are located in a YMM register, the mask operand is a YMM register, and the destination is a 256-bit memory location.

VPPERM Packed Permute Bytes

Selects 16 of 32 packed bytes from two concatenated sources, applies a logical transformation to each selected byte, then writes the byte to a specified position in the destination.

There are four operands: VPPERM *dest, src1, src2, src3*

The second (*src2*) and first (*src1*) sources are concatenated to form the 32-byte source.

The *src1* operand is an XMM register specified by XOP.vvvv.

The third source (*src3*) contains 16 control bytes. Each control byte specifies the source byte and the logical operation to perform on that byte. The order of the bytes in the destination is the same as that of the control bytes in the *src3*.

For each byte of the 16-byte result, the corresponding *src3* byte is used as follows:

- Bits [7:5] select a logical operation to perform on the selected byte.

Bit Value	Selected Operation
000	Source byte (no logical operation)
001	Invert source byte
010	Bit reverse of source byte
011	Bit reverse of inverted source byte
100	00h (zero-fill)
101	FFh (ones-fill)
110	Most significant bit of source byte replicated in all bit positions.
111	Invert most significant bit of source byte and replicate in all bit positions.

- Bits [4:0] select a source byte to move from *src2*:*src1*.

Bit Value	Source Byte	Bit Value	Source Byte	Bit Value	Source Byte	Bit Value	Source Byte
00000	*src1*[7:0]	01000	*src1*[71:64]	10000	*src2*[7:0]	11000	*src2*[71:64]
00001	*src1*[15:8]	01001	*src1*[79:72]	10001	*src2*[15:8]	11001	*src2*[79:72]
00010	*src1*[23:16]	01010	*src1*[87:80]	10010	*src2*[23:16]	11010	*src2*[87:80]
00011	*src1*[31:24]	01011	*src1*[95:88]	10011	*src2*[31:24]	11011	*src2*[95:88]
00100	*src1*[39:32]	01100	*src1*[103:96]	10100	*src2*[39:32]	11100	*src2*[103:96]
00101	*src1*[47:40]	01101	*src1*[111:104]	10101	*src2*[47:40]	11101	*src2*[111:104]
00110	*src1*[55:48]	01110	*src1*[119:112]	10110	*src2*[55:48]	11110	*src2*[119:112]
00111	*src1*[63:56]	01111	*src1*[127:120]	10111	*src2*[63:56]	11111	*src2*[127:120]

XOP.W and an immediate byte (*imm8*) determine register configuration.

- When XOP.W = 0, *src2* is either an XMM register or a 128-bit memory location specified by ModRM.r/m and *src3* is an XMM register specified by *imm8[7:4]*.

- When XOP.W = 1, *src2* is an XMM register specified by *imm8[7:4]* and *src3* is either an XMM register or a 128-bit memory location specified by ModRM.r/m.

The destination (*dest*) is an XMM register specified by ModRM.reg. When the result is written to the *dest* XMM register, bits [255:128] of the corresponding YMM register are cleared.

VPROTB Packed Rotate Bytes

Rotates each byte of the source as specified by a count operand and writes the result to the corresponding byte of the destination.

There are two versions of the instruction, one for each source of the count byte:

- VPROTB *dest, src, fixed-count*
- VPROTB *dest, src, variable-count*

For both versions of the instruction, the destination (*dest*) operand is an XMM register specified by ModRM.reg.

The *fixed-count* version of the instruction rotates each byte of the source (*src*) the number of bits specified by the immediate *fixed-count* byte. All bytes are rotated the same amount. The source XMM register or memory location is selected by the ModRM.r/m field.

The *variable-count* version of the instruction rotates each byte of the source the amount specified in the corresponding byte element of the *variable-count*. Both *src* and *variable-count* are configured by XOP.W.

- When XOP.W = 0, *variable-count* is an XMM register specified by XOP.vvvv and *src* is either an XMM register or a 128-bit memory location specified by ModRM.r/m.
- When XOP.W = 1, *variable-count* is either an XMM register or a 128-bit memory location specified by ModRM.r/m and *src* is an XMM register specified by XOP.vvvv.

When the count value is positive, bits are rotated to the left (toward the more significant bit positions). The bits rotated out left of the most significant bit are rotated back in at the right end (least-significant bit) of the byte.

When the count value is negative, bits are rotated to the right (toward the least significant bit positions). The bits rotated to the right out of the least significant bit are rotated back in at the left end (most-significant bit) of the byte.

Bits [255:128] of the YMM register that corresponds to the destination are cleared.

VPROTD Packed Rotate Doublewords

Rotates each doubleword of the source as specified by a count operand and writes the result to the corresponding doubleword of the destination.

There are two versions of the instruction, one for each source of the count byte:

- VPROTD *dest, src, fixed-count*
- VPROTD *dest, src, variable-count*

For both versions of the instruction, the *dest* operand is an XMM register specified by ModRM.reg.

The fixed count version of the instruction rotates each doubleword of the source operand the number of bits specified by the immediate *fixed-count* byte operand. All doublewords are rotated the same amount. The *src* XMM register or memory location is selected by the ModRM.r/m field.

The variable count version of the instruction rotates each doubleword of the source by the amount specified in the low order byte of the corresponding doubleword of the *variable-count* operand vector.

Both *src* and *variable-count* are configured by XOP.W.

- When XOP.W = 0, *src* is either an XMM register or a128-bit memory location specified by the ModRM.r/m field and *variable-count* is an XMM register specified by XOP.vvvv.
- When XOP.W = 1, *src* is an XMM register specified by XOP.vvvv and *variable-count* is either an XMM register or a 128-bit memory location specified by the ModRM.r/m field.

When the count value is positive, bits are rotated to the left (toward the more significant bit positions). The bits rotated out to the left of the most significant bit of each source doubleword operand are rotated back in at the right end (least-significant bit) of the doubleword.

When the count value is negative, bits are rotated to the right (toward the least significant bit positions). The bits rotated to the right out of the least significant bit of each source doubleword operand are rotated back in at the left end (most-significant bit) of the doubleword.

Bits [255:128] of the YMM register that corresponds to the destination are cleared.

VPROTQ Packed Rotate Quadwords

Rotates each quadword of the source operand as specified by a count operand and writes the result to the corresponding quadword of the destination.

There are two versions of the instruction, one for each source of the count byte:

- VPROTQ *dest, src, fixed-count*
- VPROTQ *dest, src, variable-count*

For both versions of the instruction, the *dest* operand is an XMM register specified by ModRM.reg.

The fixed count version of the instruction rotates each quadword in the source the number of bits specified by the immediate *fixed-count* byte operand. All quadword elements of the source are rotated the same amount. The *src* XMM register or memory location is selected by the ModRM.r/m field.

The variable count version of the instruction rotates each quadword of the source the amount specified ny the low order byte of the corresponding quadword of the *variable-count* operand.

Both *src* and *variable-count* are configured by XOP.W.

- When XOP.W = 0, *src* is either an XMM register or a 128-bit memory location specified by ModRM.r/m and *variable-count* is an XMM register specified by XOP.vvvv.
- When XOP.W = 1, *src* is an XMM register specified by XOP.vvvv and *variable-count* is either an XMM register or a128-bit memory location specified by ModRM.r/m.

When the count value is positive, bits are rotated to the left (toward the more significant bit positions) of the operand element. The bits rotated out to the left of the most significant bit of the word element are rotated back in at the right end (least-significant bit).

When the count value is negative, operand element bits are rotated to the right (toward the least significant bit positions). The bits rotated to the right out of the least significant bit are rotated back in at the left end (most-significant bit) of the word element.

Bits [255:128] of the YMM register that corresponds to the destination are cleared.

VPROTW Packed Rotate Words

Rotates each word of the source as specified by a count operand and writes the result to the corresponding word of the destination.

There are two versions of the instruction, one for each source of the count byte:

- VPROTW dest, *src*, *fixed-count*
- VPROTW dest, *src*, *variable-count*

For both versions of the instruction, the *dest* operand is an XMM register specified by ModRM.reg.

The fixed count version of the instruction rotates each word of the source the number of bits specified by the immediate *fixed-count* byte operand. All words of the source operand are rotated the same amount. The *src* XMM register or memory location is selected by the ModRM.r/m field.

The variable count version of this instruction rotates each word of the source operand by the amount specified in the low order byte of the corresponding word of the *variable-count* operand.

Both *src* and *variable-count* are configured by XOP.W.

- When XOP.W = 0, *src* is either an XMM register or a 128-bit memory location specified by ModRM.r/m and *variable-count* is an XMM register specified by XOP.vvvv.
- When XOP.W = 1, *src* is an XMM register specified by XOP.vvvv and *variable-count* is either an XMM register or a 128-bit memory location specified by ModRM.r/m.

When the count value is positive, bits are rotated to the left (toward the more significant bit positions). The bits rotated out to the left of the most significant bit of an element are rotated back in at the right end (least-significant bit) of the word element.

When the count value is negative, bits are rotated to the right (toward the least significant bit positions) of the element. The bits rotated to the right out of the least significant bit of an element are rotated back in at the left end (most-significant bit) of the word element.

Bits [255:128] of the YMM register that corresponds to the destination are cleared.

VPSHAB Packed Shift Arithmetic Bytes

Shifts each signed byte of the source as specified by a count byte and writes the result to the corresponding byte of the destination.

The count bytes are 8-bit signed two's-complement values in the corresponding bytes of the *count* operand.

When the count value is positive, bits are shifted to the left (toward the more significant bit positions). Zeros are shifted in at the right end (least-significant bit) of the byte.

When the count value is negative, bits are shifted to the right (toward the least significant bit positions). The most significant bit (sign bit) is replicated and shifted in at the left end (most-significant bit) of the byte.

There are three operands: VPSHAB *dest*, *src*, *count*

The destination (*dest*) is an XMM register specified by ModRM.reg.

Both *src* and *count* are configured by XOP.W.

- When XOP.W = 0, *count* is an XMM register specified by XOP.vvvv and *src* is either an XMM register or a128-bit memory location specified by ModRM.r/m.
- When XOP.W = 1, *count* is either an XMM register or a 128-bit memory location specified by ModRM.r/m and *src* is an XMM register specified by XOP.vvvv.

Bits [255:128] of the YMM register that corresponds to the destination are cleared.

VPSLLVD Variable Shift Left Logical Doublewords

Left-shifts the bits of each doubleword in the first source operand by a count specified in the corresponding doubleword of a second source operand and writes the shifted values to the destination.

The second source operand is treated as an array of unsigned 32-bit integers. Each integer specifies the shift count of the corresponding doubleword of the first source operand. Each doubleword is shifted independently.

Low-order bits emptied by shifting are cleared. High-order bits shifted out of each doubleword are discarded. When the shift count for any doubleword is greater than 31, that doubleword is cleared in the destination.

This instruction has 128-bit and 256-bit encodings:

XMM Encoding

The first source operand is an XMM register. The shift count array is specified by either a second XMM register or a 128-bit memory location. The destination is an XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The shift count array is specified by either a second YMM register or a 256-bit memory location. The destination is a YMM register.

Instruction Support

VPSLLVQ Variable Shift Left Logical Quadwords

Left-shifts the bits of each quadword in the first source operand by a count specified in the corresponding quadword of a second source operand and writes the shifted values to the destination.

The second source operand is treated as an array of unsigned 64-bit integers. Each integer specifies the shift count of the corresponding quadword of the first source operand. Each quadword is shifted independently.

Low-order bits emptied by shifting are cleared. High-order bits shifted out of each quadword are discarded. When the shift count for any quadword is greater than 63, that quadword is cleared in the destination.

This instruction has 128-bit and 256-bit encodings:

XMM Encoding

The first source operand is an XMM register. The shift count array is specified by either a second XMM register or a 128-bit memory location. The destination is an XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

VPSRAVD Variable Shift Right Arithmetic Doublewords

Performs a right arithmetic shift of each signed 32-bit integer in the first source operand by a count specified in the corresponding doubleword of a second source operand and writes the shifted values to the destination.

The second source operand is treated as an array of unsigned 32-bit integers. Each integer specifies the shift count of the corresponding doubleword of the first source operand. Each doubleword is shifted independently.

A copy of the sign bit is shifted into the most-significant bit of the element on each right-shift. Low-order bits shifted out of each element are discarded. If a doubleword contains a positive integer and the shift count is greater than 31, that doubleword is cleared in the destination. If a doubleword contains a negative integer and the shift count is greater than 31, that doubleword is set to -1 in the destination.

This instruction has 128-bit and 256-bit encodings:

XMM Encoding

The first source operand is an XMM register. The shift count array is specified by either a second XMM register or a 128-bit memory location. The destination is an XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The shift count array is specified by either a second YMM register or a 256-bit memory location. The destination is a YMM register.

VTESTPD Packed Bit Test

Performs two different logical operations on the sign bits of the first and second packed floating-point operands and updates the ZF and CF flags based on the results.

First, performs a bitwise AND of the sign bits of each double-precision floating-point element of the first source operand with the sign bits of the corresponding elements of the second source operand. Sets rFLAGS.ZF when all bit operations = 0; else, clears ZF.

Second, performs a bitwise AND of the complements (NOT) of the sign bits of each double-precision floating-point element of the first source with the sign bits of the corresponding elements of the second source operand. Sets rFLAGS.CF when all bit operations = 0; else, clears CF.

Neither source operand is modified.

This extended-form instruction has both 128-bit and 256-bit encoding.

XMM Encoding

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location.

YMM Encoding

The first source operand is a YMM register. The second source operand is either a YMM register or a 256-bit memory location.

Instruction Support

VTESTPS Packed Bit Test

Performs two different logical operations on the sign bits of the first and second packed floating-point operands and updates the ZF and CF flags based on the results.

First, performs a bitwise AND of the sign bits of each single-precision floating-point element of the first source operand with the sign bits of the corresponding elements of the second source operand. Sets rFLAGS.ZF when all bit operations = 0; else, clears ZF.

Second, performs a bitwise AND of the complements (NOT) of the sign bits of each single-precision floating-point element of the first source with the sign bits of the corresponding elements of the second source operand. Sets rFLAGS.CF when all bit operations = 0; else, clears CF.

Neither source operand is modified.

This extended-form instruction has both 128-bit and 256-bit encoding.

XMM Encoding

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location.

YMM Encoding

The first source operand is a YMM register. The second source operand is either a YMM register or a 256-bit memory location.

A — AVX exception.				

XGETBV Get Extended Control Register Value

Copies the content of the extended control register (XCR) specified by the ECX register into the EDX:EAX register pair. The high-order 32 bits of the XCR are loaded into EDX and the low-order 32 bits are loaded into EAX. The corresponding high-order 32 bits of RAX and RDX are cleared.

This instruction and associated data structures extend the FXSAVE/FXRSTOR memory image used to manage processor states and provide additional functionality. See the XSAVE instruction description for more information.

Values returned to EDX:EAX in unimplemented bit locations are undefined.

Specifying a reserved or unimplemented XCR in ECX causes a general protection exception.

Currently, only XCR0 (the XFEATURE_ENABLED_MASK register) is supported. If CPUID reports support for ECX=1 (see table below), then the XGETBV instruction supports an ECX value of 1. When ECX=1, XGETBV returns the logical and of XCR0 and the current value of the XINUSE state-component bitmap.

Instruction Support

Form	Subset	Feature Flag
XGETBV	XSAVE/XRSTOR	CPUID Fn0000_0001_ECX[XSAVE] (bit 26)
XGETBV	ECX=1 support	CPUID Fn0000_000D_EAX_x1[2] = 1

For more on using the CPUID instruction to obtain processor feature support information, see Appendix E of Volume 3.

Instruction Encoding

Mnemonic	Opcode	Description
XGETBV	0F 01 D0	Copies content of the XCR specified by ECX into EDX:EAX.

XORPD VXORPD XOR Packed Double-Precision Floating-Point

Performs bitwise XOR of two packed double-precision floating-point values in the first source operand with the corresponding values of the second source operand and writes the results into the corresponding elements of the destination.

There are legacy and extended forms of the instruction:

XORPD

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The first source register is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VXORPD

The extended form of the instruction has both 128-bit and 256-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register and the second source operand is either a YMM register or a 256-bit memory location. The destination is a third YMM register.

Instruction Support

Form	Subset	Feature Flag
XORPD	SSE2	CPUID Fn0000_0001_EDX[SSE2] (bit 26)
VXORPD	AVX	CPUID Fn0000_0001_ECX[AVX] (bit 28)

XORPS XOR
VXORPS Packed Single-Precision Floating-Point

Performs bitwise XOR of four packed single-precision floating-point values in the first source operand with the corresponding values of the second source operand and writes the results into the corresponding elements of the destination.

There are legacy and extended forms of the instruction:

XORPS

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The first source register is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VXORPS

The extended form of the instruction has both 128-bit and 256-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register and the second source operand is either a YMM register or a 256-bit memory location. The destination is a third YMM register.

XRSTOR Restore Extended States

Restores a selected set of enabled processor state data from a save area at a specified address in memory. This instruction and associated data structures extend the FXSAVE/FXRSTOR memory image used to manage processor state and provide additional functionality. See the description of the XSAVE instruction for basic operational details.

The XRSTOR instruction may operate on the save area in standard form or a compact form. The compact form is indicated in the save area with XCOMP_BV[63]=1.

In either form, the instruction creates a Requested Feature Bit Map (RFBM) which is the logical AND of EDX:EAX and XCR0 which selects the processor components to be operated on. Then for each feature bit:

1. If RFBM = 0, XRSTOR does not update the component.
2. If RFBM = 1 but the corresponding XSTATE_BV bit is 0, the component is set to its reset state without reading anything out of the save area.
3. If RFBM =1 and XSTATE_BV =1, the component state is read from the save area.
4. XRSTOR loads an internal state value XRSTOR_INFO that can be used to further optimize a subsequent XSAVEOPT or XSAVES. This reflects the current privilege level and virtualization mode as well as the save area's base address and XCOMP_BV field.
5. If RFBM=1, the corresponding XINUSE bit is set to the state of XSTATE_BV.

For standard mode, MXCSR is loaded if RFBM[1]=1 or RFBM[2]=1. It is never initialized.

For compact mode, MXCSR is associated with RFBM[1].

In some generations, the FP error pointers were only restored if there was a Floating Point error logged. In newer generations, the FP error pointers are always restored. This is indicated by CPUID Fn8000_0008_EBX[2].

Refer to Volume 2, Section 11.5, "XSAVE/XRSTOR Instructions" for other operational detail including save area formats.

Instruction Support

Form	Subset	Feature Flag
XRSTOR	XRSTOR	CPUID Fn0000_00001_ECX[XSAVE] (bit 26)

For more on using the CPUID instruction to obtain processor feature support information, see Appendix E of Volume 3.

XRSTORS Restore Extended States Supervisor

Restores a selected set of enabled processor state data from a save area at a specified address in memory, optionally including privileged state.

XRSTORS is very similar to the XRSTOR instruction in compacted form with the following differences:

1. XRSTORS must be executed at CPL=0
2. XRSTORS must read XCOMP_BV[63]=1, otherwise it will cause a #GP(0) exception
3. XRSTORS is able to restore state enabled from the IA32_XSS MSR.

All other behavior is the same as XRSTOR with the compact form.

Instruction Support

XSAVE Save Extended States

Saves a selected set of enabled processor state data to a save area at a specified memory address.

This instruction and associated data structures extend the FXSAVE/FXRSTOR memory image used to manage numeric coprocessor state and provide additional functionality.

The XSAVE/XRSTOR save area consists of a header section, and individual save areas for each processor state component. A component is saved when both the corresponding bits in the mask operand (EDX:EAX) and the XFEATURE_ENABLED_MASK (XCR0) register are set. This bit-wise logical AND of EDX:EAX and XCR0 is known as the Requested Feature Bit Map (RFBM). A component is not saved when its corresponding RFBM bit is zero.

Software can set any bit in EDX:EAX, regardless of whether the bit position in XCR0 is valid for the processor. When the mask operand contains all 1's, all processor state components enabled in XCR0 are saved.

For each component saved, XSAVE sets the corresponding bit in the XSTATE_BV field of the save area header. XSAVE does not clear XSTATE_BV bits or modify individual save areas for components that are not saved. If a saved component is in the hardware-specified initialized state, XSAVE may clear the corresponding XSTATE_BV bit instead of setting it. This optimization is implementation-dependent.

The MXCSR register is saved if either of RFBM bits 0 or 1 are set to 1. If there is no floating point error present, some generations would not write out any of the FP error pointers. On newer generations, these fields are written to zeros. This is indicated by CPUID Fn8000_0008_EBX[2].

Refer to Volume 2, Section 11.5, "XSAVE/XRSTOR Instructions" for other operational detail including save area formats.

Instruction Support

Form	Subset	Feature Flag
XSAVE	XSAVE/XRSTOR	CPUID Fn0000_0001_ECX[XSAVE] (bit 26)

XSAVEC Save Extended States, Compacted

Saves a selected set of enabled processor state data to a save area at a specified memory address, possibly in a compacted form.

This instruction and associated data structures extend the FXSAVE/FXRSTOR memory image used to manage processor states and provides compaction functionality for more efficient context switching. See the XSAVE and XRSTOR instruction descriptions for basic operational details..

XSAVEC is very similar to XSAVE but provides the following alternate functionality:

1. XSAVEC differs from XSAVE by using the init optimization and compaction.
2. XSAVEC differs by only saving a component if its RFBM=1 and its XINUSE=1. XINUSE is a means by which the processor determines whether the feature is in its Initial state.
3. XSAVEC never writes bytes 511:464 of the legacy XSAVE data structure.
4. XSAVEC calculates XSTATE_BV by performing the logical AND of the RFBM and XINUSE bitmaps and writes it to the XSAVE area.
5. XSAVEC calculates XCOMP_BV as [63]=1 and 62:0 = RFBM, and writes it to the XSAVE area.
6. XSAVEC does not modify any other parts of the header except as indicated in 4 and 5.
7. XSAVEC uses the compacted format of the XSAVE extended region while saving state.

Instruction Support

Form	Subset	Feature Flag
XSAVE mem	XSAVEC	CPUID Fn0000_0000D_EAX_x1[XSAVEC] (bit 1)

XSAVEOPT Save Extended States, Performance Optimized

Saves a selected set of enabled processor state data to a save area at a specified memory address.

This instruction and associated data structures extend the FXSAVE/FXRSTOR memory image used to manage processor states and provide additional functionality. See the XSAVE and XRSTOR instruction descriptions for basic operational details.

The XSAVE/XRSTOR save area consists of a header section, and individual save areas for each processor state component. A component is saved when both the corresponding bits in the mask operand (EDX:EAX) and the XFEATURE_ENABLED_MASK (XCR0) register are set. A component is not saved when either of the corresponding bits in EDX:EAX or XCR0 is cleared.

Software can set any bit in EDX:EAX, regardless of whether the bit position in XCR0 is valid for the processor. When the mask operand contains all 1's, all processor state components enabled in XCR0 are saved.

For each component saved, XSAVEOPT sets the corresponding bit in the XSTATE_BV field of the save area header. XSAVEOPT does not clear XSTATE_BV bits or modify individual save areas for components that are not saved. If a saved component is in the hardware-specified initialized state, XSAVEOPT may clear the corresponding XSTATE_BV bit instead of setting it. This optimization is implementation-dependent.

XSAVEOPT may provide other implementation-specific optimizations, such as the *modified* optimization described for XSAVES.

Instruction Support

Form	Subset	Feature Flag
XSAVEOPT	XSAVEOPT	CPUID Fn0000_0000D_EAX_x1[XSAVEOPT] (bit 0)

For more on using the CPUID instruction to obtain processor feature support information, see Appendix E of Volume 3.

XSAVES Save Extended States Supervisor

Saves a selected set of enabled processor state data to a save area at a specified memory address, possibly in a compacted form, and optionally including privileged state.

This instruction and associated data structures extend the XSAVE/XRSTOR memory image used to manage processor states and provides compaction functionality. See the XSAVE and XRSTOR instruction descriptions for basic operational details.

XSAVES is very similar to XSAVEC but provides the following alternate functionality:

1. XSAVES must be executed at CPL=0
2. XSAVES can save state enabled in the IA32_XSS MSR. The specific state elements saved are determined by the logical AND of EDX:EAX with the logical OR of XCR0 with the IA32_XSS MSR.
3. XSAVES can use the *modified* optimization to not save components, even if RFBM=1 and XINUSE=1 for the stated component. If the component state has not been modified internally since the last execution of XRSTOR or XRSTORS and the XRSTOR_INFO state (an execution environment signature created by the last XRSTOR) matches the current execution state of this XSAVES, the state save can be skipped.

Instruction Support

Form	Subset	Feature Flag
XSAVES	XSAVES	CPUID Fn0000_0000D_EAX_x1[XSAVES] (bit 3)

XSETBV Set Extended Control Register Value

Writes the content of the EDX:EAX register pair into the extended control register (XCR) specified by the ECX register. The high-order 32 bits of the XCR are loaded from EDX and the low-order 32 bits are loaded from EAX. The corresponding high-order 32 bits of RAX and RDX are ignored.

This instruction and associated data structures extend the FXSAVE/FXRSTOR memory image used to manage processor states and provide additional functionality. See the XSAVE instruction description for more information.

Currently, only the XFEATURE_ENABLED_MASK register (XCR0) is supported. Specifying a reserved or unimplemented XCR in ECX causes a general protection exception (#GP).

Executing XSETBV at a privilege level other than 0 causes a general-protection exception. A general protection exception also occurs when software attempts to write to reserved bits of an XCR.

Instruction Support

Form	Subset	Feature Flag
XSETBV	XSAVE/XRSTOR	CPUID Fn0000_0001_ECX[XSAVE] (bit 26)

Appendix A AES Instructions

This appendix gives background information concerning the use of the AES instruction subset in the implementation of encryption compliant to the Advanced Encryption Standard (AES).

A.1 AES Overview

This section provides an overview of AMD64 instructions that support AES software implementation.

The U.S. National Institute of Standards and Technology has adopted the Rijndael algorithm, a block cipher that processes 16-byte data blocks using a shared key of variable length, as the Advanced Encryption Standard (AES). The standard is defined in Federal Information Processing Standards Publication 197 (FIPS 197), *Specification for the Advanced Encryption Standard (AES)*. There are three versions of the algorithm, based on key widths of 16 (AES-128), 24 (AES-192), and 32 (AES-256) bytes.

The following AMD64 instructions support AES implementation:

- AESDEC/VAESDEC and AESDECLAST/VAESDECLAST
  Perform one round of AES decryption
- AESENC/VAESENC and AESENCLAST/VAESENCLAST
  Perform one round of AES encryption
- AESIMC/VAESIMC
  Perform the AES InvMixColumn transformation
  - AESKEYGENASSIST/VAESKEYGENASSIST
    Assist AES round key generation
  - PCLMULQDQ, VPCLMULQDQ
    Perform carry-less multiplication

See Chapter 2, “Instruction Reference” for detailed descriptions of the instructions.

A.2 Coding Conventions

This overview uses descriptive code that has the following basic characteristics.

- Syntax and notation based on the C language
- Four numerical data types:
  - bool: The numbers 0 and 1, the values of the Boolean constants false and true
  - nat: The infinite set of all natural numbers, including bool as a subtype
  - int: The infinite set of all integers, including nat as a subtype
  - rat: The infinite set of all rational numbers, including int as a subtype

- Standard logical and arithmetic operators
- Enumeration (enum) types, arrays, structures (struct), and union types
- Global and local variable and constant declarations, initializations, and assignments
- Standard control constructs (if, then, else, for, while, switch, break, and continue)
- Function subroutines
- Macro definitions (#define)

A.3 AES Data Structures

The AES instructions operate on 16-byte blocks of text called the *state*. Each block is represented as a 4×4 matrix of bytes which is assigned the Galois field matrix data type (GFMatrix). In the AMD64 implementation, the matrices are formatted as 16-byte vectors in XMM registers or 128-bit memory locations. This overview represents each matrix as a sequence of 16 bytes in little-endian format (least significant byte on the right and most significant byte on the left).

Figure A-1 shows a state block in 4×4 matrix representation.

$$GFMatrix = \begin{vmatrix} X_{3,0} & X_{2,0} & X_{1,0} & X_{0,0} \\ X_{3,1} & X_{2,1} & X_{1,1} & X_{0,1} \\ X_{3,2} & X_{2,2} & X_{1,2} & X_{0,2} \\ X_{3,3} & X_{2,3} & X_{1,3} & X_{0,3} \end{vmatrix}$$

Figure A-1. GFMatrix Representation of 16-byte Block

Figure A-2 shows the AMD64 AES format, with the corresponding mapping of FIPS 197 AES "words" to operand bytes.

