CPU software is not aware of the values of these keys but the hypervisor should coordinate the loading of virtual machine keys through the AMD-SP driver. This coordination will also determine which ASID the hypervisor should use for a particular guest. Under SEV, the ASID is used as the key index that identifies which encryption key is used to encrypt/decrypt memory traffic associated with that SEV-enabled guest. Encryption keys themselves are never visible to CPU software and are never stored off-chip in the clear.

15.34.3 Enabling SEV

Prior to starting an encrypted VM, software must enable MemEncryptionModEn through MSR C001_0010 (SYSCFG) as described in Section 7.10.2, “Enabling Memory Encryption Extensions,” on page 229. SEV may then be enabled on a specific virtual machine during the VMRUN instruction if the hypervisor sets the SEV enable bit in VMCB offset 090h.

Byte Offset	Bit[s]	Description
090h	0	Enable nested paging
	1	Enable Secure Encrypted Virtualization
	2	Enable Encrypted State for Secure Encrypted Virtualization
	63-3	Reserved, SBZ

When SEV is enabled in a guest, the following additional consistency checks are performed during VMRUN:

- Nested paging (VMCB offset 090h, bit 0) must be enabled
- MSR C001_0015 (HWCR) [SmmLock] must be set
- ASID (VMCB offset 058h) must be within the allowed range for SEV

The allowed ASIDs for SEV operation may be a subset of the overall number of hardware supported ASIDs. In this scenario, SEV-enabled guests must use ASIDs in the defined subset, while non-SEV enabled guests can use the remaining ASID range. The range of ASIDs allowed for SEV-enabled guests is from 1 to a maximum value defined via CPUID 8000_001F[ECX].

Note that on systems where CPUID Fn8000_001F_EAX[11] is set to 1, the hypervisor must be in 64-bit mode in order to execute a VMRUN to an SEV-enabled guest. If not the VMRUN fails with a VMEXIT_INVALID error code.

If any of the above consistency checks fail when SEV is enabled on a guest, the VMRUN instruction will terminate with a VMEXIT_INVALID error code. If MemEncryptionModEn is 0, SEV cannot be enabled and the VMCB control bit for SEV is ignored.

15.34.4 Supported Operating Modes

Secure Encrypted Virtualization may be enabled on guests running in any operating mode. However the guest is only able to control memory encryption when operating in long mode or legacy PAE mode. In all other modes, all guest memory accesses are unconditionally considered private and are encrypted with the guest-specific key.

15.34.5 SEV Encryption Behavior

When a guest is executed with SEV enabled, the guest page tables are used to determine the C-bit for a memory page and hence the encryption status of that memory page. This allows a guest to determine which pages are private or shared, but this control is available only for data pages. Memory accesses on behalf of instruction fetches and guest page table walks are always treated as private, regardless of

the software value of the C-bit. This behavior ensures non-guest entities (such as the hypervisor) cannot inject their own code or data into an SEV-enabled guest. If a guest does wish to make data in instruction pages or page tables accessible to code outside