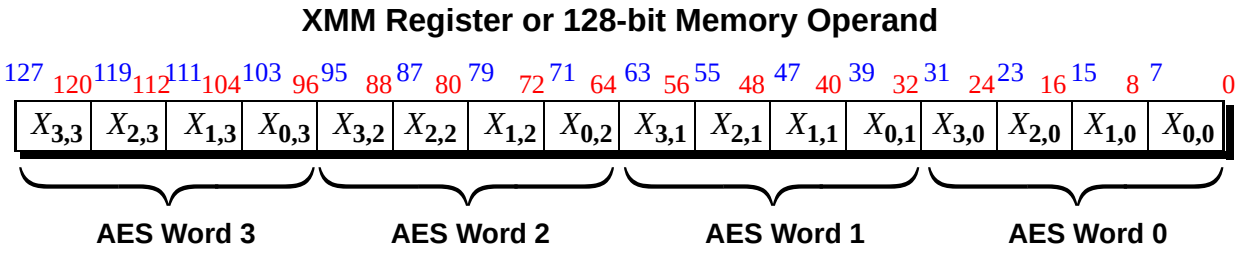

Figure A-2. GFMatrix to Operand Byte Mappings

A.4 Algebraic Preliminaries

AES operations are based on the Galois field $GF = GF(2^8)$, of order 256, constructed by adjoining a root of the irreducible polynomial

$$p(X) = X^8 + X^4 + X^3 + X + 1$$

to the field of two elements, $\mathbb{Z}_2$. Equivalently, *GF* is the quotient field $\mathbb{Z}_2[X]/p(X)$ and thus may be viewed as the set of all polynomials of degree less than 8 in $\mathbb{Z}_2[X]$ with the operations of addition and multiplication modulo $p(X)$. These operations may be implemented efficiently by exploiting the mapping from $\mathbb{Z}_2[X]$ to the natural numbers given by

$$a_nX^n + \ldots + a_1X + a_0 \rightarrow 2^n a_n + \ldots + 2a_1 + a_0 \rightarrow a_n \ldots a_1a_0\text{b}$$

For example:

$$1 \rightarrow 01\text{h}$$

$$X \rightarrow 02\text{h}$$

$$X^2 \rightarrow 04\text{h}$$

$$X^4 + X^3 + 1 \rightarrow 19\text{h}$$

$$p(X) \rightarrow 11\text{Bh}$$

Thus, each element of *GF* is identified with a unique byte. This overview uses the data type **GF256** as an alias of **nat**, to identify variables that are to be thought of as elements of *GF*.

The operations of addition and multiplication in *GF* are denoted by $\oplus$ and $\odot$, respectively. Since $\mathbb{Z}_2$ is of characteristic 2, addition is simply the "exclusive or" operation:

$$x \oplus y = x \wedge y$$

In particular, every element of *GF* is its own additive inverse.

Multiplication in *GF* may be computed as a sequence of additions and multiplications by 2. Note that this operation may be viewed as multiplication in $\mathbb{Z}_2[X]$ followed by a possible reduction modulo $p(X)$. Since 2 corresponds to the polynomial X and 11B corresponds to $p(X)$, for any $x \in GF$,

$$2 \odot x = \begin{cases} x << 1 & \text{if } x < 80\text{h} \\ (x << 1) \oplus 11\text{Bh} & \text{if } x \geq 80\text{h} \end{cases}$$

Now, if $y = b_7 \ldots b_1 b_0 b$, then

$$x \odot y = 2 \odot (\ldots (2 \odot (2 \odot (b_7 \odot x) \oplus b_6 \odot x) \oplus b_5 \odot x) \ldots b_0.$$

This computation is performed by the **GFMul( )** function.

A.4.1 Multiplication in the Field GF

The **GFMul( )** function operates on GF256 elements in SRC1 and SRC2 and returns a GF256 matrix in the destination.

```
GF256 GFMul(GF256 x, GF256 y) {
  nat sum = 0;
```

```
  for (int i=7; i>=0; i--) {
    // Multiply sum by 2. This amounts to a shift followed
    // by reduction mod 0x11B:
    sum <<= 1;
    if (sum > 0xFF) {sum = sum ^ 0x11B;}
    // Add y[i]*x:
    if (y[i]) {sum = sum ^ x;}
  }
  return sum;
}
```

Because the multiplicative group *GF** is of order 255, the inverse of an element *x* of *GF* may be computed by repeated multiplication as $x^{-1} = x^{254}$. A more efficient computation, however, is performed by the **GFInv( )** function as an application of Euclid's greatest common divisor algorithm. See Section A.11, "Computation of GFInv with Euclidean Greatest Common Divisor" for an analysis of this computation and the **GFInv( )** function.

The AES algorithms operate on the vector space GF^4, of dimension 4 over *GF*, which is represented by the array type **GFWord**. FIPS 197 refers to an object of this type as a *word*. This overview uses the term *GF word* in order to avoid confusion with the AMD64 notion of a 16-bit word.

A **GFMatrix** is an array of four *GF* words, which are viewed as the rows of a 4×4 matrix over *GF*.

The field operation symbols $\oplus$ and $\odot$ are used to denote addition and multiplication of matrices over *GF* as well. The **GFMatrixMul( )** function computes the product $A \odot B$ of 4×4 matrices.

A.4.2 Multiplication of 4x4 Matrices Over GF

```
, GFMatrix GFMatrixMul(GFMatrix a, GFMatrix b) {
  GFMatrix c;
  for (nat i=0; i<4; i++) {
    for (nat j=0; j<4; j++) {
      c[i][j] = 0;
      for (nat k=0; k<4; k++) {
        c[i][j] = c[i][j] ^ GFMul(a[i][k], b[k][j]);
      }
    }
  }
  return c;
}
```

A.5 AES Operations

The AES encryption and decryption procedures may be specified as follows, in terms of a set of basic operations that are defined later in this section. See the alphabetic instruction reference for detailed descriptions of the instructions that are used to implement the procedures.

Call the **Encrypt** or **Decrypt** procedure, which pass the same expanded key to the functions

TextBlock Cipher(TextBlock in, ExpandedKey w, nat Nk)

and

TextBlock InvCipher(TextBlock in, ExpandedKey w, nat Nk)

In both cases, the input text is converted by

GFMatrix Text2Matrix(TextBlock A)

to a matrix, which becomes the initial state of the process. This state is transformed through the sequence of N_r + 1 rounds and ultimately converted back to a linear array by

TextBlock Matrix2Text(GFMatrix M).

In each round *i*, the round key K_i is extracted from the expanded key *w* and added to the state by

GFMatrix AddRoundKey(GFMatrix state, ExpandedKey w, nat round).

Note that **AddRoundKey** does not explicitly construct K_i , but operates directly on the bytes of *w*.

The rounds of **Cipher** are numbered 0,…N_r. Let *X* be the initial state an an execution, i.e., the input in matrix format, let S_i be the state produced by round *i*, and let $Y = S_{Nr}$ be the final state. Let Σ , *R* , and *C* denote the operations performed by **SubBytes**, **ShiftRows**, **MixColumns**, respectively. Then

The initial round is a simple addition:

$$S_0 = X \oplus K_0;$$

Each of the next N_r + 1 rounds is a composition of four operations:

$$S_i = \mathcal{C}(\mathcal{R}(\Sigma(S_{i-1}))) \oplus K_i \quad \text{for} \quad i = 1, \ldots, N_r - 1;$$

The **MixColumns** transformation is omitted from the final round:

$$Y = S_{N_r} = \mathcal{R}(\Sigma(S_{N_r-1})) \oplus K_{N_r}.$$

Composing these expressions yields

$$Y = \mathcal{R}(\Sigma(\mathcal{C}(\mathcal{R}(\Sigma(\cdots(\mathcal{C}(\mathcal{R}(\Sigma(X \oplus K_0))) \oplus K_1)\cdots))) \oplus K_{N_r-1})) \oplus K_{N_r}.$$

Note that the rounds of **InvCipher** are numbered in reverse order, N_r,…,0. If *Σ*' and *Y*' are the initial and final states and S'_i is the state following round *i* , then

$$S'_{N_r} = X' \oplus K_{N_r};$$

$$S'_i = \mathcal{C}^{-1}(\Sigma^{-1}(\mathcal{R}^{-1}(S'_{i+1})) \oplus K_i) \quad \text{for} \quad i = N_r - 1, \ldots, 1;$$

$$Y' = \Sigma^{-1}(\mathcal{R}^{-1}(S'_1)) \oplus K_0.$$

Composing these expressions yields

$$Y' = \Sigma^{-1}(\mathcal{R}^{-1}(\mathcal{C}^{-1}(\Sigma^{-1}(\mathcal{R}^{-1}(\cdots(\mathcal{C}^{-1}(\Sigma^{-1}(\mathcal{R}^{-1}(X' \oplus K_{n_r}) \oplus K_{N_r-1}))\cdots)) \oplus K_1))) \oplus K_0.$$

In order to show that **InvCipher** is the inverse of **Cipher**, it is only necessary to combine these expanded expressions by replacing *X'* with *Y* and cancel inverse operations to yield *Y'* = *X*.

A.5.1 Sequence of Operations

- Use predefined **SBox** and **InvSBox** matrices or initialize the matrices using the **ComputeSBox** and **ComputeInvSBox** functions.
- Call the **Encrypt** or **Decrypt** procedure.
- For the **Encrypt** procedure:

1. Load the input **TextBlock** and **CipherKey**.
2. Expand the cipher key using the **KeyExpansion** function.
3. Call the **Cipher** function to perform the number of rounds determined by the cipher key length.
4. Perform round entry operations.
   a. Convert input text block to state matrix using the **Text2Matrix** function.
   b. Combine state and round key bytes by bitwise XOR using the **AddRoundKey** function.
5. Perform round iteration operations.
   a. Replace each state byte with another by non-linear substitution using the **SubBytes** function.
   b. Shift each row of the state cyclically using the **ShiftRows** function.
   c. Combine the four bytes in each column of the state using the **MixColumns** function.
   d. Perform **AddRoundKey**.
6. Perform round exit operations.
   a. Perform **SubBytes**.
   b. Perform **ShiftRows**.
   c. Perform **AddRoundKey**.
   d. Convert state matrix to output text block using the **Matrix2Text** function and return **TextBlock**.

- For the **Decrypt** procedure:

1. Load the input **TextBlock** and **CipherKey**.

2. Expand the cipher key using the **KeyExpansion** function.
3. Call the **InvCipher** function to perform the number of rounds determined by the cipher key length.
4. Perform round entry operations.
   a. Convert input text block to state matrix using the **Text2Matrix** function.
   b. Combine state and round key bytes by bitwise XOR using the **AddRoundKey** function.
5. Perform round iteration operations.
   a. Shift each row of the state cyclically using the **InvShiftRows** function.
   b. Replace each state byte with another by non-linear substitution using the **InvSubBytes** function.
   c. Perform **AddRoundKey**.
   d. Combine the four bytes in each column of the state using the **InvMixColumns** function.
6. Perform round exit operations.
   a. Perform **InvShiftRows**.
   b. Perform **InvSubBytes** (**InvSubWord**).
   c. Perform **AddRoundKey**.
   d. Convert state matrix to output text block using the **Matrix2Text** function and return **TextBlock**.

A.6 Initializing the Sbox and InvSBox Matrices

The AES makes use of a bijective mapping $\sigma : GF \rightarrow GF$, which is encoded, along with its inverse mapping, in the 16×16 arrays **SBox** (for encryption) and **InvSBox** (for decryption), as follows:

for all $x \in G$,

$$\sigma(x) = \text{SBox}[x[7:4], x[3:0]]$$

and

$$\sigma^{-1}(x) = \text{InvSBox}[x[7:4], x[3:0]]$$

While the FIPS 197 standard defines the contents of the **SBox[ ]** and **InvSbox [ ]** matrices, the matrices may also be initialized algebraically (and algorithmically) by means of the **ComputeSBox( )** and **ComputeInvSBox( )** functions, discussed below.

The bijective mappings for encryption and decryption are computed by the **SubByte( )** and **InvSubByte ( )** functions, respectively:

SubByte( ) computation:

```
GF256 SubByte(GF256 x) {
  return SBox[x[7:4]][x[3:0]];
}
```

InvSubByte ( ) computation:

```
GF256 InvSubByte(GF256 x) {
  return InvSBox[x[7:4]][x[3:0]];
}
```

A.6.1 Computation of SBox and InvSBox

Computation of SBox and InvSBox elements has a direct relationship to the cryptographic properties of the AES, but not to the algorithms that use the tables. Readers who prefer to view σ as a primitive operation may skip the remainder of this section.

The algorithmic definition of the bijective mapping σ is based on the consideration of *GF* as an 8-dimensional vector space over the subfield $\mathbb{Z}_2$. Let φ be a linear operator on this vector space and let $M = [a_{ij}]$ be the matrix representation of φ with respect to the ordered basis {1, 2, 4, 10, 20, 40, 80}. Then φ may be encoded concisely as an array of bytes *A* of dimension 8, each entry of which is the concatenation of the corresponding row of *M*:

$$A[i] = a_{i\mathbf{8}}\, a_{i\mathbf{7}} \ldots a_{i\mathbf{0}}$$

This expression may be represented algorithmically by means of the **ApplyLinearOp( )** function, which applies a linear operator to an element of GF. The **ApplyLinear Op( )** function is used in the initialization of both the **sBox[]** and I**nvSBox[ ]** matrices.

```
// The following function takes the array A representing a linear operator phi and
// an element x of G and returns phi(x):

GF256 ApplyLinearOp(GF256 A[8], GF256 x) {
  GF256 result = 0;
  for (nat i=0; i<8; i++) {
    bool sum = 0;
    for (nat j=0; j<8; j++) {
      sum = sum ^ (A[i][j] & x[j]);
    }
    result[i] = sum;
  }
  return result;
}
```

The definition of σ involves the linear operator φ with matrix

$$M = \begin{bmatrix} 1 & 0 & 0 & 0 & 1 & 1 & 1 & 1 \\ 1 & 1 & 0 & 0 & 0 & 1 & 1 & 1 \\ 1 & 1 & 1 & 0 & 0 & 0 & 1 & 1 \\ 1 & 1 & 1 & 1 & 0 & 0 & 0 & 1 \\ 1 & 1 & 1 & 1 & 1 & 0 & 0 & 0 \\ 0 & 1 & 1 & 1 & 1 & 1 & 0 & 0 \\ 0 & 0 & 1 & 1 & 1 & 1 & 1 & 0 \\ 0 & 0 & 0 & 1 & 1 & 1 & 1 & 1 \end{bmatrix}$$

In this case,

$$A = \{F1, E3, C7, 8F, 1F, 3E, 7C, F8\}.$$

Initialization of SBox[ ]

The mapping $\sigma : G \rightarrow G$ is defined by

$$\sigma(x) = \varphi\,(x^{-1}) \oplus 63$$

This computation is performed by **ComputeSBox( )**.

ComputeSBox( )

```
GF256[16][16] ComputeSBox() {
  GF256 result[16][16];
  GF256 A[8] = {0xF1, 0xE3, 0xC7, 0x8F, 0x1F, 0x3E, 0x7C, 0xF8};
  for (nat i=0; i<16; i++) {
    for (nat j=0; j<16; j++) {
      GF256 x = (i << 4) | j;
      result[i][j] = ApplyLinearOp(A, GFInv(x)) ^ 0x63;
    }
  }
  return result;
}

const GF256 SBox[16][16] = ComputeSBox();
```

Table A-1 shows the resulting **SBox[ ]**, as defined in FIPS 197.

Table A-1. SBox Definition

	S[3:0]																
S[7:4]		0	1	2	3	4	5	6	7	8	9	a	b	c	d	e	f

A.6.2 Initialization of InvSBox[ ]

A straightforward calculation confirms that the matrix M is nonsingular with inverse.

Thus, φ is invertible and φ^{-1} is encoded as the array

$$M^{-1} = \begin{bmatrix} 0 & 0 & 1 & 0 & 0 & 1 & 0 & 1 \\ 1 & 0 & 0 & 1 & 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 0 & 1 & 0 & 0 & 1 \\ 1 & 0 & 1 & 0 & 0 & 1 & 0 & 0 \\ 0 & 1 & 0 & 1 & 0 & 0 & 1 & 0 \\ 0 & 0 & 1 & 0 & 1 & 0 & 0 & 1 \\ 1 & 0 & 0 & 1 & 0 & 1 & 0 & 0 \\ 0 & 1 & 0 & 0 & 1 & 0 & 1 & 0 \end{bmatrix}$$

$$B = \{A4, 49, 92, 25, 4A, 94, 29, 52\}.$$

If $y = \sigma(x)$, then

$$
\begin{aligned}
(\varphi^{-1}((y) \oplus 5)^{-1} &= (\varphi^{-1}(y \oplus \varphi(5))^{-1} \\
&= (\varphi^{-1}(y \oplus 63))^{-1} \\
&= (\varphi^{-1}(\varphi(x^{-1}) \oplus 63 \oplus 63))^{-1} \\
&= (\varphi^{-1}(\varphi(x^{-1})))^{-1} \\
&= x,
\end{aligned}
$$

and σ is a permutation of *GF* with

$$\sigma^{-1}(y) = (\varphi^{-1}(y) \oplus 5)^{-1}$$

This computation is performed by **ComputeInvSBox( )**.

ComputeInvSBox( )

```
GF256[16][16] ComputeInvSBox() {
  GF256 result[16][16];
  GF256 B[8] = {0xA4, 0x49, 0x92, 0x25, 0x4A, 0x94, 0x29, 0x52};
  for (nat i=0; i<16; i++) {
    for (nat j=0; j<16; j++) {
      GF256 y = (i << 4) | j;
      result[i][j] = GFInv(ApplyLinearOp(B, y) ^ 0x5);
    }
  }
  return result;
}

const GF256 InvSBox[16][16] = ComputeInvSBox();
```

Table A-2 shows the resulting **InvSBox[ ]**, as defined in the FIPS 197.

Table A-2. InvSBox Definition

A.7 Encryption and Decryption

The AMD64 architecture implements the AES algorithm by means of an iterative function called a *round* for both encryption and the inverse operation, decryption.

The top-level encryption and decryption procedures **Encrypt( )** and **Decrypt( )** set up the rounds and invoke the functions that perform them. Each of the procedures takes two 128-bit binary arguments:

- *input data* — a 16-byte block of text stored in a source 128-bit XMM register
- *cipher key* — a 16-, 24-, or 32-byte cipher key stored in either a second 128-bit XMM register or 128-bit memory location

A.7.1 The Encrypt( ) and Decrypt( ) Procedures

```
TextBlock Encrypt(TextBlock in, CipherKey key, nat Nk) {
  return Cipher(in, ExpandKey(key, Nk), Nk);
}

TextBlock Decrypt(TextBlock in, CipherKey key, nat Nk) {
  return InvCipher(in, ExpandKey(key, Nk), Nk);
```

```
}
```

The array types **TextBlock** and **CipherKey** are introduced to accommodate the text and key parameters. The 16-, 24-, or 32-byte cipher keys correspond to AES-128, AES-192, or AES-256 key sizes. The cipher key is logically partitioned into N_k = 4, 6, or 8 AES 32-bit words. N_k is passed as a parameter to determine the AES version to be executed, and the number of rounds to be performed.

Both the **Encrypt( )** and **Decrypt( )** procedures invoke the **ExpandKey( )** function to expand the cipher key for use in round key generation. When key expansion is complete, either the **Cipher( )** or **InvCipher( )** functions are invoked.

The **Cipher( )** and **InvCipher( )** functions are the key components of the encryption and decryption process. See Section A.8, “The Cipher Function” and Section A.9, “The InvCipher Function” for detailed information.

A.7.2 Round Sequences and Key Expansion

Encryption and decryption are performed in a sequence of rounds indexed by 0, …, N_r, where N_r is determined by the number N_k of *GF* words in the cipher key. A key matrix called a *round key* is generated for each round. The number of *GF* words required to form N_r + 1 round keys is equal to , 4(N_r + 1). Table A-3 shows the relationship between cipher key length, round sequence length, and round key length.

Table A-3. Cipher Key, Round Sequence, and Round Key Length

N_k	N_r	$4(N_r + 1)$
4	10	44
6	12	52
8	14	60

Expanded keys are generated from the cipher key by the **ExpandKey( )** function, where the array type **ExpandedKey** is defined to accommodate 60 words (the maximum required) corresponding to $N_k = 8$.

The ExpandKey( ) Function

```
ExpandedKey ExpandKey(CipherKey key, nat Nk) {
  assert((Nk == 4) || (Nk == 6) || (Nk == 8));
  nat Nr = Nk + 6;
  ExpandedKey w;

  // Copy key into first Nk rows of w:
  for (nat i=0; i<Nk; i++) {
    for (nat j=0; j<4; j++) {
      w[i][j] = key[4*i+j];
    }
  }
```

```
  // Write next row of w:
  for (nat i=Nk; i<4*(Nr+1); i++) {

    // Encode preceding row:
    GFWord tmp = w[i-1];
    if (mod(i, Nk) == 0) {
      tmp = SubWord(RotWord(tmp));
      tmp[0] = tmp[0] ^ RCON[i/Nk];
    }
    else if ((Nk == 8) && (mod(i, Nk) == 4)) {
      tmp = SubWord(tmp);
    }

    // XOR tmp with w[i-Nk]:
    for (nat j=0; j<4; j++) {
      w[i][j] = w[i-Nk][j] ^ tmp[j];
    }
  }
  return w;
}
```

ExpandKey( ) begins by copying the input cipher key into the first N_k *GF* words of the expanded key *w*. The remaining $4(N_r + 1) – N_k$ GF words are computed iteratively. For each $i \geq N_k$, $w[i]$ is derived from the two *GF* words $w[i – 1]$ and $w[i – N_k]$. In most cases, $w[i]$ is simply the sum $w[i – 1] \oplus w[i – N_k]$. There are two exceptions:

- If *i* is divisible by N_k, then before adding it to $w[i – N_k]$, $w[i – 1]$ is first rotated by one position to the left by **RotWord( )**, then transformed by the substitution **SubWord( )**, and an element of the array **RCON** is added to it.

  RCON[11] = {00h, 01h, 02h, 04h, 08h, 10h, 20h, 40h, 80h, 1Bh, 36h}

- In the case $N_k = 8$, if *i* is divisible by 4 but not 8, then $w[i – 1]$ is transformed by the substitution **SubWord( )**.

The i^{th} round key K_i comprises the four *GF* words $w[4i], \ldots, w[4i + 3]$. More precisely, let W_i be the matrix

$$W = \{w[4i], w[4i + 1], w[4i + 2], w[4i + 3]\}$$

Then $K_i = W_i^t$, the transpose of W_i. Thus, the entries of the array *w* are the columns of the round keys.

A.8 The Cipher Function

This function performs encryption. It converts the input text to matrix form, generates the round key from the expanded key matrix, and iterates through the transforming functions the number of times determined by encryption key size to produce a 128-bit binary cipher matrix. As a final step, it converts the matrix to an output text block.

```
TextBlock Cipher(TextBlock in, ExpandedKey w, nat Nk) {
  assert((Nk == 4) || (Nk == 6) || (Nk == 8));
  nat Nr = Nk + 6;
  GFMatrix state = Text2Matrix(in);
  state = AddRoundKey(state, w, 0);
  for (nat round=1; round<Nr; round++) {
    state = SubBytes(state);
    state = ShiftRows(state);
    state = MixColumns(state);
    state = AddRoundKey(state, w, round);
  }
  state = SubBytes(state);
  state = ShiftRows(state);
  state = AddRoundKey(state, w, Nr);
  return Matrix2Text(state);
}
```

A.8.1 Text to Matrix Conversion

Prior to processing, the input text block must be converted to matrix form. The **Text2Matrix( )** function stores a **TextBlock** in a GFMatrix in column-major order as follows.

```
GFMatrix Text2Matrix(TextBlock A) {
  GFMatrix result;
  for (nat j=0; j<4; j++) {
    for (nat i=0; i<4; i++) {
      result[i][j] = A[4*j+i];
    }
  }
  return result;
}
```

A.8.2 Cipher Transformations

The Cipher function employs the following transformations.

SubBytes( ) — Applies a non-linear substitution table (SBox) to each byte of the state.

SubWord( ) — Uses a non-linear substitution table (SBox) to produce a four-byte AES output word from the four bytes of an AES input word.

ShiftRows( ) — Cyclically shifts the last three rows of the state by various offsets.

RotWord( ) — Rotates an AES (4-byte) word to the right.

MixColumns( ) — Mixes data in all the state columns independently to produce new columns.

AddRoundKey( ) — Extracts a 128-bit round key from the expanded key matrix and adds it to the 128-bit state using an XOR operation.

Inverses of **SubBytes( )**, **SubWord( )**, **ShiftRows( )** and **MixColumns( )** are used in decryption. See Section A.9, “The InvCipher Function” for more information.

SubBytes( ) Function

Performs a byte substitution operation using the invertible substitution table (**SBox**) to convert input text to an intermediate encryption state.

```
GFMatrix SubBytes(GFMatrix M) {
  GFMatrix result;
  for (nat i=0; i<4; i++) {
    result[i] = SubWord(M[i]);
  }
  return result;
}
```

SubWord( ) Function

Applies **SubBytes** to each element of a vector or a matrix:

```
GFWord SubWord(GFWord x) {
  GFWord result;
  for (nat i=0; i<4; i++) {
    result[i] = SubByte(x[i]);
  }
  return result;
}
```

ShiftRows( ) Function

Cyclically shifts the last three rows of the state by various offsets.

```
GFMatrix ShiftRows(GFMatrix M) {
  GFMatrix result;
  for (nat i=0; i<4; i++) {
    result[i] = RotateLeft(M[i], -i);
  }
  return result;
```

RotWord( ) Function

Performs byte-wise cyclic permutation of a 32-bit AES word.

```
GFWord RotWord(GFWord x)
{ return RotateLeft(x, 1); }
```

MixColumns( ) Function

Performs a byte-oriented column-by-column matrix multiplication

$$M \rightarrow \mathrm{C} \odot M \text{, where C is the predefined fixed matrix}$$

$$C = \begin{bmatrix} 2 & 3 & 1 & 1 \\ 1 & 2 & 3 & 1 \\ 1 & 1 & 2 & 3 \\ 3 & 1 & 1 & 2 \end{bmatrix}$$

The function is implemented as follows:

```
GFMatrix MixColumns(GFMatrix M) {
  GFMatrix C = {
    {0x02,0x03,0x01,0x01},
    {0x01,0x02,0x03,0x01},
    {0x01,0x01,0x02,0x03},
    {0x03,0x01,0x01,0x02}
  };
  return GFMatrixMul(C, M);
}
```

AddRoundKey( ) Function

Extracts the round key from the expanded key and adds it to the state using a bitwise XOR operation.

```
GFMatrix AddRoundKey(GFMatrix state, ExpandedKey w, nat round) {
  GFMatrix result = state;
  for (nat i=0; i<4; i++) {
    for (nat j=0; j<4; j++) {
      result[i][j] = result[i][j] ^ w[4*round+j][i];
    }
  }
  return result;
}
```

A.8.3 Matrix to Text Conversion

After processing, the output matrix must be converted to a text block. The **Matrix2Text( )** function converts a GFMatrix in column-major order to a **TextBlock** as follows.

```
TextBlock Matrix2Text(GFMatrix M) {
  TextBlock result;
  for (nat j=0; j<4; j++) {
    for (nat i=0; i<4; i++) {
      result[4*j+i] = M[i][j];
    }
  }
  return result;
}
```

A.9 The InvCipher Function

This function performs decryption. It iterates through the round function the number of times determined by encryption key size and produces a 128-bit block of text as output.

```
TextBlock InvCipher(TextBlock in, ExpandedKey w, nat Nk) {
  assert((Nk == 4) || (Nk == 6) || (Nk == 8));
  nat Nr = Nk + 6;
  GFMatrix state = Text2Matrix(in);
  state = AddRoundKey(state, w, Nr);
  for (nat round=Nr-1; round>0; round--) {
    state = InvShiftRows(state);
    state = InvSubBytes(state);
```

```
    state = AddRoundKey(state, w, round);
    state = InvMixColumns(state);
  }
  state = InvShiftRows(state);
  state = InvSubBytes(state);
  state = AddRoundKey(state, w, 0);
  return Matrix2Text(state);
}
```

A.9.1 Text to Matrix Conversion

Prior to processing, the input text block must be converted to matrix form. The **Text2Matrix( )** function stores a **TextBlock** in a GFMatrix in column-major order as follows.

```
GFMatrix Text2Matrix(TextBlock A) {
  GFMatrix result;
  for (nat j=0; j<4; j++) {
    for (nat i=0; i<4; i++) {
      result[i][j] = A[4*j+i];
    }
  }
  return result;
}
```

A.9.2 InvCypher Transformations

The following functions are used in decryption:

InvShiftRows( ) — The inverse of **ShiftRows( )**.

InvSubBytes( ) — The inverse of **SubBytes( )**.

InvSubWord( ) — The inverse of **SubWord( )**.

InvMixColumns( ) — The inverse of **MixColumns( )**.

AddRoundKey( ) — Is its own inverse.

Decryption is the inverse of encryption and is accomplished by means of the inverses of the, **SubBytes( )**, **SubWord( )**, **ShiftRows( )** and **MixColumns( )** transformations used in encryption.

SubWord( ), **SubBytes( )**, and **ShiftRows( )** are injective. This is also the case with **MixColumns( )**. A simple computation shows that *C* is invertible with

$$C^{-1} = \begin{bmatrix} E & B & D & 9 \\ 9 & E & B & D \\ D & 9 & E & B \\ B & D & 9 & E \end{bmatrix}$$

InvShiftRows( ) Function

The inverse of **ShiftRows( )**.

```
GFMatrix InvShiftRows(GFMatrix M) {
  GFMatrix result;
```

```
  for (nat i=0; i<4; i++) {
    result[i] = RotateLeft(M[i], -i);
  }
  return result;
```

InvSubBytes( ) Function

The inverse of *SubBytes*( ).

```
GFMatrix InvSubBytes(GFMatrix M) {
  GFMatrix result;
  for (nat i=0; i<4; i++) {
    result[i] = InvSubWord(M[i]);
  }
  return result;
}
```

InvSubWord( ) Function

The inverse of **SubWord( )**, **InvSubBytes( )** applied to each element of a vector or a matrix.

```
GFWord InvSubWord(GFWord x) {
  GFWord result;
  for (nat i=0; i<4; i++) {
    result[i] = InvSubByte(x[i]);
  }
  return result;
}
```

InvMixColumns( ) Function

The inverse of the **MixColumns( )** function. Multiplies by the inverse of the predefined fixed matrix, C, C^{-1}, as discussed previously.

```
GFMatrix InvMixColumns(GFMatrix M) {
  GFMatrix D = {
    {0x0e,0x0b,0x0d,0x09},
    {0x09,0x0e,0x0b,0x0d},
    {0x0d,0x09,0x0e,0x0b},
    {0x0b,0x0d,0x09,0x0e}
  };
  return GFMatrixMul(D, M);
}
```

AddRoundKey( ) Function

Extracts the round key from the expanded key and adds it to the state using a bitwise XOR operation.

```
GFMatrix AddRoundKey(GFMatrix state, ExpandedKey w, nat round) {
  GFMatrix result = state;
  for (nat i=0; i<4; i++) {
    for (nat j=0; j<4; j++) {
      result[i][j] = result[i][j] ^ w[4*round+j][i];
    }
  }
  return result;
```

```
}
```

A.9.3 Matrix to Text Conversion

After processing, the output matrix must be converted to a text block. The **Matrix2Text( )** function converts a GFMatrix in column-major order to a **TextBlock** as follows.

```
TextBlock Matrix2Text(GFMatrix M) {
  TextBlock result;
  for (nat j=0; j<4; j++) {
    for (nat i=0; i<4; i++) {
      result[4*j+i] = M[i][j];
    }
  }
  return result;
}
```

A.10 An Alternative Decryption Procedure

This section outlines an alternative decrypting procedure,

TextBlock EqDecrypt(TextBlock in, CipherKey key, nat Nk):

```
TextBlock EqDecrypt(TextBlock in, CipherKey key, nat Nk) {
  return EqInvCipher(in, MixRoundKeys(ExpandKey(key, Nk), Nk), Nk);
}
```

The procedure is based on a variation of **InvCipher**,

TextBlock EqInvCipher(TextBlock in, ExpandedKey w, nat Nk):

```
TextBlock EqInvCipher(TextBlock in, ExpandedKey dw, nat Nk) {
  assert((Nk == 4) || (Nk == 6) || (Nk == 8));
  nat Nr = Nk + 6;
  GFMatrix state = Text2Matrix(in);
  state = AddRoundKey(state, dw, Nr);
  for (nat round=Nr-1; round>0; round--) {
    state = InvSubBytes(state);
    state = InvShiftRows(state);
    state = InvMixColumns(state);
    state = AddRoundKey(state, dw, round);
  }
  state = InvSubBytes(state);
  state = InvShiftRows(state);
  state = AddRoundKey(state, dw, 0);
  return Matrix2Text(state);
}
```

The variant structure more closely resembles that of **Cipher**. This requires a modification of the expanded key generated by **ExpandKey**,

ExpandedKey MixRoundKeys(ExpandedKey w, nat Nk):

```
ExpandedKey MixRoundKeys(ExpandedKey w, nat Nk) {
  assert((Nk == 4) || (Nk == 6) || (Nk == 8));
  nat Nr = Nk + 6;
  ExpandedKey result;
  GFMatrix roundKey;
  for (nat round=0; round<Nr+1; round++) {
    for (nat i=0; i<4; i++) {
      roundKey[i] = w[4*round+i];
    }
    if ((round > 0) && (round < Nr)) {
      roundKey = InvMixRows(roundKey);
    }
    for (nat i=0; i<4; i++) {
      result[4*round+i] = roundKey[i];
    }
  }
  return result;
}
```

The transformation **MixRoundKeys** leaves *K0* and K_{Nr} unchanged, but for $i = 1,\ldots,N_r - 1$, it replaces W_i with the matrix product $W_i \odot Q$, where

$$Q = \begin{bmatrix} \mathrm{E} & 9 & \mathrm{D} & \mathrm{B} \\ \mathrm{B} & \mathrm{E} & 9 & \mathrm{D} \\ \mathrm{D} & \mathrm{B} & \mathrm{E} & 9 \\ 9 & \mathrm{D} & \mathrm{B} & \mathrm{E} \end{bmatrix} = \begin{bmatrix} \mathrm{E} & \mathrm{B} & \mathrm{D} & 9 \\ 9 & \mathrm{E} & \mathrm{B} & \mathrm{D} \\ \mathrm{D} & 9 & \mathrm{E} & \mathrm{B} \\ \mathrm{B} & \mathrm{D} & 9 & \mathrm{E} \end{bmatrix}^t = (C^{-1})^t.$$

The effect of this is to replace K_i with

$$(W_i \odot Q)^t = Q^t \odot W_i^t = C^{-1} \odot K_i = \mathcal{C}^{-1}(K_i)$$

for $i = 1,\ldots,N_r - 1$.

The equivalence of **EqDecrypt** and **Decrypt** follows from two properties of the basic operations:

C is a linear transformation and therefore, so is C^{-1};

Σ and R commute, and hence so do Σ^{-1} and R^{-1}, for if

$$S = \begin{bmatrix} s_{00} & s_{01} & s_{02} & s_{03} \\ s_{10} & s_{11} & s_{12} & s_{13} \\ s_{20} & s_{21} & s_{22} & s_{23} \\ s_{30} & s_{31} & s_{32} & s_{33} \end{bmatrix},$$

then

$$\Sigma(\mathcal{R}(S)) = \begin{bmatrix} \sigma(s_{00}) & \sigma(s_{01}) & \sigma(s_{02}) & \sigma(s_{03}) \\ \sigma(s_{11}) & \sigma(s_{12}) & \sigma(s_{13}) & \sigma(s_{10}) \\ \sigma(s_{22}) & \sigma(s_{23}) & \sigma(s_{20}) & \sigma(s_{21}) \\ \sigma(s_{33}) & \sigma(s_{30}) & \sigma(s_{31}) & \sigma(s_{32}) \end{bmatrix} = \mathcal{R}(\Sigma(S)).$$

Now let *X"* and *Y"* be the initial and final states of an execution of **EqDecrypt** and let $S"_i$ be the state following round *i* . Suppose *X"* = *X'*. Appealing to the definitions of **EqDecrypt** and **EqInvCipher**, we have

$$S''_{N_r} = X'' \oplus K_{N_r} = X' \oplus K_{N_r} = S'_{N_r},$$

and for $i = N_r - 1,\ldots,1$, by induction,

$$\begin{aligned} S''_i &= \mathcal{C}^{-1}(\Sigma^{-1}(\mathcal{R}^{-1}(S''_{i+1}))) \oplus \mathcal{C}^{-1}(K_{N_r}) \\ &= \mathcal{C}^{-1}(\Sigma^{-1}(\mathcal{R}^{-1}(S''_{i+1})) \oplus K_{N_r}) \\ &= \mathcal{C}^{-1}(\mathcal{R}^{-1}(\Sigma^{-1}(S''_{i+1})) \oplus K_{N_r}) \\ &= \mathcal{C}^{-1}(\mathcal{R}^{-1}(\Sigma^{-1}(S'_{i+1})) \oplus K_{N_r}) \\ &= S'_i. \end{aligned}$$

Finally,

$$\begin{aligned} Y'' = S''_0 &= \mathcal{R}^{-1}(\Sigma^{-1}(S''_1)) \oplus K_0 \\ &= \Sigma^{-1}(\mathcal{R}^{-1}(S''_1)) \oplus K_0 \\ &= \Sigma^{-1}(\mathcal{R}^{-1}(S'_1)) \oplus K_0 \\ &= S'_0 = Y'. \end{aligned}$$

A.11 Computation of GFInv with Euclidean Greatest Common Divisor

Note that the operations performed by **GFInv( )** are in the ring $\mathbb{Z}_2[X]$ rather than the quotient field *GF*.

The initial values of the variables x_1 and x_2 are the inputs *x* and 11b, the latter representing the polynomial *p*(*X*). The variables a_1 and a_2 are initialized to 1 and 0.

On each iteration of the loop, a multiple of the lesser of x1 and x2 is added to the other. If x1 ≤ x2, then the values of x2 and a2 are adjusted as follows:

$x_2 \rightarrow x_2 \oplus 2^s \odot x_1$

$a_2 \rightarrow a_2 \oplus 2^s \odot a_1$

where *s* is the difference in the exponents (*i.e.*, degrees) of x_1 and x_2 . In the remaining case, x_1 and a_1 are similarly adjusted. This step is repeated until either $x_1 = 0$ or $x_2 = 0$.

We make the following observations:

- On each iteration, the value added to *xi* has the same exponent as x_i, and hence the sum has lesser exponent. Therefore, termination is guaranteed.
- Since $p(X)$ is irreducible and x is of smaller degree than $p(X)$, the initial values of x_1 and x_2 have no non-trivial common factor. This property is clearly preserved by each step.
- Initially,

$$x_1 \oplus a_1 \odot x = x \oplus x = 0$$

and

$$x_2 \oplus a_2 \odot x = 11b \oplus 0 = 11b$$

are both divisible by 11b. This property is also invariant, since, for example, the above assignments result in

$$x_2 \oplus a_2 \odot x \rightarrow (x_2 \oplus 2^s \odot x_1) \oplus (a_2 \oplus 2^s \odot a_1) \odot x = (x_2 \oplus a2 \odot x) \oplus 2^s \odot (x_1 \oplus a_1 \odot x).$$

Now suppose that the loop terminates with $x_2 = 0$. Then x_1 has no non-trivial factor and, hence, $x_1 = 1$. Thus, $1 \oplus a_1 \odot x$ is divisible by 11b. Since the final result y is derived by reducing a_1 modulo 11b, it follows that $1 \oplus y \odot x$ is also divisible by 11b and, hence, in the quotient field *GF*, $1 + y \odot x = 0$, which implies $y \odot x = 1$.

The computation of the multiplicative inverse utilizing Euclid's algorithm is as follows:

```
// Computation of multiplicative inverse based on Euclid's algorithm:

GF256 GFInv(GF256 x) {
  if (x == 0) {
    return 0;
  }
  // Initialization:
  nat x1 = x;
  nat x2 = 0x11B; // the irreducible polynomial p(X)
  nat a1 = 1;
  nat a2 = 0;
  nat shift; // difference in exponents
  while ((x1 != 0) && (x2!= 0)) {

  // Termination is guaranteed, since either x1 or x2 decreases on each iteration.
  // We have the following loop invariants, viewing natural numbers as elements of
  // the polynomial ring Z2[X]:
  // (1) x1 and x2 have no common divisor other than 1.
  // (2) x1 ^ GFMul(a1, x) and x2 ^ GFMul(a2, x) are both divisible by p(X).

    if (x1 <= x2) {
      shift = expo(x2) - expo(x1);
      x2 = x2 ^ (x1 << shift);
      a2 = a2 ^ (a1 << shift);
    }
    else {
      shift = expo(x1) - expo(x2);
      x1 = x1 ^ (x2 << shift);
      a1 = a1 ^ (a2 << shift);
    }
  }
  nat y;

  // Since either x1 or x2 is 0, it follows from (1) above that the other is 1.

  if (x1 == 1) { // x2 == 0
    y = a1;
  }
  else if (x2 == 1) { // x1 == 0
    y = a2;
  }
  else {
    assert(false);
  }

  // Now it follows from (2) that GFMul(y, x) ^ 1 is divisible by 0x11b.
  // We need only reduce y modulo 0x11b:

  nat e = expo(y);
  while (e >= 8) {
    y = y ^ (0x11B << (e - 8));
    e = expo(y);
  }
  return y;
}
```

Revision History

Date	Revision	Description
November 2021	3.16	Added Alignment Check, #AC to FXRSTOR and FXSAVE and additional details of alignment check behavior.
May 2018	3.15	Added clarification to CVTPI2PS. Corrected PSHUFW detail.
September 2016	3.14	Modified Exceptions for Floating-Point Load under x87 Floating-Point Exception Generated, #MF.
May 2013	3.13	Corrected CPUID function and feature bit called out in text for FXSAVE/FXRSTOR optimization. Made other corrections and clarifications related to the specification of feature bits.
March 2012	3.12	Clarified exception and trap behavior for MASKMOVQ
December 2009	3.11	Revised FCOM, FCOMP, FCOMPP and FCOMI, FCOMIP instruction pages. Corrected exception tables for FPREM and FPREM1.
April 2009	3.10	Revised FCOM, FCOMP, FCOMPP description. Corrected FISTTP exception table.
September 2007	3.09	Added minor clarifications and corrected typographical and formatting errors.
July 2007	3.08	Added misaligned access support to applicable instructions. Deprecated 3DNow!™ instructions. Added Appendix A, ”Recommended Substitutions for 3DNow!™ Instructions,” on page 333. Added minor clarifications and corrected typographical and formatting errors.
September 2006	3.07	Added minor clarifications and corrected typographical and formatting errors.
December 2005	3.06	Added minor clarifications and corrected typographical and formatting errors.

Date	Revision	Description
December 2004	3.05	Added FISTTP instruction (SSE3). Updated CPUID information in exception tables. Corrected several typographical and formatting errors.
September 2003	3.04	Clarified x87 condition codes for FPREM and FPREM1 instructions. Corrected tables of numeric ranges for results of PF2ID and PF2IW instructions.
April 2003	3.03	Corrected numerous typos and stylistic errors. Corrected description of FYL2XP1 instruction. Clarified the description of the FXRSTOR instruction.

Preface

About This Book

This book is part of a multivolume work entitled the *AMD64 Architecture Programmer's Manual*. This table lists each volume and its order number.

Title	Order No.
Volume 1: Application Programming	24592
Volume 2: System Programming	24593
Volume 3: General-Purpose and System Instructions	24594
Volume 4: 128-Bit and 256-Bit Media Instructions	26568
Volume 5: 64-Bit Media and x87 Floating-Point Instructions	26569

Audience

This volume (Volume 5) is intended for all programmers writing application or system software for a processor that implements the AMD64 processor architecture.

Organization

Volumes 3, 4, and 5 describe the AMD64 instruction set in detail. Together, they cover each instruction's mnemonic syntax, opcodes, functions, affected flags, and possible exceptions.

The AMD64 instruction set is divided into five subsets:

- General-purpose instructions
- System instructions
- 128-bit and 256-bit media instructions (Streaming SIMD Extensions – SSE)
- 64-bit media instructions (MMX™)
- x87 floating-point instructions

A number of instructions belong to—and are described identically in—multiple instruction subsets.

This volume describes the 64-bit media and x87 floating-point instructions. The index at the end cross-references topics within this volume. For other topics relating to the AMD64 architecture, and for information on instructions in other subsets, see the tables of contents and indexes of the other volumes.

Conventions and Definitions

The following section **Notational Conventions** describes notational conventions used in this volume and in the remaining volumes of this *AMD64 Architecture Programmer's Manual*. This is followed by a **Definitions** section which lists a number of terms used in the manual along with their technical definitions. Finally, the **Registers** section lists the registers which are a part of the application programming model.

Notational Conventions

#GP(0)

An instruction exception—in this example, a general-protection exception with error code of 0.

1011b

A binary value—in this example, a 4-bit value.

F0EA_0B02h

A hexadecimal value. Underscore characters may be inserted to improve readability.

128

Numbers without an alpha suffix are decimal unless the context indicates otherwise.

7:4

A bit range, from bit 7 to 4, inclusive. The high-order bit is shown first. Commas may be inserted to indicate gaps.

CPUID Fn*XXXX_XXXX_RRR*[*FieldName*]

Support for optional features or the value of an implementation-specific parameter of a processor can be discovered by executing the CPUID instruction on that processor. To obtain this value, software must execute the CPUID instruction with the function code *XXXX_XXXX*h in EAX and then examine the field *FieldName* returned in register *RRR*. If the "*_RRR*" notation is followed by "_x*YYY*", register ECX must be set to the value *YYY*h before executing CPUID. When *FieldName* is not given, the entire contents of register *RRR* contains the desired value. When determining optional feature support, if the bit identified by *FieldName* is set to a one, the feature is supported on that processor.

CR0–CR4

A register range, from register CR0 through CR4, inclusive, with the low-order register first.

CR0[PE], CR0.PE

Notation for referring to a field within a register—in this case, the PE field of the CR0 register.

CR0[PE] = 1, CR0.PE = 1

The PE field of the CR0 register is set (contains the value 1).

EFER[LME] = 0, EFER.LME = 0

The LME field of the EFER register is cleared (contains a value of 0).

DS:SI

A far pointer or logical address. The real address or segment descriptor specified by the segment register (DS in this example) is combined with the offset contained in the second register (SI in this example) to form a real or virtual address.

RFLAGS[13:12]

A field within a register identified by its bit range. In this example, corresponding to the IOPL field.

Definitions

Many of the following definitions assume an in-depth knowledge of the legacy x86 architecture. See “Related Documents” on page xxviii for descriptions of the legacy x86 architecture.

128-bit media instructions

Instructions that operate on the various 128-bit vector data types. Supported within both the *legacy SSE* and *extended SSE* instruction sets.

256-bit media instructions

Instructions that operate on the various 256-bit vector data types. Supported within the *extended SSE* instruction set.

64-bit media instructions

Instructions that operate on the 64-bit vector data types. These are primarily a combination of MMX and 3DNow!™ instruction sets and their extensions, with some additional instructions from the *SSE1* and *SSE2* instruction sets.

16-bit mode

Legacy mode or compatibility mode in which a 16-bit address size is active. See *legacy mode* and *compatibility mode*.

32-bit mode

Legacy mode or compatibility mode in which a 32-bit address size is active. See *legacy mode* and *compatibility mode*.

64-bit mode

A submode of *long mode*. In 64-bit mode, the default address size is 64 bits and new features, such as register extensions, are supported for system and application software.

absolute

Said of a displacement that references the base of a code segment rather than an instruction pointer. Contrast with *relative*.

AES

Advance Encryption Standard (AES) algorithm acceleration instructions; part of *Streaming SIMD Extensions (SSE)*.

ASID

Address space identifier.

AVX

Extension of the SSE instruction set supporting 256-bit vector (packed) operands. See *Streaming SIMD Extensions*.

biased exponent

The sum of a floating-point value's exponent and a constant bias for a particular floating-point data type. The bias makes the range of the biased exponent always positive, which allows reciprocation without overflow.

byte

Eight bits.

clear

To write a bit value of 0. Compare *set*.

compatibility mode

A submode of *long mode*. In compatibility mode, the default address size is 32 bits, and legacy 16-bit and 32-bit applications run without modification.

commit

To irreversibly write, in program order, an instruction's result to software-visible storage, such as a register (including flags), the data cache, an internal write buffer, or memory.

CPL

Current privilege level.

direct

Referencing a memory location whose address is included in the instruction's syntax as an immediate operand. The address may be an absolute or relative address. Compare *indirect*.

dirty data

Data held in the processor's caches or internal buffers that is more recent than the copy held in main memory.

displacement

A signed value that is added to the base of a segment (absolute addressing) or an instruction pointer (relative addressing). Same as *offset*.

doubleword

Two words, or four bytes, or 32 bits.

double quadword

Eight words, or 16 bytes, or 128 bits. Also called *octword*.

effective address size

The address size for the current instruction after accounting for the default address size and any address-size override prefix.

effective operand size

The operand size for the current instruction after accounting for the default operand size and any operand-size override prefix.

element

See *vector*.

exception

An abnormal condition that occurs as the result of executing an instruction. The processor's response to an exception depends on the type of the exception. For all exceptions except SSE floating-point exceptions and x87 floating-point exceptions, control is transferred to the handler (or service routine) for that exception, as defined by the exception's vector. For floating-point exceptions defined by the IEEE 754 standard, there are both masked and unmasked responses. When unmasked, the exception handler is called, and when masked, a default response is provided instead of calling the handler.

extended SSE

Enhanced set of SIMD instructions supporting 256-bit vector data types and allowing the specification of up to four operands. A subset of the *Streaming SIMD Extensions (SSE)*. Includes the *AVX*, *FMA*, *FMA4*, and *XOP* instructions. Compare *legacy SSE*.

flush

An often ambiguous term meaning (1) writeback, if modified, and invalidate, as in "flush the cache line," or (2) invalidate, as in "flush the pipeline," or (3) change a value, as in "flush to zero."

FMA4

Fused Multiply Add, four operand. Part of the *extended SSE* instruction set.

FMA

Fused Multiply Add. Part of the *extended SSE* instruction set.

GDT

Global descriptor table.

GIF

Global interrupt flag.

IDT

Interrupt descriptor table.

IGN

Ignored. Value written is ignored by hardware. Value returned on a read is indeterminate. See *reserved*.

indirect

Referencing a memory location whose address is in a register or other memory location. The address may be an absolute or relative address. Compare *direct*.

IRB

The virtual-8086 mode interrupt-redirection bitmap.

IST

The long-mode interrupt-stack table.

IVT

The real-address mode interrupt-vector table.

LDT

Local descriptor table.

legacy x86

The legacy x86 architecture. See “Related Documents” on page xxviii for descriptions of the legacy x86 architecture.

legacy mode

An operating mode of the AMD64 architecture in which existing 16-bit and 32-bit applications and operating systems run without modification. A processor implementation of the AMD64 architecture can run in either *long mode* or *legacy mode*. Legacy mode has three submodes, *real mode*, *protected mode*, and *virtual-8086 mode*.

legacy SSE

A subset of the *Streaming SIMD Extensions (SSE)* composed of the *SSE1*, *SSE2*, *SSE3*, *SSSE3*, *SSE4.1*, *SSE4.2*, and *SSE4A* instruction sets. Compare *extended SSE*.

long mode

An operating mode unique to the AMD64 architecture. A processor implementation of the AMD64 architecture can run in either *long mode* or *legacy mode*. Long mode has two submodes, *64-bit mode* and *compatibility mode*.

lsb

Least-significant bit.

LSB

Least-significant byte.

main memory

Physical memory, such as RAM and ROM (but not cache memory) that is installed in a particular computer system.

mask

(1) A control bit that prevents the occurrence of a floating-point exception from invoking an exception-handling routine. (2) A field of bits used for a control purpose.

MBZ

Must be zero. If software attempts to set an MBZ bit to 1, a general-protection exception (#GP) occurs. See *reserved*.

memory

Unless otherwise specified, *main memory*.

msb

Most-significant bit.

MSB

Most-significant byte.

multimedia instructions

Those instructions that operate simultaneously on multiple elements within a vector data type. Comprises the *256-bit media instructions*, *128-bit media instructions*, and *64-bit media instructions*.

octword

Same as *double quadword.*

offset

Same as *displacement*.

overflow

The condition in which a floating-point number is larger in magnitude than the largest, finite, positive or negative number that can be represented in the data-type format being used.

packed

See *vector*.

PAE

Physical-address extensions.

physical memory

Actual memory, consisting of *main memory* and cache.

probe

A check for an address in a processor's caches or internal buffers. *External probes* originate outside the processor, and *internal probes* originate within the processor.

protected mode

A submode of *legacy mode*.

quadword

Four words, or eight bytes, or 64 bits.

RAZ

Read as zero. Value returned on a read is always zero (0) regardless of what was previously written. (See *reserved*)

real-address mode

See *real mode*.

real mode

A short name for *real-address mode*, a submode of *legacy mode*.

relative

Referencing with a displacement (also called offset) from an instruction pointer rather than the base of a code segment. Contrast with *absolute*.

reserved

Fields marked as reserved may be used at some future time.

To preserve compatibility with future processors, reserved fields require special handling when read or written by software. Software must not depend on the state of a reserved field (unless qualified as RAZ), nor upon the ability of such fields to return a previously written state.

If a field is marked reserved without qualification, software must not change the state of that field; it must reload that field with the same value returned from a prior read.

Reserved fields may be qualified as IGN, MBZ, RAZ, or SBZ (see definitions).

REX

An instruction encoding prefix that specifies a 64-bit operand size and provides access to additional registers.

RIP-relative addressing

Addressing relative to the 64-bit RIP instruction pointer.

SBZ

Should be zero. An attempt by software to set an SBZ bit to 1 results in undefined behavior. See *reserved*.

scalar

An atomic value existing independently of any specification of location, direction, etc., as opposed to *vectors*.

set

To write a bit value of 1. Compare *clear*.

SIB

A byte following an instruction opcode that specifies address calculation based on scale (S), index (I), and base (B).

SIMD

Single instruction, multiple data. See *vector*.

Streaming SIMD Extensions (SSE)

Instructions that operate on scalar or vector (packed) integer and floating point numbers. The SSE instruction set comprises the *legacy SSE* and *extended SSE* instruction sets.

SSE1

Original SSE instruction set. Includes instructions that operate on vector operands in both the MMX and the XMM registers.

SSE2

Extensions to the SSE instruction set.

SSE3

Further extensions to the SSE instruction set.

SSSE3

Further extensions to the SSE instruction set.

SSE4.1

Further extensions to the SSE instruction set.

SSE4.2

Further extensions to the SSE instruction set.

SSE4A

A minor extension to the SSE instruction set adding the instructions EXTRQ, INSERTQ, MOVNTSS, and MOVNTSD.

sticky bit

A bit that is set or cleared by hardware and that remains in that state until explicitly changed by software.

TOP

The x87 top-of-stack pointer.

TSS

Task-state segment.

underflow

The condition in which a floating-point number is smaller in magnitude than the smallest nonzero, positive or negative number that can be represented in the data-type format being used.

vector

(1) A set of integer or floating-point values, called *elements*, that are packed into a single operand. Most of the media instructions support vectors as operands. Vectors are also called *packed* or *SIMD* (single-instruction multiple-data) operands.

(2) An index into an interrupt descriptor table (IDT), used to access exception handlers. Compare *exception*.

VEX

An instruction encoding escape prefix that opens a new extended instruction encoding space, specifies a 64-bit operand size, and provides access to additional registers. See *XOP prefix*.

virtual-8086 mode

A submode of *legacy mode*.

VMCB

Virtual machine control block.

VMM

Virtual machine monitor.

word

Two bytes, or 16 bits.

XOP instructions

Part of the extended SSE instruction set using the XOP prefix. See *Streaming SIMD Extensions*.

XOP prefix

Extended instruction identifier prefix, used by XOP instructions allowing the specification of up to four operands and 128 or 256-bit operand widths.

Registers

In the following list of registers, the names are used to refer either to a given register or to the contents of that register:

AH–DH
: The high 8-bit AH, BH, CH, and DH registers. Compare *AL–DL*.

AL–DL
: The low 8-bit AL, BL, CL, and DL registers. Compare *AH–DH*.

AL–r15B
: The low 8-bit AL, BL, CL, DL, SIL, DIL, BPL, SPL, and R8B–R15B registers, available in 64-bit mode.

BP
: Base pointer register.

CR*n*
: Control register number *n*.

CS
: Code segment register.

eAX–eSP
: The 16-bit AX, BX, CX, DX, DI, SI, BP, and SP registers or the 32-bit EAX, EBX, ECX, EDX, EDI, ESI, EBP, and ESP registers. Compare *rAX–rSP*.

EBP
: Extended base pointer register.

EFER
: Extended features enable register.

eFLAGS
: 16-bit or 32-bit flags register. Compare *rFLAGS*.

EFLAGS
: 32-bit (extended) flags register.

eIP
: 16-bit or 32-bit instruction-pointer register. Compare *rIP*.

EIP
: 32-bit (extended) instruction-pointer register.

FLAGS
: 16-bit flags register.

GDTR
: Global descriptor table register.

GPRs
: General-purpose registers. For the 16-bit data size, these are AX, BX, CX, DX, DI, SI, BP, and SP. For the 32-bit data size, these are EAX, EBX, ECX, EDX, EDI, ESI, EBP, and ESP. For the 64-bit data size, these include RAX, RBX, RCX, RDX, RDI, RSI, RBP, RSP, and R8–R15.

IDTR
: Interrupt descriptor table register.

IP
: 16-bit instruction-pointer register.

LDTR
: Local descriptor table register.

MSR
: Model-specific register.

r8–r15
: The 8-bit R8B–R15B registers, or the 16-bit R8W–R15W registers, or the 32-bit R8D–R15D registers, or the 64-bit R8–R15 registers.

rAX–rSP
: The 16-bit AX, BX, CX, DX, DI, SI, BP, and SP registers, or the 32-bit EAX, EBX, ECX, EDX, EDI, ESI, EBP, and ESP registers, or the 64-bit RAX, RBX, RCX, RDX, RDI, RSI, RBP, and RSP registers. Replace the placeholder *r* with nothing for 16-bit size, “E” for 32-bit size, or “R” for 64-bit size.

RAX
: 64-bit version of the EAX register.

RBP
: 64-bit version of the EBP register.

RBX
: 64-bit version of the EBX register.

RCX
: 64-bit version of the ECX register.

RDI
: 64-bit version of the EDI register.

RDX
: 64-bit version of the EDX register.

rFLAGS
: 16-bit, 32-bit, or 64-bit flags register. Compare *RFLAGS*.

RFLAGS
: 64-bit flags register. Compare *rFLAGS*.

rIP
: 16-bit, 32-bit, or 64-bit instruction-pointer register. Compare *RIP*.

RIP
: 64-bit instruction-pointer register.

RSI
: 64-bit version of the ESI register.

RSP
: 64-bit version of the ESP register.

SP
: Stack pointer register.

SS
: Stack segment register.

TPR
: Task priority register (CR8), a new register introduced in the AMD64 architecture to speed interrupt management.

TR
: Task register.

Endian Order

The x86 and AMD64 architectures address memory using little-endian byte-ordering. Multibyte values are stored with their least-significant byte at the lowest byte address, and they are illustrated with their least significant byte at the right side. Strings are illustrated in reverse order, because the addresses of their bytes increase from right to left.

1 64-Bit Media Instruction Reference

This chapter describes the function, mnemonic syntax, opcodes, affected flags, and possible exceptions generated by the 64-bit media instructions. These instructions operate on data located in the 64-bit MMX registers. Most of the instructions operate in parallel on sets of packed elements called *vectors*, although some operate on scalars. The instructions define both integer and floating-point operations, and include the legacy MMX™ instructions, the 3DNow!™ instructions, and the AMD extensions to the MMX and 3DNow! instruction sets.

Each instruction that performs a vector (packed) operation is illustrated with a diagram. Figure 1-1 on page 1 shows the conventions used in these diagrams. The particular diagram shows the PSLLW (packed shift left logical words) instruction.

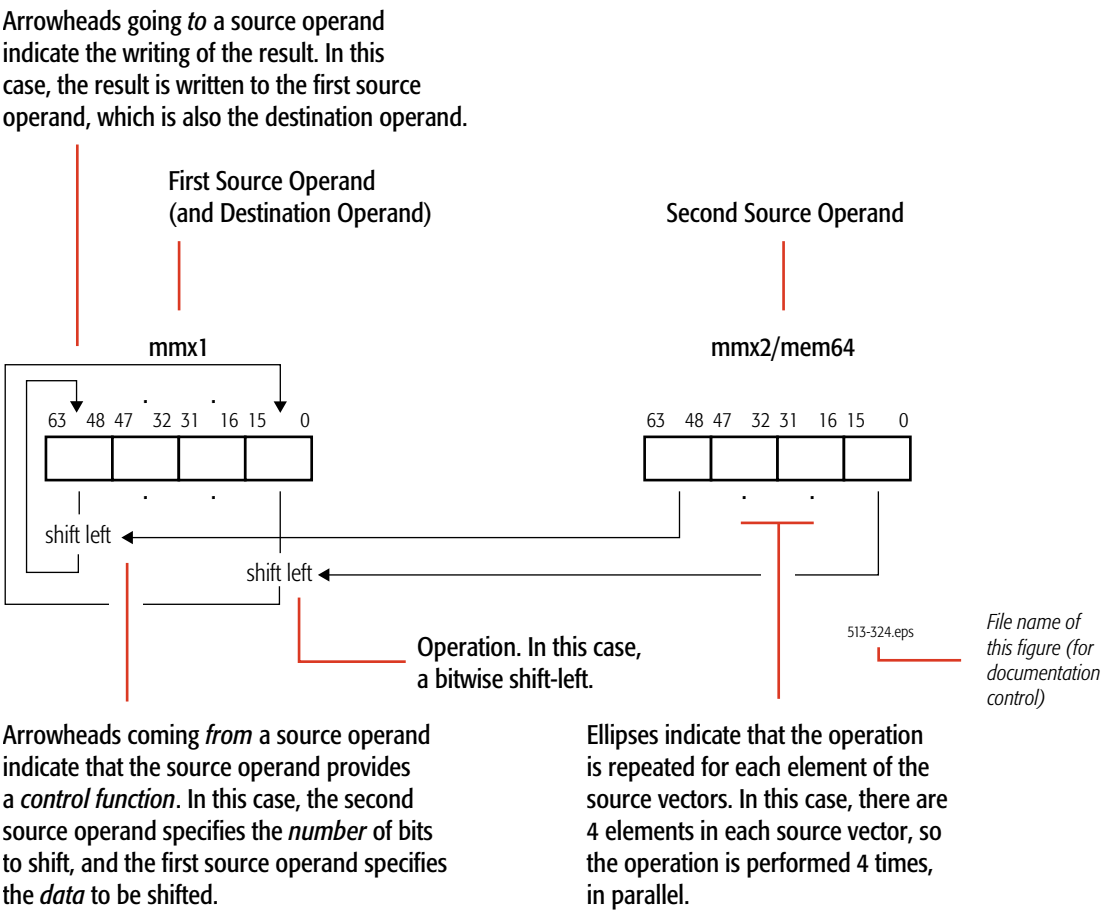

Figure 1-1. Diagram Conventions for 64-Bit Media Instructions

Gray areas in diagrams indicate unmodified operand bits.

Like the 128-bit media instructions, many of the 64-bit instructions independently and simultaneously perform a single operation on multiple elements of a vector and are thus classified as *single-instruction, multiple-data* (SIMD) instructions. A few 64-bit media instructions convert operands in MMX registers to operands in GPR, XMM, or x87 registers (or vice versa), or save or restore MMX state, or reset x87state.

Hardware support of the MMX instruction set and specific optional extensions can be determined by testing specific bits of the value returned in EDX by the CPUID instruction. If a specific bit is set in the return value, the feature is supported on the processor. The following lists the CPUID function numbers and feature bits indicating support for these features:

- MMX Instructions, indicated by EDX[23] returned by CPUID function 0000_0001h and function 8000_0001h.
- AMD Extensions to MMX Instructions, indicated by EDX[22] of CPUID function 8000_0001h.
- SSE1, indicated by EDX[25] of CPUID function 0000_0001h.
- SSE2, indicated by EDX[26] of CPUID function 0000_0001h.
- AMD 3DNow! Instructions, indicated by EDX[31] of CPUID function 8000_0001h.
- AMD Extensions to 3DNow! Instructions, indicated by EDX[30] of CPUID function 8000_0001h.
- FXSAVE and FXRSTOR, indicated by EDX[24] of CPUID function 0000_0001h and function 8000_0001h.

The 64-bit media instructions can be used in legacy mode or long mode. Their use in long mode is available if the following CPUID function return bit is set:

- Long Mode, indicated by EDX[29] of CPUID function 8000_0001h.

For more information on using the CPUID instruction, see the instruction description in Volume 3.

Compilation of 64-bit media programs for execution in 64-bit mode offers four primary advantages: access to the eight extended, 64-bit general-purpose registers (for a register set consisting of GPR0–GPR15), access to the eight extended XMM registers (for a register set consisting of XMM0–XMM15), access to the 64-bit virtual address space, and access to the RIP-relative addressing mode.

For further information, see:

- “64-Bit Media Programming” in Volume 1.
- “Summary of Registers and Data Types” in Volume 3.
- “Notation” in Volume 3.
- “Instruction Prefixes” in Volume 3.

CVTPD2PI Convert Packed Double-Precision Floating-Point to Packed Doubleword Integers

Converts two packed double-precision floating-point values in an XMM register or a 128-bit memory location to two packed 32-bit signed integer values and writes the converted values in an MMX register.

If the result of the conversion is an inexact value, the value is rounded as specified by the rounding control bits (RC) in the MXCSR register. If the floating-point value is a NaN, infinity, or if the result of the conversion is larger than the maximum signed doubleword (-2^{31} to $+2^{31} - 1$), the instruction returns the 32-bit indefinite integer value (8000_0000h) when the invalid-operation exception (IE) is masked.

The CVTPD2PI instruction is an SSE2 instruction. Support for this instruction set is indicated by CPUID Fn0000_0001_EDX[SSE2] = 1. Support for misaligned 16-byte memory accesses is indicated by CPUID Fn8000_0001_ECX[MisAlignSse] = 1.

Mnemonic	Opcode	Description
CVTPD2PI *mmx, xmm2/mem128*	66 0F 2D */r*	Converts packed double-precision floating-point values in an XMM register or 128-bit memory location to packed doubleword integers values in the destination MMX register.

	X	X	X	A source operand was too large to fit in the destination format.
Precision exception (PE)	X	X	X	A result could not be represented exactly in the destination format.

CVTPI2PD Convert Packed Doubleword Integers to Packed Double-Precision Floating-Point

Converts two packed 32-bit signed integer values in an MMX register or a 64-bit memory location to two double-precision floating-point values and writes the converted values in an XMM register.

The CVTPI2PD instruction is an SSE2 instruction. Support for this instruction set is indicated by CPUID Fn0000_0001_EDX[SSE2] = 1. See “CPUID” in Volume 3 for more information about the CPUID instruction.

Mnemonic	Opcode	Description
CVTPI2PD *xmm*, *mmx/mem64*	66 0F 2A */r*	Converts two packed doubleword integer values in an MMX register or 64-bit memory location to two packed double-precision floating-point values in the destination XMM register.

Alignment check, #AC		X	X	An unaligned memory reference was performed while alignment checking was enabled.

CVTPI2PS Convert Packed Doubleword Integers to Packed Single-Precision Floating-Point

Converts two packed 32-bit signed integer values in an MMX register or a 64-bit memory location to two single-precision floating-point values and writes the converted values in the low-order 64 bits of an XMM register. The high-order 64 bits of the XMM register are not modified. If the result of the conversion is an inexact value, the value is rounded as specified by the rounding control bits (RC) in the MXCSR register.

The CVTPI2PS instruction is an SSE1 instruction. Support for this instruction set is indicated by CPUID Fn0000_0001_EDX[SSE] = 1. See “CPUID” in Volume 3 for more information about the CPUID instruction.

Mnemonic	Opcode	Description
CVTPI2PS *xmm*, *mmx/mem64*	0F 2A */r*	Converts packed doubleword integer values in an MMX register or 64-bit memory location to single-precision floating-point values in the destination XMM register.

CVTTPD2PI Convert Packed Double-Precision Floating-Point to Packed Doubleword Integers, Truncated

Converts two packed double-precision floating-point values in an XMM register or a 128-bit memory location to two packed 32-bit signed integer values and writes the converted values in an MMX register.

If the result of the conversion is an inexact value, the value is truncated (rounded toward zero). If the floating-point value is a NaN, infinity, or if the result of the conversion is larger than the maximum signed doubleword (-2^{31} to $+2^{31} - 1$), the instruction returns the 32-bit indefinite integer value (8000_0000h) when the invalid-operation exception (IE) is masked.

The CVTTPD2PI instruction is an SSE2 instruction. Support for this instruction set is indicated by CPUID Fn0000_0001_EDX[SSE2] = 1. Support for misaligned 16-byte memory accesses is indicated by CPUID Fn8000_0001_ECX[MisAlignSse] = 1.

See “CPUID” in Volume 3 for more information about the CPUID instruction.

Mnemonic	Opcode	Description
CVTTPD2PI *mmx, xmm/mem128*	66 0F 2C */r*	Converts packed double-precision floating-point values in an XMM register or 128-bit memory location to packed doubleword integer values in the destination MMX register. Inexact results are truncated.

Precision exception (PE)	X	X	X	A result could not be represented exactly in the destination format.

EMMS Exit Multimedia State

Clears the MMX state by setting the state of the x87 stack registers to *empty* (tag-bit encoding of all 1s for all MMX registers) indicating that the contents of the registers are available for a new procedure, such as an x87 floating-point procedure. This setting of the tag bits is referred to as “clearing the MMX state”.

Because the MMX registers and tag word are shared with the x87 floating-point instructions, software should execute an EMMS instruction to clear the MMX state before executing code that includes x87 floating-point instructions.

The functions of the EMMS and FEMMS instructions are identical.

For details about the setting of x87 tag bits, see “Media and x87 Processor State” in Volume 2.

The EMMS instruction is an MMX™ instruction. Support for the MMX instruction subset is indicated by CPUID Fn0000_0001_EDX[MMX] = 1 or CPUID Fn8000_0001_EDX[MMX] = 1. See “CPUID” in Volume 3 for more information about the CPUID instruction.

Mnemonic	Opcode	Description
EMMS	0F 77	Clears the MMX state.

Exceptions

Exception	Real	Virtual 8086	Protected	Cause of Exception
Invalid opcode, #UD	X	X	X	The emulate bit (EM) of CR0 was set to 1.
	X	X	X	The MMX™ instructions are not supported, as indicated by EDX[MMX] = 0, returned by CPUID Fn0000_0001 or Fn8000_0001.
Device not available, #NM	X	X	X	The task-switch bit (TS) of CR0 was set to 1.
x87 floating-point exception pending, #MF	X	X	X	An unmasked x87 floating-point exception was pending.

FEMMS Fast Exit Multimedia State

Clears the MMX state by setting the state of the x87 stack registers to *empty* (tag-bit encoding of all 1s for all MMX registers) indicating that the contents of the registers are available for a new procedure, such as an x87 floating-point procedure. This setting of the tag bits is referred to as “clearing the MMX state”.

Because the MMX registers and tag word are shared with the x87 floating-point instructions, software should execute an EMMS or FEMMS instruction to clear the MMX state before executing code that includes x87 floating-point instructions.

The functions of the FEMMS and EMMS instructions are identical. The FEMMS instruction is supported for backward-compatibility with certain AMD processors. Software that must be both compatible with both AMD and non-AMD processors should use the EMMS instruction.

FEMMS is a 3DNow! instruction. Support for this instruction subset is indicated by CPUID Fn8000_0001_EDX[3DNow] = 1. See “CPUID” in Volume 3 for more information about the CPUID instruction.

For details about the setting of x87 tag bits, see “Media and x87 Processor State” in Volume 2.

AMD no longer recommends the use of 3DNow! instructions, which have been superceded by their more efficient 128-bit media counterparts. For a complete list of recommended instruction substitutions, see Appendix A, “Recommended Substitutions for 3DNow!™ Instructions” on page 333.

FRSTOR Floating-Point Restore x87 and MMX™ State

Restores the complete x87 state from memory starting at the specified address, as stored by a previous call to FNSAVE. The x87 state occupies 94 or 108 bytes of memory depending on whether the processor is operating in real or protected mode and whether the operand-size attribute is 16-bit or 32-bit. Because the MMX registers are mapped onto the low 64 bits of the x87 floating-point registers, this operation also restores the MMX state.

If FRSTOR results in set exception flags in the loaded x87 status word register, and these exceptions are unmasked in the x87 control word register, a floating-point exception occurs when the next floating-point instruction is executed (except for the no-wait floating-point instructions).

To avoid generating exceptions when loading a new environment, use the FCLEX or FNCLEX instruction to clear the exception flags in the x87 status word before storing that environment.

For details about the memory image restored by FRSTOR, see “Media and x87 Processor State” in Volume 2.

Mnemonic	Opcode	Description
FRSTOR *mem94/108env*	DD /4	Load the x87 state from *mem94/108env*.

FSAVE (FNSAVE) Floating-Point Save x87 and MMX™ State

Stores the complete x87 state to memory starting at the specified address and reinitializes the x87 state. The x87 state requires 94 or 108 bytes of memory, depending upon whether the processor is operating in real or protected mode and whether the operand-size attribute is 16-bit or 32-bit. Because the MMX registers are mapped onto the low 64 bits of the x87 floating-point registers, this operation also saves the MMX state. For details about the memory image saved by FNSAVE, see “Media and x87 Processor State” in Volume 2.

The FNSAVE instruction does not wait for pending unmasked x87 floating-point exceptions to be processed. Processor interrupts should be disabled before using this instruction.

Assemblers usually provide an FSAVE macro that expands into the instruction sequence:

```
WAIT                    ; Opcode 9B
FNSAVE destination      ; Opcode DD /6
```

The WAIT (9Bh) instruction checks for pending x87 exceptions and calls an exception handler, if necessary. The FNSAVE instruction then stores the x87 state to the specified destination.

Mnemonic	Opcode	Description
FNSAVE *mem94/108env*	DD /6	Copy the x87 state to *mem94/108env* without checking for pending floating-point exceptions, then reinitialize the x87 state.
FSAVE *mem94/108env*	9B DD /6	Copy the x87 state to *mem94/108env* after checking for pending floating-point exceptions, then reinitialize the x87 state.

FXRSTOR Restore XMM, MMX™, and x87 State

Restores the XMM, MMX, and x87 state from a 16-byte aligned area in memory pointed to by the source operand. The data loaded from memory is the state information previously saved using the FXSAVE instruction. Restoring data with FXRSTOR that had been previously saved with an FSAVE (rather than FXSAVE) instruction results in an incorrect restoration. If the source pointer is not 16-byte aligned, execution may be inhibited either by an #AC exception at CPL=3 if alignment checking is enabled, otherwise by a #GP(0) exception.

If FXRSTOR results in set exception flags in the loaded x87 status word register, and these exceptions are unmasked in the x87 control word register, a floating-point exception occurs when the next floating-point instruction is executed (except for the no-wait floating-point instructions).

If the restored MXCSR register contains a set bit in an exception status flag, and the corresponding exception mask bit is cleared (indicating an unmasked exception), loading the MXCSR register does not cause a SIMD floating-point exception (#XF).

FXRSTOR does not restore the x87 error pointers (last instruction pointer, last data pointer, and last opcode), except when FXRSTOR sets FSW.ES=1 after recomputing it from the error mask bits in FCW and error status bits in FSW.

The architecture supports two 512-bit memory formats for FXRSTOR, a 64-bit format that loads XMM0-XMM15, and a 32-bit legacy format that loads only XMM0-XMM7. If FXRSTOR is executed in 64-bit mode, the 64-bit format is used, otherwise the 32-bit format is used. When the 64-bit format is used, if the operand-size is 64-bit, FXRSTOR loads the x87 pointer registers as *offset64*, otherwise it loads them as *sel:offset32*. For details about the memory format used by FXRSTOR, see "Saving Media and x87 Processor State" in Volume 2.

If the fast-FXSAVE/FXRSTOR (FFXSR) feature is enabled in EFER, FXRSTOR does not restore the XMM registers (XMM0-XMM15) when executed in 64-bit mode at CPL 0. MXCSR is restored whether fast-FXSAVE/FXRSTOR is enabled or not.

Support for the fast-FXSAVE/FXRSTOR feature is indicated by CPUID Fn8000_0001_EDX[FFXSR] = 1.

If the operating-system FXSAVE/FXRSTOR support bit (OSFXSR) of CR4 is cleared to 0, the saved image of XMM0–XMM15 and MXCSR is not loaded into the processor. A general-protection exception occurs if the FXRSTOR instruction attempts to load non-zero values into reserved MXCSR bits. Software can use MXCSR_MASK to determine which bits of MXCSR are reserved. For details on the MXCSR_MASK, see “SSE, MMX, and x87 Programming” in Volume 2.

Support for this instruction is implementation-specific. CPUID Fn8000_0001_EDX[FXSR] = 1 or CPUID Fn0000_0001_EDX[FXSR] = 1 indicates support for the FXSAVE and FXRSTOR instructions. See “CPUID” in Volume 3 for more information about the CPUID instruction.

Mnemonic	Opcode	Description
FXRSTOR *mem512env*	0F AE /1	Restores XMM, MMX™, and x87 state from 512-byte memory location.

Note: *A flag that can be set to one or zero is M (modified). Unaffected flags are blank. Shaded fields are reserved.*																

Exceptions

Exception	Real	Virtual 8086	Protected	Cause of Exception
Invalid opcode, #UD	X	X	X	The FXSAVE/FXRSTOR instructions are not supported, as indicated by EDX[FXSR] = 0, returned by CPUID Fn0000_0001 or CPUID Fn8000_0001.
Device not available, #NM	X	X	X	The emulate bit (EM) of CR0 was set to 1.
	X	X	X	The task-switch bit (TS) of CR0 was set to 1.
Stack, #SS	X	X	X	A memory address exceeded the stack segment limit, or was non-canonical.
General protection, #GP	X	X	X	A memory address exceeded the data segment limit or was non-canonical.
			X	A null data segment was used to reference memory.
	X	X	X	The memory operand was not aligned on a 16-byte boundary. At CPL=3 (including virtual 8086 mode), this will be overridden by a #AC exception if alignment checking is enabled.
	X	X	X	Ones were written to the reserved bits in MXCSR.
Page fault, #PF		X	X	A page fault resulted from the execution of the instruction.
Alignment Check, #AC		X	X	An unaligned memory reference was performed while alignment checking was enabled.

FXSAVE Save XMM, MMX, and x87 State

Saves the XMM, MMX, and x87 state to a 16-byte aligned area in memory pointed to by the source operand. If the destination pointer is not 16-byte aligned, execution may be inhibited by an #AC exception at CPL=3 if alignment checking is enabled, otherwise by a #GP(0) exception.

Unlike FSAVE and FNSAVE, FXSAVE does not alter the x87 tag bits. The contents of the saved MMX/x87 data registers are retained, thus indicating that the registers may be valid (or whatever other value the x87 tag bits indicated prior to the save). To invalidate the contents of the MMX/x87 data registers after FXSAVE, software must execute an FINIT instruction. Also, FXSAVE (like FNSAVE) does not check for pending unmasked x87 floating-point exceptions. An FWAIT instruction can be used for this purpose.

FXSAVE does not save the x87 pointer registers (last instruction pointer, last data pointer, and last opcode), except in the relatively rare cases in which the exception-summary (ES) bit in the x87 status word is set to 1, indicating that an unmasked x87 exception has occurred.

The architecture supports two 512-bit memory formats for FXSAVE, a 64-bit format that saves XMM0-XMM15, and a 32-bit legacy format that saves only XMM0-XMM7. If FXSAVE is executed in 64-bit mode, the 64-bit format is used, otherwise the 32-bit format is used. When the 64-bit format is used, if the operand-size is 64-bit, FXSAVE saves the x87 pointer registers as *offset64*, otherwise it saves them as *sel:offset32*. For more details about the memory format used by FXSAVE, see “Saving Media and x87 Execution Unit State” in Volume 2.

If the fast-FXSAVE/FXRSTOR (FFXSR) feature is enabled in EFER, FXSAVE does not save the XMM registers (XMM0-XMM15) when executed in 64-bit mode at CPL 0. MXCSR is saved whether fast-FXSAVE/FXRSTOR is enabled or not.

Support for the fast-FXSAVE/FXRSTOR feature is indicated by CPUID Fn8000_0001_EDX[FFXSR] = 1.

If the operating-system FXSAVE/FXRSTOR support bit (OSFXSR) of CR4 is cleared to 0, FXSAVE does not save the image of XMM0–XMM15 or MXCSR. For details about the CR4.OSFXSR bit, see “FXSAVE/FXRSTOR Support (OSFXSR) Bit” in Volume 2.

Support for this instruction is implementation-specific. CPUID Fn8000_0001_EDX[FXSR] = 1 or CPUID Fn0000_0001_EDX[FXSR] = 1 indicates support for the FXSAVE and FXRSTOR instructions. See “CPUID” in Volume 3 for more information about the CPUID instruction.

Mnemonic	Opcode	Description

MASKMOVQ Masked Move Quadword

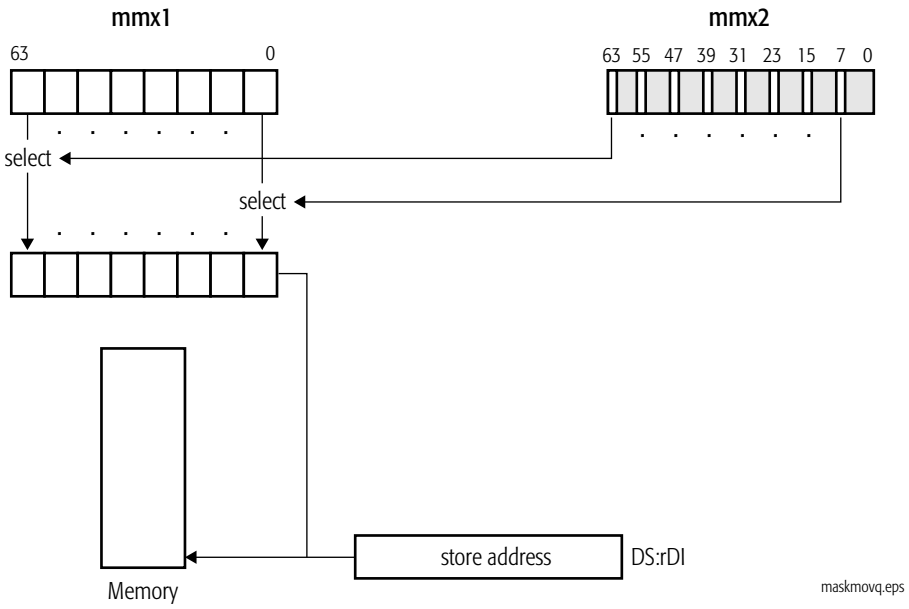
Stores bytes from the first source operand, as selected by the second source operand, to a memory location specified in the DS:rDI registers (except that DS is ignored in 64-bit mode). The first source operand is an MMX register, and the second source operand is another MMX register. The most-significant bit (msb) of each byte in the second source operand specifies the store (1 = store, 0 = no store) of the corresponding byte of the first source operand.

Exception and trap behavior for the elements not selected for storage to memory are implementation dependent. For instance, a given implementation may signal a data breakpoint or a page fault for bytes that are zero-masked and not actually written.

MASKMOVQ implicitly uses weakly-ordered, write-combining buffering for the data, as described in "Buffering and Combining Memory Writes" in Volume 2. If the stored data is shared by multiple processors, this instruction should be used together with a fence instruction in order to ensure data coherency (refer to "Cache and TLB Management" in Volume 2).

The MASKMOVQ instruction is an AMD extension to MMX™ instruction set and is an SSE1 instruction. Support for AMD extensions to the MMX instruction subset is indicated by CPUID Fn8000_0001_EDX[MmxExt] = 1. See "CPUID" in Volume 3 for more information about the CPUID instruction.

Mnemonic	Opcode	Description
MASKMOVQ *mmx1*, *mmx2*	0F F7 */r*	Store bytes from an MMX register, selected by the most-significant bit of the corresponding byte in another MMX register, to DS:rDI.



Related Instructions

MOVD Move Doubleword or Quadword

Moves a 32-bit or 64-bit value in one of the following ways:

- from a 32-bit or 64-bit general-purpose register or memory location to the low-order 32 or 64 bits of an XMM register, with zero-extension to 128 bits
- from the low-order 32 or 64 bits of an XMM to a 32-bit or 64-bit general-purpose register or memory location
- from a 32-bit or 64-bit general-purpose register or memory location to the low-order 32 bits (with zero-extension to 64 bits) or the full 64 bits of an MMX register
- from the low-order 32 or the full 64 bits of an MMX register to a 32-bit or 64-bit general-purpose register or memory location.

The MOVD instruction is a member of both the MMX and the SSE2 instruction sets. The presence of this instruction set is indicated by EDX[MMX] = 1 returned by CPUID Fn0000_0001 or CPUID Fn8000_0001. See “CPUID” in Volume 3 for more information about the CPUID instruction.

Mnemonic	Opcode	Description
MOVD *mmx*, *reg/mem32*	0F 6E */r*	Move 32-bit value from a general-purpose register or 32-bit memory location to an MMX register.
MOVD *mmx*, *reg/mem64*	0F 6E */r*	Move 64-bit value from a general-purpose register or 64-bit memory location to an MMX register.
MOVD *reg/mem32*, *mmx*	0F 7E */r*	Move 32-bit value from an MMX register to a 32-bit general-purpose register or memory location.
MOVD *reg/mem64*, *mmx*	0F 7E */r*	Move 64-bit value from an MMX register to a 64-bit general-purpose register or memory location.

The following diagrams illustrate the operation of the MOVD instruction.

MOVNTQ Move Non-Temporal Quadword

Stores a 64-bit MMX register value into a 64-bit memory location. This instruction indicates to the processor that the data is non-temporal, and is unlikely to be used again soon. The processor treats the store as a write-combining (WC) memory write, which minimizes cache pollution. The exact method by which cache pollution is minimized depends on the hardware implementation of the instruction. For further information, see “Memory Optimization” in Volume 1.

MOVNTQ is weakly-ordered with respect to other instructions that operate on memory. Software should use an SFENCE instruction to force strong memory ordering of MOVNTQ with respect to other stores.

MOVNTQ implicitly uses weakly-ordered, write-combining buffering for the data, as described in “Buffering and Combining Memory Writes” in Volume 2. For data that is shared by multiple processors, this instruction should be used together with a fence instruction in order to ensure data coherency (refer to “Cache and TLB Management” in Volume 2).

The MOVNTQ instruction is a member of both the AMD MMX extensions and the SSE1 instruction sets. Support for the SSE1 instruction subset is indicated by CPUID Fn0000_0001_EDX[SSE] = 1. Support for AMD’s extensions to the MMX instruction subset is indicated by CPUID Fn8000_0001_EDX[MmxExt] = 1. See “CPUID” in Volume 3 for more information about the CPUID instruction.

Mnemonic	Opcode	Description
MOVNTQ *mem64*, *mmx*	0F E7 */r*	Stores a 64-bit MMX register value into a 64-bit memory location, minimizing cache pollution.

MOVQ Move Quadword

Moves a 64-bit value:

- from an MMX register or 64-bit memory location to another MMX register, or
- from an MMX register to another MMX register or 64-bit memory location.

The MOVQ instruction is an MMX™ instruction. Support for this instruction subset is indicated by EDX[MMX] = 1, as returned by CPUID Fn0000_0001 or CPUID Fn8000_0001. See “CPUID” in Volume 3 for more information about the CPUID instruction.

Mnemonic	Opcode	Description
MOVQ *mmx1*, *mmx2*/*mem64*	0F 6F */r*	Moves 64-bit value from an MMX register or memory location to an MMX register.
MOVQ *mmx1*/*mem64*, *mmx2*	0F 7F */r*	Moves 64-bit value from an MMX register to an MMX register or memory location.

MOVQ2DQ Move Quadword to Quadword

Moves a 64-bit value from an MMX register to the low-order 64 bits of an XMM register, with zero-extension to 128 bits.

The MOVQ2DQ instruction is an SSE2 instruction. Support for this instruction subset is indicated by CPUID Fn0000_0001_EDX[SSE2] = 1. See “CPUID” in Volume 3 for more information about the CPUID instruction.

Mnemonic	Opcode	Description
MOVQ2DQ *xmm*, *mmx*	F3 0F D6 /r	Moves 64-bit value from an MMX register to an XMM register.

PACKSSDW Pack with Saturation Signed Doubleword to Word

Converts each 32-bit signed integer in the first and second source operands to a 16-bit signed integer and packs the converted values into words in the destination (first source). The first source/destination operand is an MMX register and the second source operand is another MMX register or 64-bit memory location.

Converted values from the first source operand are packed into the low-order words of the destination, and the converted values from the second source operand are packed into the high-order words of the destination.

For each packed value in the destination, if the value is larger than the largest signed 16-bit integer, it is saturated to 7FFFh, and if the value is smaller than the smallest signed 16-bit integer, it is saturated to 8000h.

The PACKSSDW instruction is an MMX™ instruction. Support for this instruction subset is indicated by EDX[MMX] = 1, as returned by CPUID Fn0000_0001 or CPUID Fn8000_0001. See “CPUID” in Volume 3 for more information about the CPUID instruction.

Mnemonic	Opcode	Description
PACKSSDW *mmx1*, *mmx2/mem64*	0F 6B */r*	Packs 32-bit signed integers in an MMX register and another MMX register or 64-bit memory location into 16-bit signed integers in an MMX register.

PACKSSWB Pack with Saturation Signed Word to Byte

Converts each 16-bit signed integer in the first and second source operands to an 8-bit signed integer and packs the converted values into bytes in the destination (first source). The first source/destination operand is an MMX register and the second source operand is another MMX register or 64-bit memory location.

Converted values from the first source operand are packed into the low-order bytes of the destination, and the converted values from the second source operand are packed into the high-order bytes of the destination.

For each packed value in the destination, if the value is larger than the largest signed 8-bit integer, it is saturated to 7Fh, and if the value is smaller than the smallest signed 8-bit integer, it is saturated to 80h.

The PACKSSWB instruction is an MMX instruction. Support for this instruction subset is indicated by EDX[MMX] = 1, as returned by CPUID Fn0000_0001 or CPUID Fn8000_0001. See “CPUID” in Volume 3 for more information about the CPUID instruction.

Mnemonic	Opcode	Description
PACKSSWB *mmx1*, *mmx2*/*mem64*	0F 63 */r*	Packs 16-bit signed integers in an MMX register and another MMX register or 64-bit memory location into 8-bit signed integers in an MMX register.

PACKUSWB Pack with Saturation Signed Word to Unsigned Byte

Converts each 16-bit signed integer in the first and second source operands to an 8-bit unsigned integer and packs the converted values into bytes in the destination (first source). The first source/destination operand is an MMX register and the second source operand is another MMX register or 64-bit memory location.

Converted values from the first source operand are packed into the low-order bytes of the destination, and the converted values from the second source operand are packed into the high-order bytes of the destination.

For each packed value in the destination, if the value is larger than the largest unsigned 8-bit integer, it is saturated to FFh, and if the value is smaller than the smallest unsigned 8-bit integer, it is saturated to 00h.

The PACKUSWB instruction is an MMX™ instruction. Support for this instruction subset is indicated by EDX[MMX] = 1, as returned by CPUID Fn0000_0001 or CPUID Fn8000_0001. See “CPUID” in Volume 3 for more information about the CPUID instruction.

Mnemonic	Opcode	Description
PACKUSWB *mmx1*, *mmx2/mem64*	0F 67 */r*	Packs 16-bit signed integers in an MMX register and another MMX register or 64-bit memory location into 8-bit unsigned integers in an MMX register.

PADDB Packed Add Bytes

Adds each packed 8-bit integer value in the first source operand to the corresponding packed 8-bit integer in the second source operand and writes the integer result of each addition in the corresponding byte of the destination (first source). The first source/destination operand is an MMX register and the second source operand is another MMX register or 64-bit memory location.

The PADDB instruction operates on both signed and unsigned integers. If the result overflows, the carry is ignored (neither the overflow nor carry bit in rFLAGS is set), and only the low-order 8 bits of each result are written in the destination.

The PADDB instruction is an MMX™ instruction. Support for this instruction subset is indicated by EDX[MMX] = 1, as returned by CPUID Fn0000_0001 or CPUID Fn8000_0001. See “CPUID” in Volume 3 for more information about the CPUID instruction.

Mnemonic	Opcode	Description
PADDB *mmx1*, *mmx2/mem64*	0F FC */r*	Adds packed byte integer values in an MMX register and another MMX register or 64-bit memory location and writes the result in the destination MMX register.

PADDD Packed Add Doublewords

Adds each packed 32-bit integer value in the first source operand to the corresponding packed 32-bit integer in the second source operand and writes the integer result of each addition in the corresponding doubleword of the destination (first source). The first source/destination operand is an MMX register and the second source operand is another MMX register or 64-bit memory location.

The PADDD instruction operates on both signed and unsigned integers. If the result overflows, the carry is ignored (neither the overflow nor carry bit in rFLAGS is set), and only the low-order 32 bits of each result are written in the destination.

The PADDD instruction is an MMX™ instruction. Support for this instruction subset is indicated by EDX[MMX] = 1, as returned by CPUID Fn0000_0001 or CPUID Fn8000_0001. See “CPUID” in Volume 3 for more information about the CPUID instruction.

Mnemonic	Opcode	Description
PADDD *mmx1*, *mmx2*/*mem64*	0F FE */r*	Adds packed 32-bit integer values in an MMX register and another MMX register or 64-bit memory location and writes the result in the destination MMX register.

PADDQ Packed Add Quadwords

Adds each packed 64-bit integer value in the first source operand to the corresponding packed 64-bit integer in the second source operand and writes the integer result of each addition in the corresponding quadword of the destination (first source). The first source/destination operand is an MMX register and the second source operand is another MMX register or 64-bit memory location.

The PADDQ instruction operates on both signed and unsigned integers. If the result overflows, the carry is ignored (neither the overflow nor carry bit in rFLAGS is set), and only the low-order 64 bits of each result are written in the destination.

The PADDQ instruction is an SSE2 instruction. The presence of this instruction set is indicated by a CPUID Fn0000_0001_EDX[SSE2] = 1. See “CPUID” in Volume 3 for more information about the CPUID instruction.

Mnemonic	Opcode	Description
PADDQ *mmx1*, *mmx2*/*mem64*	0F D4 */r*	Adds 64-bit integer value in an MMX register and another MMX register or 64-bit memory location and writes the result in the destination MMX register.

PAND Packed Logical Bitwise AND

Performs a bitwise logical AND of the values in the first and second source operands and writes the result in the destination (first source). The first source/destination operand is an MMX register and the second source operand is another MMX register or 64-bit memory location.

The PAND instruction is an MMX™ instruction. Support for this instruction subset is indicated by EDX[MMX] = 1, as returned by CPUID Fn0000_0001 or CPUID Fn8000_0001. See “CPUID” in Volume 3 for more information about the CPUID instruction.

Mnemonic	Opcode	Description
PAND *mmx1*, *mmx2/mem64*	0F DB */r*	Performs bitwise logical AND of values in an MMX register and in another MMX register or 64-bit memory location and writes the result in the destination MMX register.

PANDN Packed Logical Bitwise AND NOT

Performs a bitwise logical AND of the value in the second source operand and the one's complement of the value in the first source operand and writes the result in the destination (first source). The first source/destination operand is an MMX register and the second source operand is another MMX register or 64-bit memory location.

The PANDN instruction is an MMX™ instruction. Support for this instruction subset is indicated by EDX[MMX] = 1, as returned by CPUID Fn0000_0001 or CPUID Fn8000_0001. See "CPUID" in Volume 3 for more information about the CPUID instruction.

Mnemonic	Opcode	Description
PANDN *mmx1*, *mmx2*/*mem64*	0F DF */r*	Performs bitwise logical AND NOT of values in an MMX register and in another MMX register or 64-bit memory location and writes the result in the destination MMX register.

PAVGB Packed Average Unsigned Bytes

Computes the rounded average of each packed unsigned 8-bit integer value in the first source operand and the corresponding packed 8-bit unsigned integer in the second source operand and writes each average in the corresponding byte of the destination (first source). The average is computed by adding each pair of operands, adding 1 to the 9-bit temporary sum, and then right-shifting the temporary sum by one bit position. The destination and source operands are an MMX register and another MMX register or 64-bit memory location.

The PAVGB instruction is a member of both the AMD MMX™ extensions and the SSE1 instruction sets. Support for the SSE1 instruction subset is indicated by CPUID Fn0000_0001_EDX[SSE] = 1. Support for AMD's extensions to the MMX instruction subset is indicated by CPUID Fn8000_0001_EDX[MmxExt] = 1. See "CPUID" in Volume 3 for more information about the CPUID instruction.

Mnemonic	Opcode	Description
PAVGB *mmx1*, *mmx2/mem64*	0F E0 */r*	Averages packed 8-bit unsigned integer values in an MMX register and another MMX register or 64-bit memory location and writes the result in the destination MMX register.

PAVGUSB Packed Average Unsigned Bytes

Computes the rounded-up average of each packed unsigned 8-bit integer value in the first source operand and the corresponding packed 8-bit unsigned integer in the second source operand and writes each average in the corresponding byte of the destination (first source). The average is computed by adding each pair of operands, adding 1 to the 9-bit temporary sum, and then right-shifting the temporary sum by one bit position. The first source/destination operand is an MMX register. The second source operand is another MMX register or 64-bit memory location.

The PAVGUSB instruction performs a function identical to the 64-bit version of the PAVGB instruction, although the two instructions have different opcodes. PAVGUSB is a 3DNow! instruction. It is useful for pixel averaging in MPEG-2 motion compensation and video scaling operations.

The PAVGUSB instruction is an AMD 3DNow!™ instruction. The presence of this instruction set is indicated by a CPUID feature bit. See “CPUID” in Volume 3 for more information about the CPUID instruction.

AMD no longer recommends the use of 3DNow! instructions, which have been superceded by their more efficient 128-bit media counterparts. For a complete list of recommended instruction substitutions, see Appendix A, “Recommended Substitutions for 3DNow!™ Instructions” on page 333.

PAVGW Packed Average Unsigned Words

Computes the rounded average of each packed unsigned 16-bit integer value in the first source operand and the corresponding packed 16-bit unsigned integer in the second source operand and writes each average in the corresponding word of the destination (first source). The average is computed by adding each pair of operands, adding 1 to the 17-bit temporary sum, and then right-shifting the temporary sum by one bit position. The first source/destination operand is an MMX register and the second source operand is another MMX register or 64-bit memory location.

The PAVGW instruction is a member of both the AMD MMX™ extensions and the SSE1 instruction sets. Support for the SSE1 instruction subset is indicated by CPUID Fn0000_0001_EDX[SSE] = 1. Support for AMD's extensions to the MMX instruction subset is indicated by CPUID Fn8000_0001_EDX[MmxExt] = 1. See "CPUID" in Volume 3 for more information about the CPUID instruction.

Mnemonic	Opcode	Description
PAVGW *mmx1*, *mmx2*/*mem64*	0F E3 */r*	Averages packed 16-bit unsigned integer values in an MMX register and another MMX register or 64-bit memory location and writes the result in the destination MMX register.

PF2ID Packed Floating-Point to Integer Doubleword Converson

Converts two packed single-precision floating-point values in an MMX register or a 64-bit memory location to two packed 32-bit signed integer values and writes the converted values in another MMX register. If the result of the conversion is an inexact value, the value is truncated (rounded toward zero). The numeric range for source and destination operands is shown in Table 1-2 on page 89.

The PF2ID instruction is an AMD 3DNow!™ instruction. The presence of this instruction set is indicated by CPUID feature bits. See “CPUID” in Volume 3 for more information about the CPUID instruction.

AMD no longer recommends the use of 3DNow! instructions, which have been superceded by their more efficient 128-bit media counterparts. For a complete list of recommended instruction substitutions, see Appendix A, “Recommended Substitutions for 3DNow!™ Instructions” on page 333.

Recommended Instruction Substitution

CVTTPS2DQ

Mnemonic	Opcode	Description
PF2ID *mmx1*, *mmx2/mem64*	0F 0F /r 1D	Converts packed single-precision floating-point values in an MMX register or memory location to a doubleword integer value in the destination MMX register.

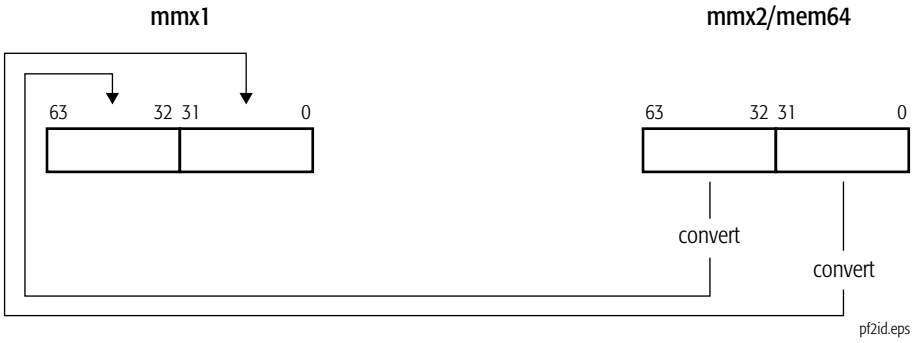

Table 1-2. Numeric Range for PF2ID Results

Source 2	Source 1 and Destination
0	0
Normal, abs(Source 2) < 1	0
Normal, -2^{31} < Source 2 <= –1	Round to zero (Source 2)
Normal, 1 <= Source 2 < 2^{31}	Round to zero (Source 2)

PF2IW Packed Floating-Point to Integer Word Conversion

Converts two packed single-precision floating-point values in an MMX register or a 64-bit memory location to two packed 16-bit signed integer values, sign-extended to 32 bits, and writes the converted values in another MMX register. If the result of the conversion is an inexact value, the value is truncated (rounded toward zero). The numeric range for source and destination operands is shown in Table 1-3 on page 91. Arguments outside the range representable by signed 16-bit integers are saturated to the largest and smallest 16-bit integer, depending on their sign.

The PF2IW instruction is an extension to the AMD 3DNow!™ instruction set. The presence of this instruction set is indicated by CPUID feature bits. See “CPUID” in Volume 3 for more information about the CPUID instruction.

AMD no longer recommends the use of 3DNow! instructions, which have been superceded by their more efficient 128-bit media counterparts. For a complete list of recommended instruction substitutions, see Appendix A, “Recommended Substitutions for 3DNow!™ Instructions” on page 333.

Recommended Instruction Substitution

CVTTPS2DQ

Mnemonic	Opcode	Description
PF2IW *mmx1*, *mmx2/mem64*	0F 0F /r 1C	Converts packed single-precision floating-point values in an MMX register or memory location to word integer values in the destination MMX register.

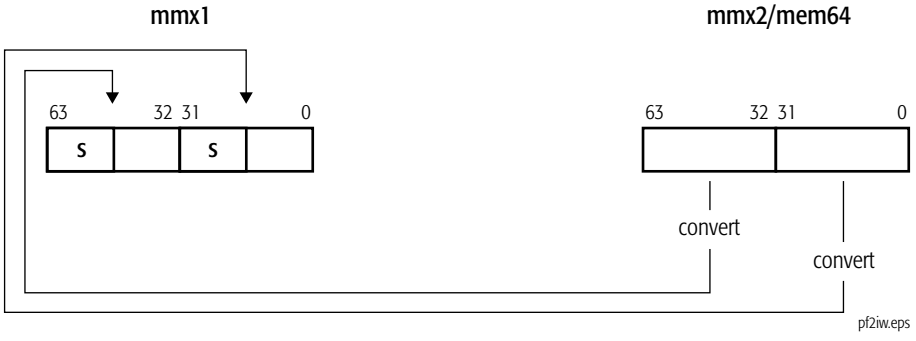

Table 1-3. Numeric Range for PF2IW Results

Source 2	Source 1 and Destination
0	0
Normal, abs(Source 2) < 1	0
Normal, -2^{15} < Source 2 <= –1	Round to zero (Source 2)
Normal, 1 <= Source 2 < 2^{15}	Round to zero (Source 2)
Normal, Source 2 >= 2^{15}	0000_7FFFh
Normal, Source 2 <= -2^{15}	FFFF_8000h
Unsupported	Undefined

PFACC Packed Floating-Point Accumulate

Adds the two single-precision floating-point values in the first source operand and adds the two single-precision values in the second source operand and writes the two results to the low-order and high-order doubleword, respectively, of the destination (first source). The first source/destination operand is an MMX register. The second source operand is another MMX register or 64-bit memory location.

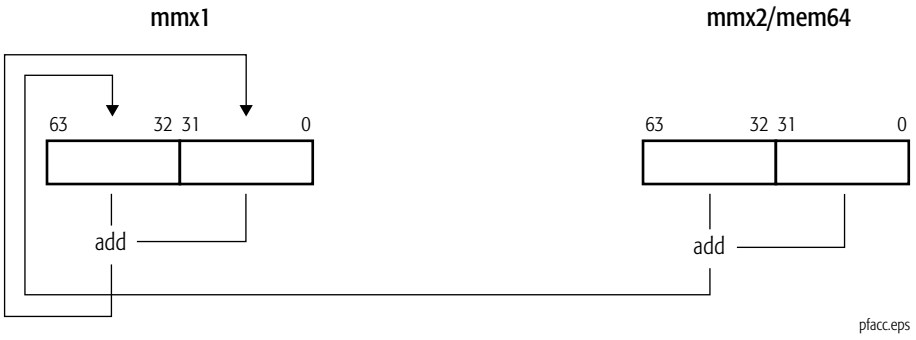
The PFACC instruction is an AMD 3DNow!™ instruction. The presence of this instruction set is indicated by CPUID feature bits. See “CPUID” in Volume 3 for more information about the CPUID instruction.

AMD no longer recommends the use of 3DNow! instructions, which have been superceded by their more efficient 128-bit media counterparts. For a complete list of recommended instruction substitutions, see Appendix A, “Recommended Substitutions for 3DNow!™ Instructions” on page 333.

Recommended Instruction Substitution

HADDPS

Mnemonic	Opcode	Description
PFACC *mmx1*, *mmx2/mem64*	0F 0F /r AE	Accumulates packed single-precision floating-point values in an MMX register or 64-bit memory location and another MMX register and writes each result in the destination MMX register.



The numeric range for operands is shown in Table 1-4 on page 93.

Table 1-4. Numeric Range for PFACC Results

Source Operand		High Operand[2]		
		0	Normal	Unsupported
Low Operand[1]	0	+/– 0[3]	High Operand	High Operand
	Normal	Low Operand	Normal, +/– 0[4]	Undefined
	Unsupported[5]	Low Operand	Undefined	Undefined

Note:

1. *Least-significant floating-point value in first or second source operand.*
2. *Most-significant floating-point value in first or second source operand.*
3. *The sign of the result is the logical AND of the signs of the low and high operands.*
4. *If the absolute value of the infinitely precise result is less than 2^{-126} (but not zero), the result is a zero with the sign of the operand (low or high) that is larger in magnitude. If the infinitely precise result is exactly zero, the result is zero with the sign of the low operand. If the absolute value of the infinitely precise result is greater than or equal to 2^{128}, the result is the largest normal number with the sign of the low operand.*
5. *"Unsupported" means that the exponent is all ones (1s).*

PFNACC Packed Floating-Point Negative Accumulate

Subtracts the first source operand's high-order single-precision floating-point value from its low-order single-precision floating-point value, subtracts the second source operand's high-order single-precision floating-point value from its low-order single-precision floating-point value, and writes each result to the low-order or high-order doubleword, respectively, of the destination (first source). The first source/destination operand is an MMX register. The second source operand is another MMX register or 64-bit memory location.

The numeric range for operands is shown in Table 1-12 on page 110.

The PFNACC instruction is an extension to the AMD 3DNow!™ instruction set. The presence of this instruction set is indicated by CPUID Fn8000_0001_EDX[3DNowExt] =1. See "CPUID" in Volume 3 for more information about the CPUID instruction.

AMD no longer recommends the use of 3DNow! instructions, which have been superceded by their more efficient 128-bit media counterparts. For a complete list of recommended instruction substitutions, see Appendix A, "Recommended Substitutions for 3DNow!™ Instructions" on page 333.

PFRCP Floating-Point Reciprocal Approximation

Computes the approximate reciprocal of the single-precision floating-point value in the low-order 32 bits of an MMX register or 64-bit memory location and writes the result in both doublewords of another MMX register. The result is accurate to 14 bits.

The PFRCP result can be forwarded to the Newton-Raphson iteration step 1 (PFRCPIT1) and Newton-Raphson iteration step 2 (PFRCPIT2) instructions to increase the accuracy of the reciprocal. The first stage of this refinement in accuracy (PFRCPIT1) requires that the input and output of the previously executed PFRCP instruction be used as input to the PFRCPIT1 instruction.

The estimate contains the correct round-to-nearest value for approximately 99% of all arguments. The remaining arguments differ from the correct round-to-nearest value for the reciprocal by 1 unit-in-the-last-place (ulp). For details, see the data sheet or other software-optimization documentation relating to particular hardware implementations.

PFRCP(x) returns 0 for x >= 2^{-126}. The numeric range for operands is shown in Table 1-15 on page 116.

The PFRCP instruction is an AMD 3DNow!™ instruction. The presence of this instruction set is indicated by CPUID feature bits. See “CPUID” in Volume 3 for more information about the CPUID instruction.

AMD no longer recommends the use of 3DNow! instructions, which have been superceded by their more efficient 128-bit media counterparts. For a complete list of recommended instruction substitutions, see Appendix A, “Recommended Substitutions for 3DNow!™ Instructions” on page 333.

Recommended Instruction Substitution

RCPSS

Mnemonic	Opcode	Description
PFRCP *mmx1*, *mmx2/mem64*	0F 0F /r 96	Computes approximate reciprocal of single-precision floating-point value in an MMX register or 64-bit memory location and writes the result in both doublewords of the destination MMX register.

Table 1-15. Numeric Range for the PFRCP Result

Operand		Source 1 and Destination
Source 2	0	+/– Maximum Normal[1]
	Normal	Normal, +/– 0[2]
	Unsupported[3]	Undefined

Note:

1. *The result has the same sign as the source operand.*
2. *If the absolute value of the result is less than 2^{-126}, the result is zero with the sign being the sign of the source operand. Otherwise, the result is a normal with the sign being the same sign as the source operand.*
3. *"Unsupported" means that the exponent is all ones (1s).*

Examples

The general Newton-Raphson recurrence for the reciprocal 1/b is:

$$Z_{i+1} \leftarrow Z_i \cdot (2 - b \cdot Z_i)$$

The following code sequence shows the computation of a/b:

```
X0 = PFRCP(b)
X1 = PFRCPIT1(b, X0)
X2 = PFRCPIT2(X1, X0)
q = PFMUL(a, X2)
```

The 24-bit final reciprocal value is X_2. The quotient is formed in the last step by multiplying the reciprocal by the dividend a.

PFRCPIT1 Packed Floating-Point Reciprocal Iteration 1

Performs the first step in the Newton-Raphson iteration to refine the reciprocal approximation produced by the PFRCP instruction. The first source/destination operand is an MMX register containing the results of two previous PFRCP instructions, and the second source operand is another MMX register or 64-bit memory location containing the source operands from the same PFRCP instructions.

This instruction is only defined for those combinations of operands such that the first source operand (mmx1) is the approximate reciprocal of the second source operand (mmx2/mem64), and thus the range of the product, mmx1 * mmx2/mem64, is (0.5, 2). The initial approximation of an operand is accurate to about 12 bits, and the length of the operand itself is 24 bits, so the product of these two operands is greater than 24 bits. PFRCPIT1 applies the one's complement of the product and rounds the result to 32 bits. It then compresses the result to fit into 24 bits by removing the 8 redundant most-significant bits after the hidden integer bit.

The estimate contains the correct round-to-nearest value for approximately 99% of all arguments. The remaining arguments differ from the correct round-to-nearest value for the reciprocal by 1 unit-in-the-last-place (ulp). For details, see the data sheet or other software-optimization documentation relating to particular hardware implementations.

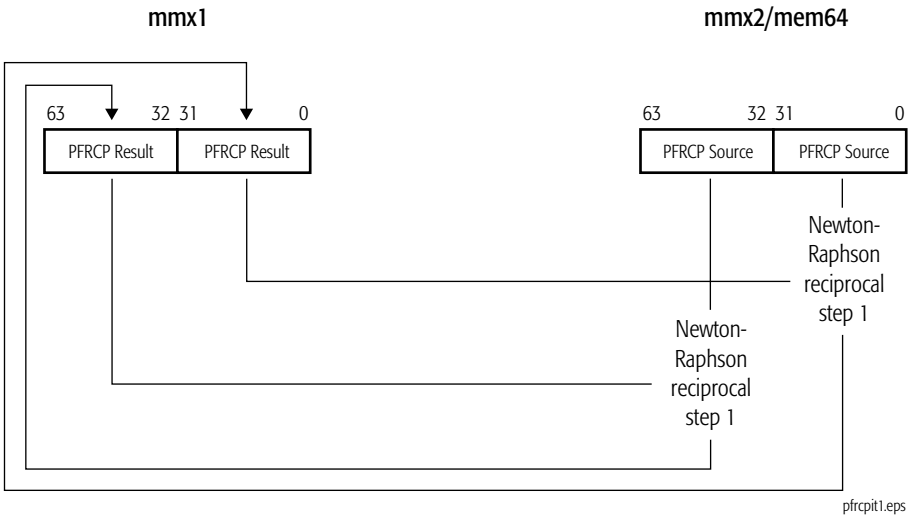
The PFRCPIT1 instruction is an AMD 3DNow!™ instruction. The presence of this instruction set is indicated by CPUID feature bits. See “CPUID” in Volume 3 for more information about the CPUID instruction.

AMD no longer recommends the use of 3DNow! instructions, which have been superceded by their more efficient 128-bit media counterparts. For a complete list of recommended instruction substitutions, see Appendix A, “Recommended Substitutions for 3DNow!™ Instructions” on page 333.

Recommended Instruction Substitution

PFRCP

Mnemonic	Opcode	Description
PFRCPIT1 *mmx1*, *mmx2/mem64*	0F 0F /r A6	Refine approximate reciprocal of result from previous PFRCP instruction.



Operation

```
mmx1[31:0] = Compress (2 - mmx1[31:0] * (mmx2/mem64[31:0]) - 2^31);
mmx1[63:32] = Compress (2 - mmx1[63:32] * (mmx2/mem64[63:32]) - 2^31);
```

where:

“Compress” means discard the 8 redundant most-significant bits after the hidden integer bit.

Examples

The general Newton-Raphson recurrence for the reciprocal 1/b is:

$Z_{i+1} \leftarrow Z_i \cdot (2 - b \cdot Z_i)$

The following code sequence computes a 24-bit approximation to a/b with one Newton-Raphson iteration:

```
X0 = PFRCP(b)
X1 = PFRCPIT1(b, X0)
X2 = PFRCPIT2(X1, X0)
q = PFMUL(a, X2)
```

a/b is formed in the last step by multiplying the reciprocal approximation by a.

PFRCPIT2 Packed Floating-Point Reciprocal or Reciprocal Square Root Iteration 2

Performs the second and final step in the Newton-Raphson iteration to refine the reciprocal approximation produced by the PFRCP instruction or the reciprocal square-root approximation produced by the PFSQRT instruction. PFRCPIT2 takes two paired elements in each source operand. These paired elements are the results of a PFRCP and PFRCPIT1 instruction sequence or of a PFRSQRT and PFRSQIT1 instruction sequence. The first source/destination operand is an MMX register that contains the PFRCPIT1 or PFRSQIT1 results and the second source operand is another MMX register or 64-bit memory location that contains the PFRCP or PFRSQRT results.

The PFRCPIT2 instruction expands the compressed PFRCPIT1 or PFRSQIT1 results from 24 to 32 bits and multiplies them by their respective source operands. An optimal correction factor is added to the product, which is then rounded to 24 bits.

The estimate contains the correct round-to-nearest value for approximately 99% of all arguments. The remaining arguments differ from the correct round-to-nearest value for the reciprocal by 1 unit-in-the-last-place (ulp). For details, see the data sheet or other software-optimization documentation relating to particular hardware implementations.

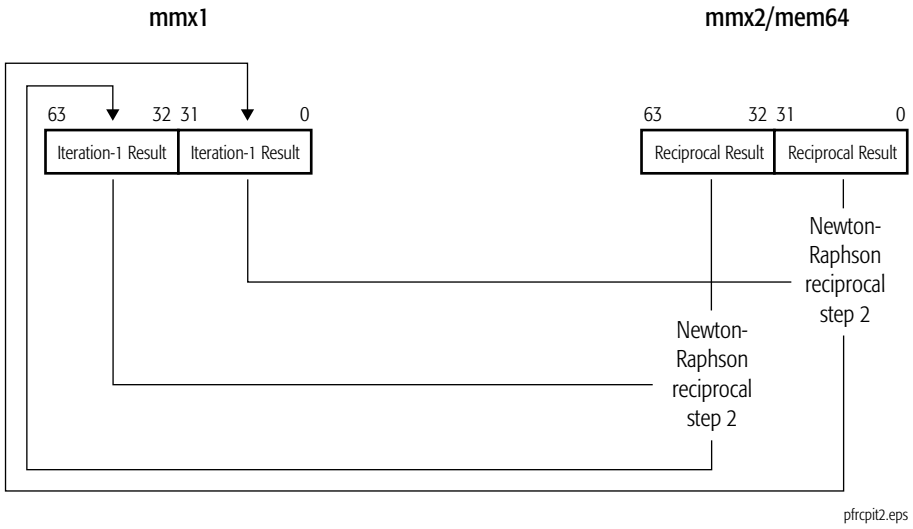
The PFRCPIT2 instruction is an AMD 3DNow!™ instruction. The presence of this instruction set is indicated by CPUID feature bits. See “CPUID” in Volume 3 for more information about the CPUID instruction.

AMD no longer recommends the use of 3DNow! instructions, which have been superceded by their more efficient 128-bit media counterparts. For a complete list of recommended instruction substitutions, see Appendix A, “Recommended Substitutions for 3DNow!™ Instructions” on page 333.

Recommended Instruction Substitution

PFRCP

Mnemonic	Opcode	Description
PFRCPIT2 *mmx1*, *mmx2/mem64*	0F 0F /r B6	Refines approximate reciprocal result from previous PFRCP and PFRCPIT1 instructions or from previous PFRSQRT and PFRSQIT1 instructions.



Operation

```
mmx1[31:0] = Expand(mmx1[31:0]) * mmx2/mem64[31:0];
mmx1[63:32] = Expand(mmx1[63:32]) * mmx2/mem64[63:32];
```

where:

“Expand” means convert a 24-bit significand to a 32-bit significand according to the following rule:

```
temp[31:0] = {1'b1, 8{mmx1[22]}, mmx1[22:0]};
```

Examples

The general Newton-Raphson recurrence for the reciprocal 1/b is:

$Z_{i+1} \leftarrow Z_i \cdot (2 - b \cdot Z_i)$

The following code sequence computes a 24-bit approximation to a/b with one Newton-Raphson iteration:

```
X0 = PFRCP(b)
X1 = PFRCPIT1(b, X0)
X2 = PFRCPIT2(X1, X0)
q = PFMUL(a, X2)
```

a/b is formed in the last step by multiplying the reciprocal approximation by a.

PFRSQIT1 Packed Floating-Point Reciprocal Square Root Iteration 1

Performs the first step in the Newton-Raphson iteration to refine the reciprocal square-root approximation produced by the PFSQRT instruction. The first source/destination operand is an MMX register containing the result from a previous PFRSQRT instruction, and the second source operand is another MMX register or 64-bit memory location containing the source operand from the same PFRSQRT instruction.

This instruction is only defined for those combinations of operands such that the first source operand (mmx1) is the approximate reciprocal of the second source operand (mmx2/mem64), and thus the range of the product, mmx1 * mmx2/mem64, is (0.5, 2). The length of both operands is 24 bits, so the product of these two operands is greater than 24 bits. The product is normalized and then rounded to 32 bits. The one's complement of the result is applied, a 1 is added as the most-significant bit, and the result re-normalized. The result is then compressed to fit into 24 bits by removing 8 redundant most-significant bits after the hidden integer bit, and the exponent is reduced by 1 to account for the division by 2.

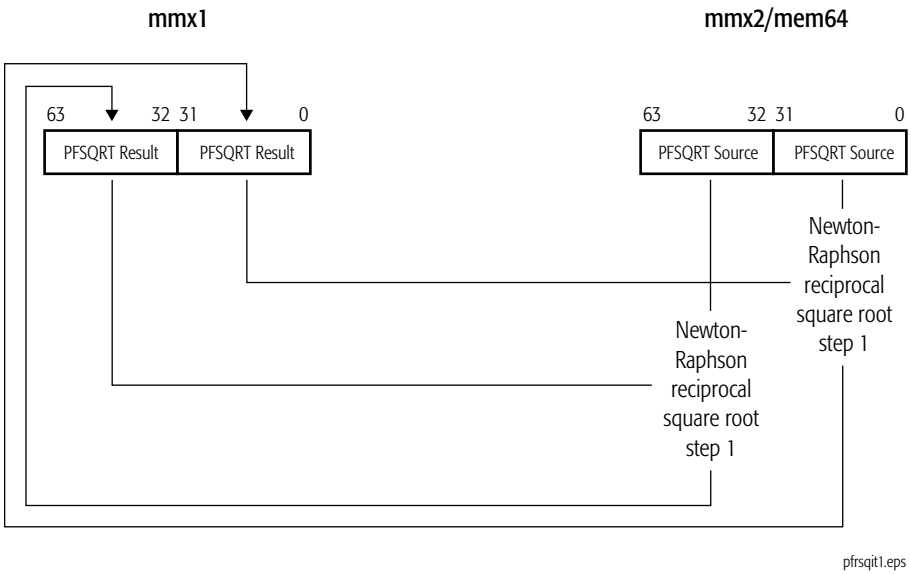
The PFRSQIT1 instruction is an AMD 3DNow!™ instruction. The presence of this instruction set is indicated by CPUID feature bits. See “CPUID” in Volume 3 for more information about the CPUID instruction.

AMD no longer recommends the use of 3DNow! instructions, which have been superceded by their more efficient 128-bit media counterparts. For a complete list of recommended instruction substitutions, see Appendix A, “Recommended Substitutions for 3DNow!™ Instructions” on page 333.

Recommended Instruction Substitution

PFRSQRT

Mnemonic	Opcode	Description
PFRSQIT1 *mmx1*, *mmx2/mem64*	0F 0F /r A7	Refines reciprocal square root approximation of previous PFRSQRT instruction.



Operation

```
mmx1[31:0] = Compress ((3 - mmx1[31:0] * (mmx2/mem64[31:0]) - 2^31)/2);
mmx1[63:32] = Compress ((3 - mmx1[63:32] * (mmx2/mem64[63:32]) - 2^31)/2);
```

where:

“Compress” means discard the 8 redundant most-significant bits after the hidden integer bit.

Examples

The following code sequence shows how the PFRSQRT and PFMUL instructions can be used to compute a = 1/sqrt (b):

```
X0 = PFRSQRT(b)
X1 = PFMUL(X0,X0)
X2 = PFRSQIT1(b,X1)
a = PFRCPIT2(X2,X0)
```

PFRSQRT Packed Floating-Point Reciprocal Square Root Approximation

Computes the approximate reciprocal square root of the single-precision floating-point value in the low-order 32 bits of an MMX register or 64-bit memory location and writes the result in each doubleword of another MMX register. The source operand is single-precision with a 24-bit significand, and the result is accurate to 15 bits. Negative operands are treated as positive operands for purposes of reciprocal square-root computation, with the sign of the result the same as the sign of the source operand.

This instruction can be used together with the PFRSQIT1 and PFRCPIT2 instructions to increase accuracy. The first stage of this refinement in accuracy (PFRSQIT1) requires that the input and output of the previously executed PFRSQRT instruction be used as input to the PFRSQIT1 instruction.

The estimate contains the correct round-to-nearest value for approximately 99% of all arguments. The remaining arguments differ from the correct round-to-nearest value for the reciprocal by 1 unit-in-the-last-place (ulp). For details, see the data sheet or other software-optimization documentation relating to particular hardware implementations.

The PFRSQRT instruction is an AMD 3DNow!™ instruction. The presence of this instruction set is indicated by CPUID feature bits. See “CPUID” in Volume 3 for more information about the CPUID instruction.

The numeric range for operands is shown in Table 1-16 on page 128.

AMD no longer recommends the use of 3DNow! instructions, which have been superceded by their more efficient 128-bit media counterparts. For a complete list of recommended instruction substitutions, see Appendix A, “Recommended Substitutions for 3DNow!™ Instructions” on page 333.

SUBPS

Mnemonic	Opcode	Description
PFSUB *mmx1*, *mmx2/mem64*	0F 0F /r 9A	Subtracts packed single-precision floating-point values in an MMX register or 64-bit memory location from packed single-precision floating-point values in another MMX register and writes the result in the destination MMX register.

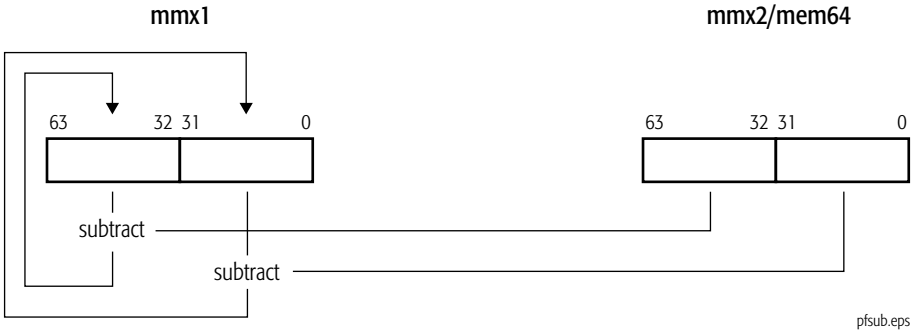

Table 1-17. Numeric Range for the PFSUB Results

Source Operand		Source 2		
		0	Normal	Unsupported
Source 1 and Destination	0	+/– 0[1]	- Source 2	- Source 2
	Normal	Source 1	Normal, +/– 0[2]	Undefined
	Unsupported[3]	Source 1	Undefined	Undefined

Note:

1. *The sign of the result is the logical AND of the sign of source 1 and the inverse of the sign of source 2.*
2. *If the absolute value of the infinitely precise result is less than 2^{-126} (but not zero), the result is a zero. If the source operand that is larger in magnitude is source 1, the sign of this zero is the same as the sign of source 1, else it is the inverse of the sign of source 2. If the infinitely precise result is exactly zero, the result is zero with the sign of source 1. If the absolute value of the infinitely precise result is greater than or equal to 2^{128}, the result is the largest normal number with the sign of source 1.*
3. *"Unsupported" means that the exponent is all ones (1s).*

PFSUBR Packed Floating-Point Subtract Reverse

Subtracts each packed single-precision floating-point value in the first source operand from the corresponding packed single-precision floating-point value in the second source operand and writes the result of each subtraction in the corresponding dword of the destination (first source). The first source/destination operand is an MMX register. The second source operand is another MMX register or 64-bit memory location. The numeric range for operands is shown in Table 1-18 on page 133.

The PFSUBR instruction is an AMD 3DNow!™ instruction. The presence of this instruction set is indicated by CPUID feature bits. See “CPUID” in Volume 3 for more information about the CPUID instruction.

AMD no longer recommends the use of 3DNow! instructions, which have been superceded by their more efficient 128-bit media counterparts. For a complete list of recommended instruction substitutions, see Appendix A, “Recommended Substitutions for 3DNow!™ Instructions” on page 333.

PI2FD Packed Integer to Floating-Point Doubleword Conversion

Converts two packed 32-bit signed integer values in an MMX register or a 64-bit memory location to two packed single-precision floating-point values and writes the converted values in another MMX register. If the result of the conversion is an inexact value, the value is truncated (rounded toward zero).

The PI2FD instruction is an AMD 3DNow!™ instruction. The presence of this instruction set is indicated by CPUID feature bits. See “CPUID” in Volume 3 for more information about the CPUID instruction.

AMD no longer recommends the use of 3DNow! instructions, which have been superceded by their more efficient 128-bit media counterparts. For a complete list of recommended instruction substitutions, see Appendix A, “Recommended Substitutions for 3DNow!™ Instructions” on page 333.

PINSRW Packed Insert Word

Inserts a 16-bit value from the low-order word of a 32-bit general purpose register or a 16-bit memory location into an MMX register. The location in the destination register is selected by the immediate byte operand, a shown in Table 1-19. The other words in the destination register operand are not modified.

The PINSRW instruction is an AMD extension to MMX™ instruction set and is an SSE1 instruction. The presence of this instruction set is indicated by CPUID feature bits. See “CPUID” in Volume 3 for more information about the CPUID instruction.

Mnemonic	Opcode	Description
PINSRW *mmx, reg32/mem16, imm8*	0F C4 */r ib*	Inserts a 16-bit value from a general-purpose register or memory location into an MMX register.

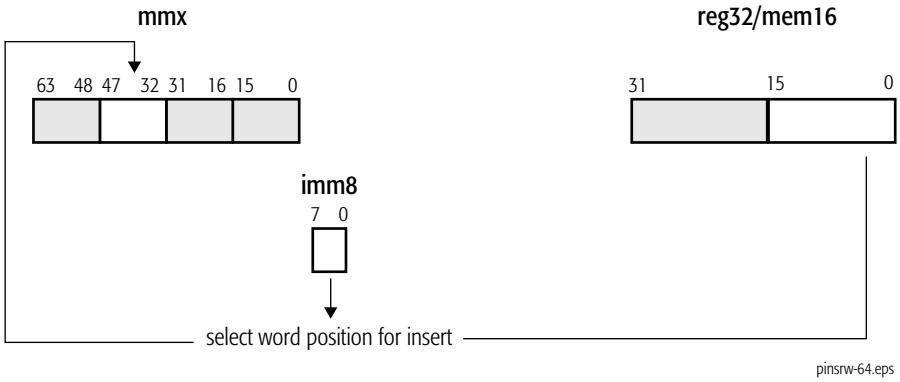

Table 1-19. Immediate-Byte Operand Encoding for 64-Bit PINSRW

PMADDWD Packed Multiply Words and Add Doublewords

Multiplies each packed 16-bit signed value in the first source operand by the corresponding packed 16-bit signed value in the second source operand, adds the adjacent intermediate 32-bit results of each multiplication (for example, the multiplication results for the adjacent bit fields 63–48 and 47–32, and 31–16 and 15–0), and writes the 32-bit result of each addition in the corresponding doubleword of the destination (first source). The first source/destination operand is an MMX register and the second source operand is another MMX register or 64-bit memory location.

If all four of the 16-bit source operands used to produce a 32-bit multiply-add result have the value 8000h, the 32-bit result is 8000_0000h, which is not the correct 32-bit signed result.

The PMADDWD instruction is an MMX™ instruction. The presence of this instruction set is indicated by CPUID feature bits. See “CPUID” in Volume 3 for more information about the CPUID instruction.

Mnemonic	Opcode	Description
PMADDWD *mmx1*, *mmx2/mem64*	0F F5 */r*	Multiplies four packed 16-bit signed values in an MMX register and another MMX register or 64-bit memory location, adds intermediate results, and writes the result in the destination MMX register.

PMAXSW Packed Maximum Signed Words

Compares each of the packed 16-bit signed integer values in the first source operand with the corresponding packed 16-bit signed integer value in the second source operand and writes the maximum of the two values for each comparison in the corresponding word of the destination (first source). The first source/destination and second source operands are an MMX register and an MMX register or 64-bit memory location.

The PMAXSW instruction is an AMD extension to MMX™ instruction set and is an SSE1 instruction. The presence of this instruction set is indicated by CPUID feature bits. See “CPUID” in Volume 3 for more information about the CPUID instruction.

Mnemonic	Opcode	Description
PMAXSW *mmx1*, *mmx2/mem64*	0F EE */r*	Compares packed signed 16-bit integer values in an MMX register and another MMX register or 64-bit memory location and writes the maximum value of each compare in destination MMX register.

PMULHRW Packed Multiply High Rounded Word

Multiplies each of the four packed 16-bit signed integer values in the first source operand by the corresponding packed 16-bit integer value in the second source operand, adds 8000h to the lower 16 bits of the intermediate 32-bit result of each multiplication, and writes the high-order 16 bits of each result in the corresponding word of the destination (first source). The addition of 8000h results in the rounding of the result, providing a numerically more accurate result than the PMULHW instruction, which truncates the result. The first source/destination operand is an MMX register. The second source operand is another MMX register or 64-bit memory location.

The PMULHRW instruction is an AMD 3DNow!™ instruction. The presence of this instruction set is indicated by CPUID feature bits. See “CPUID” in Volume 3 for more information about the CPUID instruction.

Mnemonic	Opcode	Description
PMULHRW *mmx1*, *mmx2*/*mem64*	0F 0F /r B7	Multiply 16-bit signed integer values in an MMX register and another MMX register or 64-bit memory location and write rounded result in the destination MMX register.

PMULLW Packed Multiply Low Signed Word

Multiplies each packed 16-bit signed integer value in the first source operand by the corresponding packed 16-bit signed integer in the second source operand and writes the low-order 16 bits of the intermediate 32-bit result of each multiplication in the corresponding word of the destination (first source). The first source/destination operand is an MMX register and the second source operand is another MMX register or 64-bit memory location.

The PMULLW instruction is an MMX™ instruction. The presence of this instruction set is indicated by CPUID feature bits. See “CPUID” in Volume 3 for more information about the CPUID instruction.

Mnemonic	Opcode	Description
PMULLW *mmx1*, *mmx2/mem64*	0F D5 */r*	Multiplies packed 16-bit signed integer values in an MMX register and another MMX register or 64-bit memory location and writes the low-order 16 bits of each result in the destination MMX register.

PMULUDQ Packed Multiply Unsigned Doubleword and Store Quadword

Multiplies two 32-bit unsigned integer values in the low-order doubleword of the first and second source operands and writes the 64-bit result in the destination (first source). The first source/destination operand is an MMX register and the second source operand is another MMX register or 64-bit memory location.

The PMULUDQ instruction is an SSE2 instruction. The presence of this instruction set is indicated by CPUID feature bits. See “CPUID” in Volume 3 for more information about the CPUID instruction.

Mnemonic	Opcode	Description
PMULUDQ *mmx1*, *mmx2/mem64*	0F F4 */r*	Multiplies low-order 32-bit unsigned integer value in an MMX register and another MMX register or 64-bit memory location and writes the 64-bit result in the destination MMX register.

PSADBW Packed Sum of Absolute Differences of Bytes Into a Word

Computes the absolute differences of eight corresponding packed 8-bit unsigned integers in the first and second source operands and writes the unsigned 16-bit integer result of the sum of the eight differences in a word in the destination (first source). The first source/destination operand is an MMX register and the second source operand is another MMX register or 64-bit memory location. The result is stored in the low-order word of the destination operand, and the remaining bytes in the destination are cleared to all 0s.

The PSADBW instruction is an AMD extension to MMX™ instruction set and is an SSE1 instruction. The presence of this instruction set is indicated by CPUID feature bits. See “CPUID” in Volume 3 for more information about the CPUID instruction.

Mnemonic	Opcode	Description
PSADBW *mmx1*, *mmx2/mem64*	0F F6 */r*	Compute the sum of the absolute differences of packed 8-bit unsigned integer values in an MMX register and another MMX register or 64-bit memory location and writes the 16-bit unsigned integer result in the destination MMX register.

PSHUFW Packed Shuffle Words

Moves any one of the four packed words in an MMX register or 64-bit memory location to a specified word location in another MMX register. In each case, the selection of the value of the destination word is determined by a two-bit field in the immediate-byte operand, with bits 0 and 1 selecting the contents of the low-order word, bits 2 and 3 selecting the second word, bits 4 and 5 selecting the third word, and bits 6 and 7 selecting the high-order word. Refer to Table 1-20 on page 167. A word in the source operand may be copied to more than one word in the destination.

The PSHUFW instruction is an AMD extension to MMX™ instruction set and is an SSE1 instruction. The presence of this instruction set is indicated by CPUID feature bits. See “CPUID” in Volume 3 for more information about the CPUID instruction.

Mnemonic	Opcode	Description
PSHUFW *mmx1*, *mmx2/mem64*, *imm8*	0F 70 */r ib*	Shuffles packed 16-bit values in an MMX register or 64-bit memory location and puts the result in another MMX register.

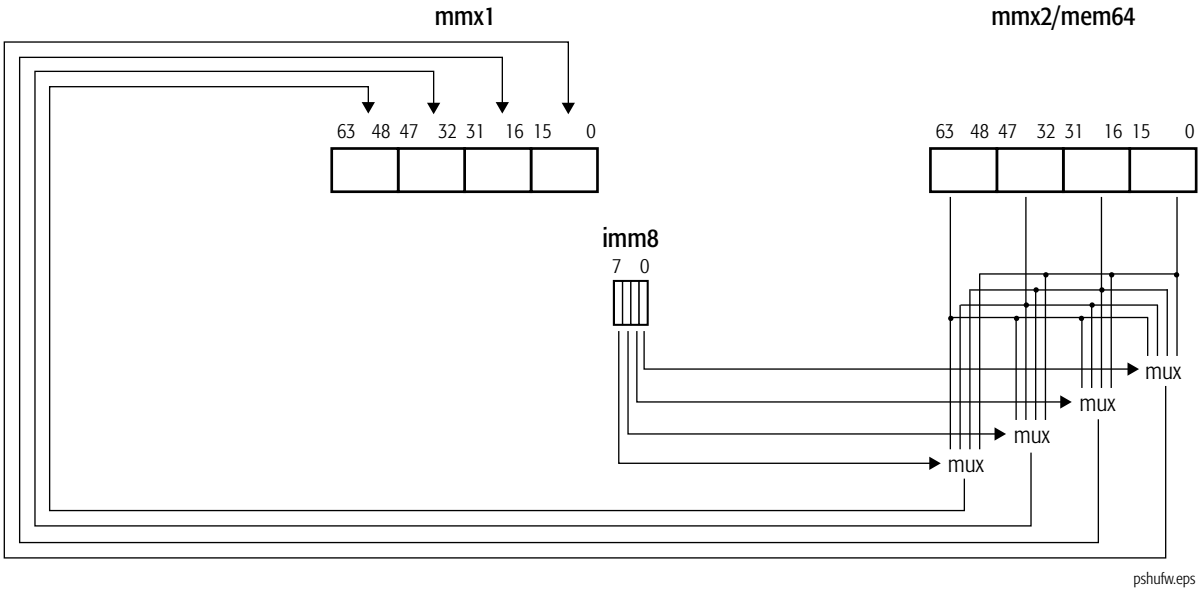

Table 1-20. Immediate-Byte Operand Encoding for PSHUFW

Destination Bits Filled	Immediate-Byte Bit Field	Value of Bit Field	Source Bits Moved
15–0	1–0	0	15–0

PSLLD Packed Shift Left Logical Doublewords

Left-shifts each of the packed 32-bit values in the first source operand by the number of bits specified in the second source operand and writes each shifted value in the corresponding doubleword of the destination (first source). The first source/destination and second source operands are:

- an MMX register and another MMX register or 64-bit memory location, or
- an MMX register and an immediate byte value.

The low-order bits that are emptied by the shift operation are cleared to 0. If the shift value is greater than 31, the destination is cleared to all 0s.

The PSLLD instruction is an MMX™ instruction. The presence of this instruction set is indicated by CPUID feature bits. See “CPUID” in Volume 3 for more information about the CPUID instruction.

Mnemonic	Opcode	Description
PSLLD *mmx1*, *mmx2/mem64*	0F F2 */r*	Left-shifts packed doublewords in an MMX register by the amount specified in an MMX register or 64-bit memory location.
PSLLD *mmx*, *imm8*	0F 72 /6 *ib*	Left-shifts packed doublewords in an MMX register by the amount specified in an immediate byte value.

PSUBB Packed Subtract Bytes

Subtracts each packed 8-bit integer value in the second source operand from the corresponding packed 8-bit integer in the first source operand and writes the integer result of each subtraction in the corresponding byte of the destination (first source). The first source/destination operand is an MMX register and the second source operand is another MMX register or 64-bit memory location.

This instruction operates on both signed and unsigned integers. If the result overflows, the carry is ignored (neither the overflow nor carry bit in rFLAGS is set), and only the low-order 8 bits of each result are written in the destination.

The PSUBB instruction is an MMX™ instruction. The presence of this instruction set is indicated by CPUID feature bits. See “CPUID” in Volume 3 for more information about the CPUID instruction.

Mnemonic	Opcode	Description
PSUBB *mmx1*, *mmx2/mem64*	0F F8 */r*	Subtracts packed byte integer values in an MMX register or 64-bit memory location from packed byte integer values in another MMX register and writes the result in the destination MMX register.

PSUBD Packed Subtract Doublewords

Subtracts each packed 32-bit integer value in the second source operand from the corresponding packed 32-bit integer in the first source operand and writes the integer result of each subtraction in the corresponding doubleword of the destination (first source). The first source/destination operand is an MMX register and the second source operand is another MMX register or 64-bit memory location.

This instruction operates on both signed and unsigned integers. If the result overflows, the carry is ignored (neither the overflow nor carry bit in rFLAGS is set), and only the low-order 32 bits of each result are written in the destination.

The PSUBD instruction is an MMX™ instruction. The presence of this instruction set is indicated by CPUID feature bits. See “CPUID” in Volume 3 for more information about the CPUID instruction.

Mnemonic	Opcode	Description
PSUBD *mmx1*, *mmx2/mem64*	0F FA */r*	Subtracts packed 32-bit integer values in an MMX register or 64-bit memory location from packed 32-bit integer values in another MMX register and writes the result in the destination MMX register.

PSUBQ Packed Subtract Quadword

Subtracts each packed 64-bit integer value in the second source operand from the corresponding packed 64-bit integer in the first source operand and writes the integer result of each subtraction in the corresponding quadword of the destination (first source). The first source/destination and source operands are an MMX register and another MMX register or 64-bit memory location.

The PSUBQ instruction is an SSE2 instruction; check the status of EDX bit 26 returned by CPUID function 0000_0001h. See “CPUID” in Volume 3 for more information about the CPUID instruction.

This instruction operates on both signed and unsigned integers. If the result overflows, the carry is ignored (neither the overflow nor carry bit in rFLAGS is set), and only the low-order 64 bits of each result are written in the destination.

Mnemonic	Opcode	Description
PSUBQ *mmx1*, *mmx2/mem64*	0F FB */r*	Subtracts packed 64-bit integer values in an MMX register or 64-bit memory location from packed 64-bit integer values in another MMX register and writes the result in the destination MMX register.

PSUBSB Packed Subtract Signed With Saturation Bytes

Subtracts each packed 8-bit signed integer value in the second source operand from the corresponding packed 8-bit signed integer in the first source operand and writes the signed integer result of each subtraction in the corresponding byte of the destination (first source). The first source/destination operand is an MMX register and the second source operand is another MMX register or 64-bit memory location.

For each packed value in the destination, if the value is larger than the largest signed 8-bit integer, it is saturated to 7Fh, and if the value is smaller than the smallest signed 8-bit integer, it is saturated to 80h.

The PSUBBSB instruction is an MMX™ instruction. The presence of this instruction set is indicated by CPUID feature bits. See “CPUID” in Volume 3 for more information about the CPUID instruction.

Mnemonic	Opcode	Description
PSUBSB *mmx1*, *mmx2/mem64*	0F E8 */r*	Subtracts packed byte signed integer values in an MMX register or 64-bit memory location from packed byte integer values in another MMX register and writes the result in the destination MMX register.

PSUBSW Packed Subtract Signed With Saturation Words

Subtracts each packed 16-bit signed integer value in the second source operand from the corresponding packed 16-bit signed integer in the first source operand and writes the signed integer result of each subtraction in the corresponding word of the destination (first source). The first source/destination and source operands are an MMX register and another MMX register or 64-bit memory location.

For each packed value in the destination, if the value is larger than the largest signed 16-bit integer, it is saturated to 7FFFh, and if the value is smaller than the smallest signed 16-bit integer, it is saturated to 8000h.

The PSUBSW instruction is an MMX™ instruction. The presence of this instruction set is indicated by CPUID feature bits. See “CPUID” in Volume 3 for more information about the CPUID instruction.

Mnemonic	Opcode	Description
PSUBSW *mmx1*, *mmx2/mem64*	0F E9 */r*	Subtracts packed 16-bit signed integer values in an MMX register or 64-bit memory location from packed 16-bit integer values in another MMX register and writes the result in the destination MMX register.

PSWAPD Packed Swap Doubleword

Swaps (reverses) the two packed 32-bit values in the source operand and writes each swapped value in the corresponding doubleword of the destination. The source operand is an MMX register or 64-bit memory location. The destination is another MMX register.

The PSWAPD instruction is an extension to the AMD 3DNow!™ instruction set. The presence of this instruction set is indicated by CPUID feature bits. See “CPUID” in Volume 3 for more information about the CPUID instruction.

Mnemonic	Opcode	Description
PSWAPD *mmx1*, *mmx2/mem64*	0F 0F /r BB	Swaps packed 32-bit values in an MMX register or 64-bit memory location and writes each value in the destination MMX register.

PUNPCKHBW Unpack and Interleave High Bytes

Unpacks the high-order bytes from the first and second source operands and packs them into interleaved-byte words in the destination (first source). The low-order bytes of the source operands are ignored. The first source/destination operand is an MMX register and the second source operand is another MMX register or 64-bit memory location.

If the second source operand is all 0s, the destination contains the bytes from the first source operand zero-extended to 16 bits. This operation is useful for expanding unsigned 8-bit values to unsigned 16-bit operands for subsequent processing that requires higher precision.

The PUNPCKHBW instruction is an MMX™ instruction. The presence of this instruction set is indicated by CPUID feature bits. See “CPUID” in Volume 3 for more information about the CPUID instruction.

Mnemonic	Opcode	Description
PUNPCKHBW *mmx1*, *mmx2/mem64*	0F 68 */r*	Unpacks the four high-order bytes in an MMX register and another MMX register or 64-bit memory location and packs them into interleaved bytes in the destination MMX register.

Device not available, #NM	X	X	X	The task-switch bit (TS) of CR0 was set to 1.
Stack, #SS	X	X	X	A memory address exceeded the stack segment limit or was non-canonical.
General protection, #GP	X	X	X	A memory address exceeded a data segment limit or was non-canonical.
			X	A null data segment was used to reference memory.
Page fault, #PF		X	X	A page fault resulted from the execution of the instruction.
x87 floating-point exception pending, #MF	X	X	X	An unmasked x87 floating-point exception was pending.
Alignment check, #AC		X	X	An unaligned memory reference was performed while alignment checking was enabled.

PUNPCKLDQ Unpack and Interleave Low Doublewords

Unpacks the low-order doublewords from the first and second source operands and packs them into interleaved-doubleword quadwords in the destination (first source). The high-order doublewords of the source operands are ignored. The first source/destination operand is an MMX register and the second source operand is another MMX register or 32-bit memory location.

If the second source operand is all 0s, the destination contains the doubleword(s) from the first source operand zero-extended to 64 bits. This operation is useful for expanding unsigned 32-bit values to unsigned 64-bit operands for subsequent processing that requires higher precision.

The PUNPCKLDQ instruction is an MMX™ instruction. The presence of this instruction set is indicated by CPUID feature bits. See “CPUID” in Volume 3 for more information about the CPUID instruction.

Mnemonic	Opcode	Description
PUNPCKLDQ *mmx1*, *mmx2/mem32*	0F 62 */r*	Unpacks the low-order doubleword in an MMX register and another MMX register or 32-bit memory location and packs them into interleaved doublewords in the destination MMX register.

Alignment check, #AC		X	X	An unaligned memory reference was performed while alignment checking was enabled.

PUNPCKLWD Unpack and Interleave Low Words

Unpacks the low-order words from the first and second source operands and packs them into interleaved-word doublewords in the destination (first source). The high-order words of the source operands are ignored. The first source/destination operand is an MMX register and the second source operand is another MMX register or 32-bit memory location.

If the second source operand is all 0s, the destination contains the words from the first source operand zero-extended to 32 bits. This operation is useful for expanding unsigned 16-bit values to unsigned 32-bit operands for subsequent processing that requires higher precision.

The PUNPCKLWD instruction is an MMX™ instruction. The presence of this instruction set is indicated by CPUID feature bits. See “CPUID” in Volume 3 for more information about the CPUID instruction.

Mnemonic	Opcode	Description
PUNPCKLWD *mmx1*, *mmx2/mem32*	0F 61 */r*	Unpacks the two low-order words in an MMX register and another MMX register or 32-bit memory location and packs them into interleaved words in the destination MMX register.

PXOR Packed Logical Bitwise Exclusive OR

Performs a bitwise exclusive OR of the values in the first and second source operands and writes the result in the destination (first source). The first source/destination operand is an MMX register and the second source operand is another MMX register or 64-bit memory location.

The PXOR instruction is an MMX™ instruction. The presence of this instruction set is indicated by CPUID feature bits. See “CPUID” in Volume 3 for more information about the CPUID instruction.

Mnemonic	Opcode	Description
PXOR *mmx1*, *mmx2*/*mem64*	0F EF */r*	Performs bitwise logical XOR of values in an MMX register and in another MMX register or 64-bit memory location and writes the result in the destination MMX register.

2 x87 Floating-Point Instruction Reference

This chapter describes the function, mnemonic syntax, opcodes, condition codes, affected flags, and possible exceptions generated by the x87 floating-point instructions. The x87 floating-point instructions are used in legacy floating-point applications. Most of these instructions load, store, or operate on data located in the x87 ST(0)–ST(7) stack registers (the FPR0–FPR7 physical registers). The remaining instructions within this category are used to manage the x87 floating-point environment.

The AMD64 architecture requires support of the x87 floating-point instruction subset including the floating-point conditional moves and the FCOMI(P) and FUCOMI(P) instructions. On compliant processor implementations both the FPU and the CMOV feature flags are set. These are indicated by EDX[FPU] (bit 0) and EDX[CMOV] (bit 15) respectively returned by CPUID Fn0000_0001 or CPUID Fn8000_0001.

This is augmented by instructions that are members of the MMX, 3DNow!™, SSE3, and FXSR subsets. Support for the following instructions is implementation-specific:

- EMMS, which is an MMX instruction. Support for this instruction is indicated by CPUID Fn0000_0001_EDX[MMX] = 1 or CPUID Fn8000_0001_EDX[MMX] = 1.
- FEMMS, which is a 3DNow!™ instruction. Support for this instruction is indicated by CPUID Fn8000_0001_EDX[3DNow] = 1.
- FISTTP, which is an SSE3 instruction. Support for this instruction is indicated by CPUID Fn0000_0001_ECX[SSE3] = 1.
- FXSAVE / FXRSTOR. Support for these instructions is indicated by CPUID Fn8000_0001_EDX[FXSR] = 1 or CPUID Fn0000_0001_EDX[FXSR] = 1

EMMS and FEMMS are described in Chapter 1, “64-Bit Media Instruction Reference”, on page 1.

The x87 instructions can be used in legacy mode or long mode. Their use in long mode is available if the following feature bit is set:

- Long Mode, as indicated by CPUID Fn8000_0001_EDX[LM] = 1.

Compilation of x87 media programs for execution in 64-bit mode offers two primary advantages: access to the 64-bit virtual address space and access to the RIP-relative addressing mode.

For further information about the x87 floating-point instructions and register resources, see:

- “x87 Floating-Point Programming” in Volume 1.
- “SSE, MMX, and x87 Programming” in Volume 2.
- “Summary of Registers and Data Types” in Volume 3.
- “Notation” in Volume 3.
- “Instruction Prefixes” in Volume 3.

For information on using the CPUID instruction, see the instruction description in Volume 3.

F2XM1 Floating-Point Compute 2^x-1

Raises 2 to the power specified by the value in ST(0), subtracts 1, and stores the result in ST(0). The source value must be in the range –1.0 to +1.0. The result is undefined for source values outside this range.

This instruction, when used in conjunction with the FYL2X instruction, can be applied to calculate $z = x^y$ by taking advantage of the log property $x^y = 2^{y*\log_2 x}$.

Mnemonic	Opcode	Description
F2XM1	D9 F0	Replace ST(0) with $(2^{ST(0)} - 1)$.

x87 Condition Code

x87 Condition Code	Value	Description
C0	U	
C1	0	No precision exception occurred.
	0	x87 stack underflow, if an x87 register stack fault was detected.
	0	Result was rounded down, if a precision exception was detected.
	1	Result was rounded up, if a precision exception was detected.
C2	U	
C3	U	

Note: *A flag set to 1 or cleared to 0 is M (modified). Unaffected flags are blank. Undefined flags are U.*

Exceptions

Exception	Real	Virtual 8086	Protected	Cause of Exception
Device not available, #NM	X	X	X	The emulate bit (EM) or the task switch bit (TS) of the control register (CR0) were set to 1.
x87 floating-point exception pending, #MF	X	X	X	An unmasked x87 floating-point exception was pending.
x87 Floating-Point Exception Generated, #MF				
Invalid-operation exception (IE)	X	X	X	A source operand was an SNaN value or an unsupported format.
Invalid-operation exception (IE) with stack fault (SF)	X	X	X	An x87 stack underflow occurred.
Denormalized-operand exception (DE)	X	X	X	A source operand was a denormal value.
Underflow exception (UE)	X	X	X	A rounded result was too small to fit into the format of the destination operand.
Precision exception (PE)	X	X	X	A result could not be represented exactly in the destination format.

FABS Floating-Point Absolute Value

Converts the value in ST(0) to its absolute value by clearing the sign bit. The resulting value depends upon the type of number used as the source value:

Source Value (ST(0))	Result (ST(0))
-∞	+∞
-FiniteReal	+FiniteReal
-0	+0
+0	+0
+FiniteReal	+FiniteReal
+∞	+∞
NaN	NaN

This operation applies even if the value in ST(0) is negative zero or negative infinity.

Mnemonic	Opcode	Description
FABS	D9 E1	Replace ST(0) with its absolute value.

Invalid-operation exception (IE) with stack fault (SF)	X	X	X	An x87 stack underflow occurred.

FADD
FADDP
FIADD

Floating-Point Add

Adds two values and stores the result in a floating-point register. If two operands are specified, the values are in ST(0) and another floating-point register and the instruction stores the result in the first register specified. If one operand is specified, the instruction adds the 32-bit or 64-bit value in the specified memory location to the value in ST(0).

The FADDP instruction adds the value in ST(0) to the value in another floating-point register and pops the register stack. If two operands are specified, the first operand is the other register. If no operand is specified, then the other register is ST(1).

The FIADD instruction reads a 16-bit or 32-bit signed integer value from the specified memory location, converts it to double-extended-real format, and adds it to the value in ST(0).

Mnemonic	Opcode	Description
FADD ST(0),ST(*i*)	D8 C0+*i*	Replace ST(0) with ST(0) + ST(*i*).
FADD ST(*i*),ST(0)	DC C0+*i*	Replace ST(*i*) with ST(0) + ST(*i*).
FADD *mem32real*	D8 /0	Replace ST(0) with ST(0) + *mem32real*.
FADD *mem64real*	DC /0	Replace ST(0) with ST(0) + *mem64real*.
FADDP	DE C1	Replace ST(1) with ST(0) + ST(1), and pop the x87 register stack.
FADDP ST(*i*),ST(0)	DE C0+*i*	Replace ST(*i*) with ST(0) + ST(*i*), and pop the x87 register stack.
FIADD *mem16int*	DE /0	Replace ST(0) with ST(0) + *mem16int*.
FIADD *mem32int*	DA /0	Replace ST(0) with ST(0) + *mem32int*.

Precision exception (PE)	X	X	X	A result could not be represented exactly in the destination format.

FBLD Floating-Point Load Binary-Coded Decimal

Converts a 10-byte packed BCD value in memory into double-extended-precision format, and pushes the result onto the x87 stack. In the process, it preserves the sign of the source value.

The packed BCD digits should be in the range 0 to 9. Attempting to load invalid digits (Ah through Fh) produces undefined results.

Mnemonic	Opcode	Description
FBLD *mem80dec*	DF /4	Convert a packed BCD value to floating-point and push the result onto the x87 register stack.

FBSTP Floating-Point Store Binary-Coded Decimal and Pop

Converts the value in ST(0) to an 18-digit packed BCD integer, stores the result in the specified memory location, and pops the register stack. It rounds a non-integral value to an integer value, depending on the rounding mode specified by the RC field of the x87 control word.

The operand specifies the memory address of the first byte of the resulting 10-byte value.

Mnemonic	Opcode	Description
FBSTP *mem80dec*	DF /6	Convert the floating-point value in ST(0) to BCD, store the result in mem80, and pop the x87 register stack.

FCLEX (FNCLEX) Floating-Point Clear Flags

Clears the following flags in the x87 status word:

- Floating-point exception flags (PE, UE, OE, ZE, DE, and IE)
- Stack fault flag (SF)
- Exception summary status flag (ES)
- Busy flag (B)

It leaves the four condition-code bits undefined. It does not check for possible floating-point exceptions before clearing the flags.

Assemblers usually provide an FCLEX macro that expands into the instruction sequence

```
WAIT                    ; Opcode 9B
FNCLEX destination      ; Opcode DB E2
```

The WAIT (9Bh) instruction checks for pending x87 exceptions and calls an exception handler, if necessary. The FNCLEX instruction then clears all the relevant x87 exception flags.

Mnemonic	Opcode	Description
FCLEX	9B DB E2	Perform a WAIT (9B) to check for pending floating-point exceptions, and then clear the floating-point exception flags.
FNCLEX	DB E2	Clear the floating-point flags without checking for pending unmasked floating-point exceptions.

FCMOV*cc* Floating-Point Conditional Move

Tests the flags in the rFLAGS register and, depending upon the values encountered, moves the value in another stack register to ST(0).

This set of instructions includes the mnemonics FCMOVB, FCMOVBE, FCMOVE, FCMOVNB, FCMOVNBE, FCMOVNE, FCMOVNU, and FCMOVU.

Support for the FCMOV*cc* instruction is indicated when both EDX[FPU] (bit 0) and EDX[CMOV] (bit 15) are set, as returned by either CPUID function 0000_0001h or function 8000_0001h.

Mnemonic	Opcode	Description
FCMOVB ST(0),ST(*i*)	DA C0+*i*	Move the contents of ST(*i*) into ST(0) if below (CF = 1).
FCMOVBE ST(0),ST(*i*)	DA D0+*i*	Move the contents of ST(*i*) into ST(0) if below or equal (CF = 1 or ZF = 1).
FCMOVE ST(0),ST(*i*)	DA C8+*i*	Move the contents of ST(*i*) into ST(0) if equal (ZF = 1).
FCMOVNB ST(0),ST(*i*)	DB C0+*i*	Move the contents of ST(*i*) into ST(0) if not below (CF = 0).
FCMOVNBE ST(0),ST(*i*)	DB D0+*i*	Move the contents of ST(*i*) into ST(0) if not below or equal (CF = 0 and ZF = 0).
FCMOVNE ST(0),ST(*i*)	DB C8+*i*	Move the contents of ST(*i*) into ST(0) if not equal (ZF = 0).
FCMOVNU ST(0),ST(*i*)	DB D8+*i*	Move the contents of ST(*i*) into ST(0) if not unordered (PF = 0).
FCMOVU ST(0),ST(*i*)	DA D8+*i*	Move the contents of ST(*i*) into ST(0) if unordered (PF = 1).

FCOM
FCOMP
FCOMPP
Floating-Point Compare

Compares the specified value to the value in ST(0) and sets the C0, C2, and C3 condition code flags in the x87 status word as shown in the x87 Condition Code table below. The specified value can be in a floating-point register or a memory location.

The no-operand version compares the value in ST(1) with the value in ST(0).

The comparison operation ignores the sign of zero (–0.0 = +0.0).

After performing the comparison operation, the FCOMP instruction pops the x87 register stack and the FCOMPP instruction pops the x87 register stack twice.

If either or both of the compared values is a NaN or is in an unsupported format, the FCOMx instruction sets the invalid-operation exception (IE) bit in the x87 status word to 1, and sets the condition flags to 'unordered.'

The FUCOMx instructions perform the same operations as the FCOMx instructions, but do not set the IE bit for QNaNs.

Mnemonic	Opcode	Description
FCOM	D8 D1	Compare the contents of ST(0) to the contents of ST(1) and set condition flags to reflect the results of the comparison.
FCOM ST(*i*)	D8 D0+*i*	Compare the contents of ST(0) to the contents of ST(*i*) and set condition flags to reflect the results of the comparison.
FCOM *mem32real*	D8 /2	Compare the contents of ST(0) to the contents of *mem32real* and set condition flags to reflect the results of the comparison.
FCOM *mem64real*	DC /2	Compare the contents of ST(0) to the contents of *mem64real* and set condition flags to reflect the results of the comparison.

Denormalized-operand exception (DE)	X	X	X	A source operand was a denormal value.

FCOMI FCOMIP Floating-Point Compare and Set Flags

Compares the value in ST(0) with the value in another floating-point register and sets the zero flag (ZF), parity flag (PF), and carry flag (CF) in the rFLAGS register based on the result as shown in the table in the x87 Condition Code section.

The comparison operation ignores the sign of zero (–0.0 = +0.0).

After performing the comparison operation, FCOMIP pops the x87 register stack.

If either or both of the compared values is a NaN or is in an unsupported format, the FCOMIx instruction sets the invalid-operation exception (IE) bit in the x87 status word to 1 and sets the flags to "unordered."

The FUCOMIx instructions perform the same operations as the FCOMIx instructions, but do not set the IE bit for QNaNs.

Support for the FCOMI*x* instruction can be determined by executing either CPUID Fn0000_0001 or CPUID Fn8000_0001. Support is indicated when both EDX[FPU] (bit 0) and EDX[CMOV] (bit 15) are set.

Mnemonic	Opcode	Description
FCOMI ST(0),ST(*i*)	DB F0+*i*	Compare the contents of ST(0) with the contents of ST(*i*) and set status flags to reflect the results of the comparison.
FCOMIP ST(0),ST(*i*)	DF F0+*i*	Compare the contents of ST(0) with the contents of ST(*i*), set status flags to reflect the results of the comparison, and pop the x87 register stack.

FDIV
FDIVP
FIDIV

Floating-Point Divide

Divides the value in a floating-point register by the value in another register or a memory location and stores the result in the register containing the dividend. For the FDIV and FDIVP instructions, the divisor value in memory can be stored in single-precision or double-precision floating-point format.

If only one operand is specified, the instruction divides the value in ST(0) by the value in the specified memory location.

If no operands are specified, the FDIVP instruction divides the value in ST(1) by the value in ST(0), stores the result in ST(1), and pops the x87 register stack.

The FIDIV instruction converts a divisor in word integer or short integer format to double-extended-precision floating-point format before performing the division. It treats an integer 0 as +0.

If the zero-divide exception is not masked (ZM bit cleared to 0 in the x87 control word) and the operation causes a zero-divide exception (sets the ZE bit in the x87 status word to 1), the operation stores no result. If the zero-divide exception is masked (ZM bit set to 1), a zero-divide exception causes ±∞ to be stored.

The sign of the operands, even if one of the operands is 0, determines the sign of the result.

Mnemonic	Opcode	Description
FDIV ST(0),ST(*i*)	D8 F0+*i*	Replace ST(0) with ST(0)/ST(*i*).
FDIV ST(*i*),ST(0)	DC F8+*i*	Replace ST(*i*) with ST(*i*)/ST(0).

FDIVR
FDIVRP
FIDIVR
Floating-Point Divide Reverse

Divides a value in a floating-point register or a memory location by the value in a floating-point register and stores the result in the register containing the divisor. For the FDIVR and FDIVRP instructions, a dividend value in memory can be stored in single-precision or double-precision floating-point format.

If one operand is specified, the instruction divides the value at the specified memory location by the value in ST(0). If two operands are specified, it divides the value in ST(0) by the value in another x87 stack register or vice versa.

The FIDIVR instruction converts a dividend in word integer or short integer format to double-extended-precision format before performing the division.

The FDIVRP instruction pops the x87 register stack after performing the division operation. If no operand is specified, the FDIVRP instruction divides the value in ST(0) by the value in ST(1).

If the zero-divide exception is not masked (ZM bit cleared to 0 in the x87 control word) and the operation causes a zero-divide exception (sets the ZE bit in the x87 status word to 1), the operation stores no result. If the zero-divide exception is masked (ZM bit set to 1), a zero-divide exception causes ±∞ to be stored.

The sign of the operands, even if one of the operands is 0, determines the sign of the result.

Mnemonic	Opcode	Description
FDIVR ST(0),ST(*i*)	D8 F8+*i*	Replace ST(0) with ST(*i*)/ST(0).
FDIVR ST(*i*), ST(0)	DC F0+*i*	Replace ST(*i*) with ST(0)/ST(*i*).

FICOM FICOMP Floating-Point Integer Compare

Converts a 16-bit or 32-bit signed integer value to double-extended-precision format, compares it to the value in ST(0), and sets the C0, C2, and C3 condition code flags in the x87 status word to reflect the results.

The comparison operation ignores the sign of zero (–0.0 = +0.0).

After performing the comparison operation, the FICOMP instruction pops the x87 register stack.

If ST(0) is a NaN or is in an unsupported format, the instruction sets the condition flags to "unordered."

Mnemonic	Opcode	Description
FICOM *mem16int*	DE /2	Convert the contents of *mem16int* to double-extended-precision format, compare the result to the contents of ST(0), and set condition flags to reflect the results of the comparison.
FICOM *mem32int*	DA /2	Convert the contents of *mem32int* to double-extended-precision format, compare the result to the contents of ST(0), and set condition flags to reflect the results of the comparison.
FICOMP *mem16int*	DE /3	Convert the contents of *mem16int* to double-extended-precision format, compare the result to the contents of ST(0), set condition flags to reflect the results of the comparison, and pop the x87 register stack.
FICOMP *mem32int*	DA /3	Convert the contents of *mem32int* to double-extended-precision format, compare the result to the contents of ST(0), set condition flags to reflect the results of the comparison, and pop the x87 register stack.

FINIT
FNINIT
Floating-Point Initialize

Sets the x87 control word register, status word register, tag word register, instruction pointer, and data pointer to their default states as follows:

- Sets the x87 control word to 037Fh—round to nearest (RC = 00b); double-extended-precision (PC = 11b); all exceptions masked (PM, UM, OM, ZM, DM, and IM all set to 1).
- Clears all bits in the x87 status word (TOP is set to 0, which maps ST(0) onto FPR0).
- Marks all x87 stack registers as empty (11b) in the x87 tag register.
- Clears the instruction pointer and the data pointer.

These instructions do not actually zero out the x87 stack registers.

Assemblers usually provide an FINIT macro that expands into the instruction sequence

```
WAIT                    ; Opcode 9B
FNINIT destination      ; Opcode DB E3
```

The WAIT (9Bh) instruction checks for pending x87 exceptions and calls an exception handler, if necessary. The FNINIT instruction then resets the x87 environment to its default state.

Mnemonic	Opcode	Description
FINIT	9B DB E3	Perform a WAIT (9B) to check for pending floating-point exceptions and then initialize the x87 unit.
FNINIT	DB E3	Initialize the x87 unit without checking for unmasked floating-point exceptions.

FIST
FISTP
Floating-Point Integer Store

Converts the value in ST(0) to a signed integer, rounds it if necessary, and copies it to the specified memory location. The rounding control (RC) field of the x87 control word determines the type of rounding used.

The FIST instruction supports 16-bit and 32-bit values. The FISTP instructions supports 16-bit, 32-bit, and 64-bit values.

The FISTP instruction pops the stack after storing the rounded value in memory.

If the value is too large for the destination location, is a NaN, or is in an unsupported format, the instruction sets the invalid-operation exception (IE) bit in the x87 status word to 1. Then, if the exception is masked (IM bit set to 1 in the x87 control word), the instruction stores the integer indefinite value. If the exception is unmasked (IM bit cleared to 0), the instruction does not store the value.

Mnemonic	Opcode	Description
FIST *mem16int*	DF /2	Convert the contents of ST(0) to integer and store the result in *mem16int*.
FIST *mem32int*	DB /2	Convert the contents of ST(0) to integer and store the result in *mem32int*.
FISTP *mem16int*	DF /3	Convert the contents of ST(0) to integer, store the result in *mem16int*, and pop the x87 register stack.
FISTP *mem32int*	DB /3	Convert the contents of ST(0) to integer, store the result in *mem32int*, and pop the x87 register stack.
FISTP *mem64int*	DF /7	Convert the contents of ST(0) to integer, store the result in *mem64int*, and pop the x87 register stack.

Table 2-1 shows the results of storing various types of numbers as integers.

Table 2-1. Storing Numbers as Integers

ST(0)	DEST
-∞	Invalid-operation (IE) exception
–Finite-real < –1	–Integer (Invalid-operation (IE) exception if the integer is too large for the destination)
–1 < –Finite-real< –0	0 or –1, depending on the rounding mode
-0	0
+0	0
+0 < +Finite-real < +1	0 or +1, depending on the rounding mode

Table 2-1. Storing Numbers as Integers (continued)

ST(0)	DEST
+Finite-real > +1	+Integer (Invalid-operation (IE) exception if the integer is too large for the destination)
+∞	Invalid-operation (IE) exception
NaN	Invalid-operation (IE) exception

x87 Floating-Point Exception Generated, #MF				
Invalid-operation exception (IE)	X	X	X	The source operand was too large for the destination format.
	X	X	X	A source operand was an SNaN value, a QNaN value, +-infinity, or an unsupported format.
Invalid-operation exception (IE) with stack fault (SF)	X	X	X	An x87 stack underflow occurred.
Precision exception (PE)	X	X	X	A result could not be represented exactly in the destination format.

FISTTP Floating Point Integer Truncate and Store

Converts a floating-point value in ST(0) to an integer by truncating the fractional part of the number and storing the integer result to the memory address specified by the destination operand. FISTTP then pops the floating point register stack. The FISTTP instruction ignores the rounding mode specified by the x87 control word.

The FISTTP instruction applies to 16-bit, 32-bit, and 64-bit operands.

The FISTTP instruction is an SSE3 instruction. Support for this instruction subset is indicated by CPUID Fn0000_0001_ECX[SSE3] = 1. See “CPUID” in Volume 3 for more information about the CPUID instruction.

Mnemonic	Opcode	Description
FISTTP *mem16int*	DF /1	Store the truncated floating-point value in ST(0) in memory location *mem16int* and pop the floating-point register stack.
FISTTP *mem32int*	DB /1	Store the truncated floating-point value in ST(0) in memory location *mem32int* and pop the floating-point register stack.
FISTTP *mem64int*	DD /1	Store the truncated floating-point value in ST(0) in memory location *mem64int* and pop the floating-point register stack.

Table 2-2 shows the results of storing various types of numbers as integers.

Table 2-2. Storing Numbers as Integers

ST(0)	DESTINATION

Precision exception (PE)	X	X	X	A result could not be represented exactly in the destination format.

FLD Floating-Point Load

Pushes a value in memory or in a floating-point register onto the register stack. If in memory, the value can be a single-precision, double-precision, or double-extended-precision floating-point value. The operation converts a single-precision or double-precision value to double-extended-precision format before pushing it onto the stack.

Mnemonic	Opcode	Description
FLD ST(*i*)	D9 C0+*i*	Push the contents of ST(*i*) onto the x87 register stack.
FLD *mem32real*	D9 /0	Push the contents of *mem32real* onto the x87 register stack.
FLD *mem64real*	DD /0	Push the contents of *mem64real* onto the x87 register stack.
FLD *mem80real*	DB /5	Push the contents of *mem80real* onto the x87 register stack.

FLDENV Floating-Point Load x87 Environment

Restores the x87 environment from memory starting at the specified address. The x87 environment consists of the x87 control, status, and tag word registers, the last non-control x87 instruction pointer, the last x87 data pointer, and the opcode of the last completed non-control x87 instruction.

The FLDENV instruction takes a memory operand that specifies the starting address of either a 14-byte or 28-byte area in memory. The 14-byte operand is required for a 16-bit operand-size; the 28-byte memory area is required for both 32-bit and 64-bit operand sizes. The layout of the saved x87 environment within the specified memory area depends on whether the processor is operating in protected or real mode. See “Media and x87 Processor State” in Volume 2 for details on how this instruction loads the x87 environment from memory. (Because FSTENV does not save the full 64-bit data and instruction pointers, 64-bit applications should use FXSAVE/FXRSTOR, rather than FSTENV/FLDENV.)

The environment to be loaded is typically stored by a previous FNSTENV or FSTENV instruction. The FLDENV instruction should be executed in the same operating mode as the instruction that stored the x87 environment.

If FLDENV results in set exception flags in the loaded x87 status word register, and these exceptions are unmasked in the x87 control word register, a floating-point exception occurs when the next floating-point instruction is executed (except for the no-wait floating-point instructions).

To avoid generating exceptions when loading a new environment, use the FCLEX or FNCLEX instruction to clear the exception flags in the x87 status word before storing that environment.

Mnemonic	Opcode	Description
FLDENV *mem14/28env*	D9 /4	Load the complete contents of the x87 environment from *mem14/28env*.

FMUL
FMULP
FIMUL

Floating-Point Multiply

Multiplies the value in a floating-point register by the value in a memory location or another stack register and stores the result in the first register. The instruction converts a single-precision or double-precision value in memory to double-extended-precision format before multiplying.

If one operand is specified, the instruction multiplies the value in the ST(0) register by the value in the specified memory location and stores the result in the ST(0) register.

If two operands are specified, the instruction multiplies the value in the ST(0) register by the value in another specified floating-point register and stores the result in the register specified in the first operand.

The FMULP instruction pops the x87 stack after storing the product. The no-operand version of the FMULP instruction multiplies the value in the ST(1) register by the value in the ST(0) register and stores the product in the ST(1) register.

The FIMUL instruction converts a short-integer or word-integer value in memory to double-extended-precision format, multiplies it by the value in ST(0), and stores the product in ST(0).

Mnemonic	Opcode	Description
FMUL ST(0),ST(*i*)	D8 C8+*i*	Replace ST(0) with ST(0) ∗ ST(*i*).
FMUL ST(*i*),ST(0)	DC C8+*i*	Replace ST(*i*) with ST(0) ∗ ST(*i*).
FMUL *mem32real*	D8 /1	Replace ST(0) with *mem32real* ∗ ST(0).
FMUL *mem64real*	DC /1	Replace ST(0) with *mem64real* ∗ ST(0).
FMULP	DE C9	Replace ST(1) with ST(0) ∗ ST(1), and pop the x87 register stack.
FMULP ST(*i*),ST(0)	DE C8+*i*	Replace ST(*i*) with ST(0) ∗ ST(*i*), and pop the x87 register stack.
FIMUL *mem16int*	DE /1	Replace ST(0) with *mem16int* ∗ ST(0).
FIMUL *mem32int*	DA /1	Replace ST(0) with *mem32int* ∗ ST(0).

Device not available, #NM	X	X	X	The emulate bit (EM) or the task switch bit (TS) of the control register (CR0) was set to 1.
x87 floating-point exception pending, #MF	X	X	X	An unmasked x87 floating-point exception was pending.

FPATAN Floating-Point Partial Arctangent

Computes the arctangent of the ordinate (Y) in ST(1) divided by the abscissa (X) in ST(0), which is the angle in radians between the X axis and the radius vector from the origin to the point (X, Y). It then stores the result in ST(1) and pops the x87 register stack. The resulting value has the same sign as the ordinate value and a magnitude less than or equal to π.

There is no restriction on the range of values that FPATAN can accept. Table 2-3 shows the results obtained when computing the arctangent of various classes of numbers, assuming that underflow does not occur:

Table 2-3. Computing Arctangent of Numbers

		X (ST(0))						
		–∞	**–Finite**	**–0**	**+0**	**+Finite**	**+∞**	**NaN**
Y (ST(1))	**–∞**	–3π/4	–π/2	–π/2	–π/2	–π/2	–π/4	NaN
	–Finite	–π	–π to –π/2	–π/2	–π/2	–π/2 to –0	—0	NaN
	–0	–π	–π	–π	–0	–0	—0	NaN
	+0	+π	+π	+π	+0	+0	+0	NaN
	+Finite	+π	+π to +π/2	+π/2	+π/2	+π/2 to +0	+0	NaN
	+∞	+3π/4	+π/2	+π/2	+π/2	+π/2	+π/4	NaN
	NaN	NaN	NaN	NaN	NaN	NaN	NaN	NaN

Mnemonic	Opcode	Description
FPATAN	D9 F3	Compute arctan(ST(1)/ST(0)), store the result in ST(1), and pop the x87 register stack.

Underflow exception (UE)	X	X	X	A rounded result was too small to fit into the format of the destination operand.
Precision exception (PE)	X	X	X	A result could not be represented exactly in the destination format.

FPREM Floating-Point Partial Remainder

Computes the exact remainder obtained by dividing the value in ST(0) by that in ST(1), and stores the result in ST(0). It computes the remainder by an iterative subtract-and-shift long division algorithm in which one quotient bit is calculated in each iteration.

If the exponent difference between ST(0) and ST(1) is less than 64, the instruction computes all integer bits of the quotient, guaranteeing that the remainder is less in magnitude than the divisor in ST(1). If the exponent difference is equal to or greater than 64, it computes only the subset of integer quotient bits numbering between 32 and 63, returns a partial remainder, and sets the C2 condition code bit to 1.

FPREM is supported for software that was written for early x87 coprocessors. Unlike the FPREM1 instruction, FPREM does not compute the partial remainder as specified in IEEE Standard 754.

Mnemonic	Opcode	Description
FPREM	D9 F8	Compute the remainder of the division of ST(0) by ST(1) and store the result in ST(0).

Action

```
ExpDiff = Exponent(ST(0)) - Exponent(ST(1))
IF (ExpDiff < 0)
{
   SW.C2 = 0
   {SW.C0, SW.C3, SW.C1} = 0
}
ELSIF (ExpDiff < 64)
{
   Quotient = Truncate(ST(0)/ST(1))
   ST(0) = ST(0) - (ST(1) * Quotient)
   SW.C2 = 0
   {SW.C0, SW.C3, SW.C1} = Quotient mod 8
}
ELSE
{
   N = 32 + (ExpDiff mod 32)
   Quotient = Truncate ((ST(0)/ST(1))/2^(ExpDiff-N))
   ST(0) = ST(0) - (ST(1) * Quotient * 2^(ExpDiff-N))
   SW.C2 = 1
   {SW.C0, SW.C3, SW.C1} = 0
}
```

x87 Condition Code

x87 Condition Code	Value	Description
C0	M	Set equal to the value of bit 2 of the quotient.
C1	0	x87 stack underflow, if an x87 register stack fault was detected.
	M	Set equal to the value of bit 0 of the quotient, if there was no fault.
C2	0	FPREM generated the partial remainder.
	1	The source operands differed by more than a factor of 2^{64}, so the result is incomplete.
C3	M	Set equal to the value of bit 1 of the quotient.

Note: *A flag set to 1 or cleared to 0 is M (modified). Unaffected flags are blank. Undefined flags are U.*

Exceptions

Exception	Real	Virtual 8086	Protected	Cause of Exception
Device not available, #NM	X	X	X	The emulate bit (EM) or the task switch bit (TS) of the control register (CR0) is set to 1.
x87 floating-point exception pending, #MF	X	X	X	An unmasked x87 floating-point exception was pending.
x87 Floating-Point Exception Generated, #MF				
Invalid-operation exception (IE)	X	X	X	A source operand was an SNaN value or an unsupported format.
	X	X	X	ST(0) was ±infinity.
	X	X	X	ST(1) was ±zero.
Invalid-operation exception (IE) with stack fault (SF)	X	X	X	An x87 stack underflow occurred.
Denormalized-operand exception (DE)	X	X	X	A source operand was a denormal value.
Underflow exception (UE)	X	X	X	A rounded result was too small to fit into the format of the destination operand.

FPREM1 Floating-Point Partial Remainder

Computes the IEEE Standard 754 remainder obtained by dividing the value in ST(0) by that in ST(1), and stores the result in ST(0). Unlike FPREM, it rounds the integer quotient to the nearest even integer and returns the remainder corresponding to the back multiply of the rounded quotient.

If the exponent difference between ST(0) and ST(1) is less than 64, the instruction computes all integer as well as additional fractional bits of the quotient to do the rounding. The remainder returned is a complete remainder and is less than or equal to one half of the magnitude of the divisor. If the exponent difference is equal to or greater than 64, it computes only the subset of integer quotient bits numbering between 32 and 63, returns the partial remainder, and sets the C2 condition code bit to 1.

Rounding control has no effect. FPREM1 results are exact.

Mnemonic	Opcode	Description
FPREM1	D9 F5	Compute the IEEE standard 754 remainder of the division of ST(0) by ST(1) and store the result in ST(0).

Action

```
ExpDiff = Exponent(ST(0)) - Exponent(ST(1))
IF (ExpDiff < 0)
{
   SW.C2 = 0
   {SW.C0, SW.C3, SW.C1} = 0
}
ELSIF (ExpDiff < 64)
{
   Quotient = Integer obtained by rounding (ST(0)/ST(1))
          to nearest even integer
   ST(0) = ST(0) - (ST(1) * Quotient)
   SW.C2 = 0
   {SW.C0, SW.C3, SW.C1} = Quotient mod 8
}
ELSE
{
   N = 32 + (ExpDiff mod 32)
   Quotient = Truncate ((ST(0)/ST(1))/2^(ExpDiff-N))
   ST(0) = ST(0) - (ST(1) * Quotient * 2^(ExpDiff-N))
   SW.C2 = 1
   {SW.C0, SW.C3, SW.C1} = 0
}
```

Underflow exception (UE)	X	X	X	A rounded result was too small to fit into the format of the destination operand.

FPTAN Floating-Point Partial Tangent

Computes the tangent of the radian value in ST(0), stores the result in ST(0), and pushes a value of 1.0 onto the x87 register stack.

The source value must be between -2^{63} and $+2^{63}$ radians. If the source value lies outside the specified range, the instruction sets the C2 bit of the x87 status word to 1 and does not change the value in ST(0).

Mnemonic	Opcode	Description
FPTAN	D9 F2	Replace ST(0) with the tangent of ST(0), then push 1.0 onto the x87 register stack.

Precision exception (PE)	X	X	X	A result could not be represented exactly in the destination format.

FRNDINT Floating-Point Round to Integer

Rounds the value in ST(0) to an integer, depending on the setting of the rounding control (RC) field of the x87 control word, and stores the result in ST(0).

If the initial value in ST(0) is ∞, the instruction does not change ST(0). If the value in ST(0) is not an integer, it sets the precision exception (PE) bit of the x87 status word to 1.

Mnemonic	Opcode	Description
FRNDINT	D9 FC	Round the contents of ST(0) to an integer.

FRSTOR Floating-Point Restore x87 and MMX™ State

Restores the complete x87 state from memory starting at the specified address, as stored by a previous call to F(N)SAVE.

The FRSTOR instruction takes a memory operand that specifies the starting address of either a 94-byte or 108-byte area in memory. The 94-byte operand is required for a 16-bit operand-size; the 108-byte memory area is required for both 32-bit and 64-bit operand sizes. The layout of the saved x87 state within the specified memory area depends on whether the processor is operating in protected or real mode. See “Media and x87 Processor State” in Volume 2 for details on how this instruction stores the x87 environment in memory. (Because FSAVE does not save the full 64-bit data and instruction pointers, 64-bit applications should use FXSAVE/FXRSTOR, rather than FSAVE/FRSTOR.)

Because the MMX registers are mapped onto the low 64 bits of the x87 floating-point registers, this operation also restores the MMX state.

If FRSTOR results in set exception flags in the loaded x87 status word register, and these exceptions are unmasked in the x87 control word register, a floating-point exception occurs when the next floating-point instruction is executed (except for the no-wait floating-point instructions).

To avoid generating exceptions when loading a new environment, use the FCLEX or FNCLEX instruction to clear the exception flags in the x87 status word before storing that environment.

For details about the memory image restored by FRSTOR, see “Media and x87 Processor State” in Volume 2.

Mnemonic	Opcode	Description
FRSTOR *mem94/108env*	DD /4	Load the x87 state from *mem94/108env*.

FSAVE FNSAVE Floating-Point Save x87 and MMX™ State

Stores the complete x87 state to memory starting at the specified address and reinitializes the x87 state.

The FSAVE instruction takes a memory operand that specifies the starting address of either a 94-byte or 108-byte area in memory. The 94-byte operand is required for a 16-bit operand-size; the 108-byte memory area is required for both 32-bit and 64-bit operand sizes. The layout of the saved x87 state within the specified memory area depends on whether the processor is operating in protected or real mode. See “Media and x87 Processor State” in Volume 2 for details on how this instruction stores the x87 environment in memory. (Because FSAVE does not save the full 64-bit data and instruction pointers, 64-bit applications should use FXSAVE/FXRSTOR, rather than FSAVE/FRSTOR.)

Because the MMX registers are mapped onto the low 64 bits of the x87 floating-point registers, this operation also saves the MMX state.

The FNSAVE instruction does not wait for pending unmasked x87 floating-point exceptions to be processed.

Assemblers usually provide an FSAVE macro that expands into the instruction sequence

```
WAIT                    ; Opcode 9B
FNSAVE destination      ; Opcode DD /6
```

The WAIT (9Bh) instruction checks for pending x87 exceptions and calls an exception handler, if necessary. The FNSAVE instruction then stores the x87 state to the specified destination.

Mnemonic	Opcode	Description
FSAVE *mem94/108env*	9B DD /6	Copy the x87 state to *mem94/108env* after checking for pending floating-point exceptions, then reinitialize the x87 state.
FNSAVE *mem94/108env*	DD /6	Copy the x87 state to *mem94/108env* without checking for pending floating-point exceptions, then reinitialize the x87 state.

FSCALE Floating-Point Scale

Multiplies the floating-point value in ST(0) by 2 to the power of the integer portion of the floating-point value in ST(1).

This instruction provides an efficient method of multiplying (or dividing) by integral powers of 2 because, typically, it simply adds the integer value to the exponent of the value in ST(0), leaving the significand unaffected. However, if the value in ST(0) is a denormal value, the mantissa is also modified and the result may end up being a normalized number. Likewise, if overflow or underflow results from a scale operation, the mantissa of the resulting value will be different from that of the source.

The FSCALE instruction performs the reverse operation to that of the FXTRACT instruction.

Mnemonic	Opcode	Description
FSCALE	D9 FD	Replace ST(0) with ST(0) $*$ $2^{rndint(ST(1))}$

x87 Floating-Point Exception Generated, #MF				
Invalid-operation exception (IE)	X	X	X	A source operand was an SNaN value or an unsupported format.
	X	X	X	A source operand was a negative value (not including -zero).
Invalid-operation exception (IE) with stack fault (SF)	X	X	X	An x87 stack underflow occurred.
Denormalized-operand exception (DE)	X	X	X	A source operand was a denormal value.
Precision exception (PE)	X	X	X	A result could not be represented exactly in the destination format.

FST
FSTP
Floating-Point Store Stack Top

Copies the value in ST(0) to the specified floating-point register or memory location.

The FSTP instruction pops the x87 stack after copying the value. The instruction FSTP ST(0) is the same as popping the stack with no data transfer.

If the specified destination is a single-precision or double-precision memory location, the instruction converts the value to the appropriate precision format. It does this by rounding the significand of the source value as specified by the rounding mode determined by the RC field of the x87 control word and then converting to the format of destination. It also converts the exponent to the width and bias of the destination format.

If the value is too large for the destination format, the instruction sets the overflow exception (OE) bit of the x87 status word. Then, if the overflow exception is unmasked (OM bit cleared to 0 in the x87 control word), the instruction does not perform the store.

If the value is a denormal value, the instruction sets the underflow exception (UE) bit in the x87 status word.

If the value is ±0, ±∞, or a NaN, the instruction truncates the least significant bits of the significand and exponent to fit the destination location.

Mnemonic	Opcode	Description
FST ST(*i*)	DD D0+*i*	Copy the contents of ST(0) to ST(*i*).
FST *mem32real*	D9 /2	Copy the contents of ST(0) to *mem32real*.
FST *mem64real*	DD /2	Copy the contents of ST(0) to *mem64real.*
FSTP ST(*i*)	DD D8+*i*	Copy the contents of ST(0) to ST(*i*) and pop the x87 register stack.
FSTP *mem32real*	D9 /3	Copy the contents of ST(0) to *mem32real* and pop the x87 register stack
FSTP *mem64real*	DD /3	Copy the contents of ST(0) to *mem64real* and pop the x87 register stack.
FSTP *mem80real*	DB /7	Copy the contents of ST(0) to *mem80real* and pop the x87 register stack.

Precision exception (PE)	X	X	X	A result could not be represented exactly in the destination format.

FSTCW (FNSTCW) Floating-Point Store Control Word

Stores the x87 control word in the specified 2-byte memory location. The FNSTCW instruction does not check for possible floating-point exceptions before copying the image of the x87 status register.

Assemblers usually provide an FSTCW macro that expands into the instruction sequence:

```
WAIT                    ; Opcode 9B
FNSTCW destination      ; Opcode D9 /7
```

The WAIT (9Bh) instruction checks for pending x87 exception and calls an exception handler, if necessary. The FNSTCW instruction then stores the state of the x87 control register to the desired destination.

Mnemonic	Opcode	Description
FSTCW *mem2env*	9B D9 /7	Perform a WAIT (9B) to check for pending floating-point exceptions, then copy the x87 control word to *mem2env*.
FNSTCW *mem2env*	D9 /7	Copy the x87 control word to *mem2env* without checking for floating-point exceptions.

Alignment check, #AC		X	X	An unaligned memory reference was performed while alignment checking was enabled.

FSTENV (FNSTENV) Floating-Point Store Environment

Stores the current x87 environment to memory starting at the specified address, and then masks all floating-point exceptions. The x87 environment consists of the x87 control, status, and tag word registers, the last non-control x87 instruction pointer, the last x87 data pointer, and the opcode of the last completed non-control x87 instruction.

The FSTENV instruction takes a memory operand that specifies the start of either a 14-byte or 28-byte area in memory. The 14-byte operand is required for a 16-bit operand-size; the 28-byte memory area is required for both 32-bit and 64-bit operand sizes. The layout of the saved x87 environment within the specified memory area depends on whether the processor is operating in protected or real mode. See "Media and x87 Processor State" in Volume 2 for details on how this instruction stores the x87 environment in memory. (Because FLDENV/FSTENV do not save the full 64-bit data and instruction pointers, 64-bit applications should use FXSAVE/FXRSTOR, rather than FLDENV/FSTENV.)

The FNSTENV instruction does not check for possible floating-point exceptions before storing the environment.

Assemblers usually provide an FSTENV macro that expands into the instruction sequence

```
WAIT                    ; Opcode 9B
FNSTENV destination     ; Opcode D9 /6
```

The WAIT (9Bh) instruction checks for pending x87 exceptions and calls an exception handler if necessary. The FNSTENV instruction then stores the state of the x87 environment to the specified destination.

Exception handlers often use these instructions because they provide access to the x87 instruction and data pointers. An exception handler typically saves the environment on the stack. The instructions mask all floating-point exceptions after saving the environment to prevent those exceptions from interrupting the exception handler.

Mnemonic	Opcode	Description
FSTENV *mem14/28env*	9B D9 /6	Perform a WAIT (9B) to check for pending floating-point exceptions, then copy the x87 environment to *mem14/28env* and mask the floating-point exceptions.
FNSTENV *mem14/28env*	D9 /6	Copy the x87 environment to *mem14/28env* without checking for pending floating-point exceptions, and mask the exceptions.

Alignment check, #AC		X	X	An unaligned memory reference was performed while alignment checking was enabled.

FSTSW (FNSTSW) Floating-Point Store Status Word

Stores the current state of the x87 status word register in either the AX register or a specified two-byte memory location. The image of the status word placed in the AX register always reflects the result after the execution of the previous x87 instruction.

The AX form of the instruction is useful for performing conditional branching operations based on the values of x87 condition flags.

The FNSTSW instruction does not check for possible floating-point exceptions before storing the x87 status word.

Assemblers usually provide an FSTSW macro that expands into the instruction sequence:

```
WAIT                    ; Opcode 9B
FNSTSW destination      ; Opcode DD /7 or DF E0
```

The WAIT (9Bh) instruction checks for pending x87 exceptions and calls an exception handler if necessary. The FNSTSW instruction then stores the state of the x87 status register to the desired destination.

Mnemonic	Opcode	Description
FSTSW AX	9B DF E0	Perform a WAIT (9B) to check for pending floating-point exceptions, then copy the x87 status word to the AX register.
FSTSW *mem2env*	9B DD /7	Perform a WAIT (9B) to check for pending floating-point exceptions, then copy the x87 status word to *mem12byte*.
FNSTSW AX	DF E0	Copy the x87 status word to the AX register without checking for pending floating-point exceptions.
FNSTSW *mem2env*	DD /7	Copy the x87 status word to *mem12byte* without checking for pending floating-point exceptions.

FSUB
FSUBP
FISUB
Floating-Point Subtract

Subtracts the value in a floating-point register or memory location from the value in another register and stores the result in that register.

If no operands are specified, the instruction subtracts the value in ST(0) from that in ST(1) and stores the result in ST(1).

If one operand is specified, it subtracts a floating-point or integer value in memory from the contents of ST(0) and stores the result in ST(0).

If two operands are specified, it subtracts the value in ST(0) from the value in another floating-point register or vice versa.

The FSUBP instruction pops the x87 register stack after performing the subtraction.

The no-operand version of the instruction always pops the register stack. In some assemblers, the mnemonic for this instruction is FSUB rather than FSUBP.

The FISUB instruction converts a signed integer value to double-extended-precision format before performing the subtraction.

Mnemonic	Opcode	Description
FSUB ST(0),ST(*i*)	D8 E0+*i*	Replace ST(0) with ST(0) – ST(*i*).
FSUB ST(*i*),ST(0)	DC E8+*i*	Replace ST(*i*) with ST(*i*) – ST(0).
FSUB *mem32real*	D8 /4	Replace ST(0) with ST(0) – *mem32real*.
FSUB *mem64real*	DC /4	Replace ST(0) with ST(0) – *mem64real*.
FSUBP	DE E9	Replace ST(1) with ST(1) – ST(0) and pop the x87 register stack.
FSUBP ST(*i*),ST(0)	DE E8+*i*	Replace ST(*i*) with ST(*i*) – ST(0), and pop the x87 register stack.
FISUB *mem16int*	DE /4	Replace ST(0) with ST(0) – *mem16int*.
FISUB *mem32int*	DA /4	Replace ST(0) with ST(0) – *mem32int*.

FISUBR

Floating-Point Subtract Reverse

Subtracts the value in a floating-point register from the value in another register or a memory location, and stores the result in the first specified register. Values in memory can be in single-precision or double-precision floating-point, word integer, or short integer format.

If one operand is specified, the instruction subtracts the value in ST(0) from the value in memory and stores the result in ST(0).

If two operands are specified, it subtracts the value in ST(0) from the value in another floating-point register or vice versa.

The FSUBRP instruction pops the x87 register stack after performing the subtraction.

The no-operand version of the instruction always pops the register stack. In some assemblers, the mnemonic for this instruction is FSUBR rather than FSUBRP.

The FISUBR instruction converts a signed integer operand to double-extended-precision format before performing the subtraction.

The FSUBR instructions perform the reverse operations of the FSUB instructions.

Mnemonic	Opcode	Description
FSUBR ST(0),ST(*i*)	D8 E8+*i*	Replace ST(0) with ST(*i*) - ST(0).
FSUBR ST(*i*),ST(0)	DC E0+*i*	Replace ST(*i*) with ST(0) - ST(*i*).
FSUBR *mem32real*	D8 /5	Replace ST(0) with *mem32real* - ST(0).
FSUBR *mem64real*	DC /5	Replace ST(0) with *mem64real* - ST(0).

FUCOM
FUCOMP
FUCOMPP
Floating-Point Unordered Compare

Compares the value in ST(0) to the value in another x87 register, and sets the condition codes in the x87 status word as shown in the x87 Condition Code table below.

If no source operand is specified, the instruction compares the value in ST(0) to that in ST(1).

After making the comparison, the FUCOMP instruction pops the x87 stack register and the FUCOMPP instruction pops the x87 stack register twice.

The instruction carries out the same comparison operation as the FCOM instructions, but sets the invalid-operation exception (IE) bit in the x87 status word to 1 when either or both operands are an SNaN or are in an unsupported format. If either or both operands is a QNaN, it sets the condition code flags to unordered, but does not set the IE bit. The FCOM instructions, on the other hand, raise an IE exception when either or both of the operands are a NaN value or are in an unsupported format.

Support for the FCOM(P(P)) instruction can be determined by executing either CPUID function 0000_0001h or CPUID function 8000_0001. Support is indicated when both the EDX[FPU] (bit 0) and EDX[CMOV] (bit 15) feature flags are set.

Mnemonic	Opcode	Description
FUCOM	DD E1	Compare ST(0) to ST(1) and set condition code flags to reflect the results of the comparison.
FUCOM ST(*i*)	DD E0+*i*	Compare ST(0) to ST(*i*) and set condition code flags to reflect the results of the comparison.
FUCOMP	DD E9	Compare ST(0) to ST(1), set condition code flags to reflect the results of the comparison, and pop the x87 register stack.
FUCOMP ST(*i*)	DD E8+*i*	Compare ST(0) to ST(*i*), set condition code flags to reflect the results of the comparison, and pop the x87 register stack.
FUCOMPP	DA E9	Compare ST(0) to ST(1), set condition code flags to reflect the results of the comparison, and pop the x87 register stack twice.

Denormalized-operand exception (DE)	X	X	X	A source operand was a denormal value.

FWAIT (WAIT) — Wait for Unmasked x87 Floating-Point Exceptions

Forces the processor to test for pending unmasked floating-point exceptions before proceeding.

If there is a pending floating-point exception and CR0.NE = 1, a numeric exception (#MF) is generated. If there is a pending floating-point exception and CR0.NE = 0, FWAIT asserts the FERR output signal, then waits for an external interrupt.

This instruction is useful for insuring that unmasked floating-point exceptions are handled before altering the results of a floating point instruction.

FWAIT and WAIT are synonyms for the same opcode.

Mnemonic	Opcode	Description
FWAIT	9B	Check for any pending floating-point exceptions.

Exceptions

Exception	Real	Virtual 8086	Protected	Cause of Exception
Device not available, #NM	X	X	X	The monitor coprocessor bit (MP) and the task switch bit (TS) of the control register (CR0) were both set to 1.
x87 floating-point exception pending, #MF	X	X	X	An unmasked x87 floating-point exception was pending.

FXAM Floating-Point Examine

Examines the value in ST(0) and sets the C0, C2, and C3 condition code flags in the x87 status word as shown in the x87 Condition Code table below to indicate whether the value is a NaN, infinity, zero, empty, denormal, normal finite, or unsupported value. The instruction also sets the C1 flag to indicate the sign of the value in ST(0) (0 = positive, 1 = negative).

Mnemonic	Opcode	Description
FXAM	D9 E5	Characterize the number in the ST(0) register.

x87 Condition Code

C3	C2	C1	C0	Meaning
0	0	0	0	+unsupported format
0	0	0	1	+NaN
0	0	1	0	–unsupported format
0	0	1	1	–NaN
0	1	0	0	+normal
0	1	0	1	+infinity
0	1	1	0	–normal
0	1	1	1	–infinity
1	0	0	0	+0
1	0	0	1	+empty
1	0	1	0	–0
1	0	1	1	–empty
1	1	0	0	+denormal
1	1	1	0	–denormal

Exceptions

Exception	Real	Virtual 8086	Protected	Cause of Exception
Device not available, #NM	X	X	X	The emulate bit (EM) or the task switch bit (TS) of the control register (CR0) is set to 1.
x87 floating-point exception pending, #MF	X	X	X	An unmasked x87 floating-point exception was pending.

FXCH Floating-Point Exchange

Exchanges the value in ST(0) with the value in any other x87 register. If no operand is specified, the instruction exchanges the values in ST(0) and ST(1).

Use this instruction to move a value from an x87 register to ST(0) for subsequent processing by a floating-point instruction that can only operate on ST(0).

Mnemonic	Opcode	Description
FXCH	D9 C9	Exchange the contents of ST(0) and ST(1).
FXCH ST(*i*)	D9 C8+*i*	Exchange the contents of ST(0) and ST(*i*).

x87 Condition Code

x87 Condition Code	Value	Description
C0	U	
C1	0	
C2	U	
C3	U	
Note: *A flag set to 1 or cleared to 0 is M (modified). Unaffected flags are blank. Undefined flags are U.*		

Exceptions

Exception	Real	Virtual 8086	Protected	Cause of Exception
Device not available, #NM	X	X	X	The emulate bit (EM) or the task switch bit (TS) of the control register (CR0) was set to 1.
x87 floating-point exception pending, #MF	X	X	X	An unmasked x87 floating-point exception was pending.
x87 Floating-Point Exception Generated, #MF				
Invalid-operation exception (IE) with stack fault (SF)	X	X	X	An x87 stack underflow occurred.

FXTRACT Floating-Point Extract Exponent and Significand

Extracts the exponent and significand portions of the floating-point value in ST(0), stores the exponent in ST(0), and then pushes the significand onto the x87 register stack. After this operation, the new ST(0) contains a real number with the sign and value of the original significand and an exponent of 3FFFh (biased value for true exponent of zero), and ST(1) contains a real number that is the value of the original value's true (unbiased) exponent.

The FXTRACT instruction is useful for converting a double-extended-precision number to its decimal representation.

If the zero-divide-exception mask (ZM) bit of the x87 control word is set to 1 and the source value is ±0, then the instruction stores ±zero in ST(0) and an exponent value of –∞ in register ST(1).

Mnemonic	Opcode	Description
FXTRACT	D9 F4	Extract the exponent and significand of ST(0), store the exponent in ST(0), and push the significand onto the x87 register stack.

x87 Condition Code

x87 Condition Code	Value	Description
C0	U	
C1	0	x87 stack underflow, if an x87 register stack fault was detected.
	1	x87 stack overflow, if an x87 register stack fault was detected.
C2	U	
C3	U	
Note: *A flag set to 1 or cleared to 0 is M (modified). Unaffected flags are blank. Undefined flags are U.*		

Exceptions

Exception	Real	Virtual 8086	Protected	Cause of Exception
Device not available, #NM	X	X	X	The emulate bit (EM) or the task switch bit (TS) of the control register (CR0) is set to 1.
x87 floating-point exception pending, #MF	X	X	X	An unmasked x87 floating-point exception was pending.
x87 Floating-Point Exception Generated, #MF				
Invalid-operation exception (IE)	X	X	X	A source operand was an SNaN value or an unsupported format.
Invalid-operation exception (IE) with stack fault (SF)	X	X	X	An x87 stack underflow occurred.
	X	X	X	An x87 stack overflow occurred.
Denormalized-operand exception (DE)	X	X	X	A source operand was a denormal value.
Zero-divide exception (ZE)	X	X	X	The source operand was ±zero.

FYL2X Floating-Point y ∗ Log_2 (x)

Computes (ST(1) ∗ $\log_2$(ST(0))), stores the result in ST(1), and pops the x87 register stack. The value in ST(0) must be greater than zero.

If the zero-divide-exception mask (ZM) bit in the x87 control word is set to 1 and ST(0) contains ±zero, the instruction returns ∞ with the opposite sign of the value in register ST(1).

Mnemonic	Opcode	Description
FYL2X	D9 F1	Replace ST(1) with ST(1) ∗ $\log_2$(ST(0)), then pop the x87 register stack.

x87 floating-point exception pending, #MF	X	X	X	An unmasked x87 floating-point exception was pending.
x87 Floating-Point Exception Generated, #MF				
Invalid-operation exception (IE)	X	X	X	A source operand was an SNaN value or an unsupported format.
	X	X	X	The source operand in ST(0) was a negative finite value (not -zero).
	X	X	X	The source operand in ST(0) was +1 and the source operand in ST(1) was ±infinity.
	X	X	X	The source operand in ST(0) was -infinity.
	X	X	X	The source operand in ST(0) was ±zero or ±infinity and the source operand in ST(1) was ±zero.
Invalid-operation exception (IE) with stack fault (SF)	X	X	X	An x87 stack underflow occurred.
Denormalized-operand exception (DE)	X	X	X	A source operand was a denormal value.
Zero-divide exception (ZE)	X	X	X	The source operand in ST(0) was ±zero and the source operand in ST(1) was a finite value.
Overflow exception (OE)	X	X	X	A rounded result was too large to fit into the format of the destination operand.
Underflow exception (UE)	X	X	X	A rounded result was too small to fit into the format of the destination operand.
Precision exception (PE)	X	X	X	A result could not be represented exactly in the destination format.

FYL2XP1 Floating-Point y ∗ Log_2 (x+1)

Computes (ST(1) ∗ $\log_2$(ST(0) + 1.0)), stores the result in ST(1), and pops the x87 register stack. The value in ST(0) must be in the range sqrt(1/2)–1 to sqrt(2)-1.

Mnemonic	Opcode	Description
FYL2XP1	D9 F9	Replace ST(1) with ST(1) ∗ $\log_2$(ST(0) + 1.0), then pop the x87 register stack.

Appendix A Recommended Substitutions for 3DNow!™ Instructions

Table A-1 lists the deprecated 3DNow!™ instructions and the recommended substitutions.

Table A-1. Substitutions for 3DNow!™ Instructions

64-Bit 3DNow!™ Instruction	128-Bit SSE Instruction	64-Bit MMX™ Instruction	Notes
FEMMS	N/A	EMMS (MMX)	
PAVGUSB	PAVGB	PAVGB	SSE and MMX™ instructions round according to the current rounding mode; 3DNow!™ instructions always round up.
PF2ID	CVTTPS2DQ		
PF2IW			CVTTPS2DQ may be used if 16-bit result is not necessary.
PFACC	HADDPS		
PFADD	ADDPS		
PFCMPEQ	CMPPS		
PFCMPGE	CMPPS		
PFCMPGT	CMPPS		
PFMAX	MAXPS		MAXPS may return -0.0.
PFMIN	MINPS		MINPS may return -0.0.
PFMUL	MULPS		
PFNACC	HSUBPS		
PFPNACC	ADDSUBPS		ADDSUBPS expects arguments in different positions from PFPNACC.
PFRCP			RCPSS may be used in conjunction with the Newton-Raphson algorithm.
PFRCPIT1			See PFRCP.
PFRCPIT2			See PFRCP.
PFRSQIT1			See PFRSQRT.
PFRSQRT			RSQRTSS may be used in conjunction with the Newton-Raphson algorithm.
PFSUB	SUBPS		
PFSUBR			SUBPS may be used.
PI2FD	CVTDQ2PS		SSE instructions round according to the current rounding mode; 3DNow! instructions always truncate.
PI2FW			
PMULHRW			PMULHW may be used if rounding is not necessary.
PSWAPD	PSHUFD
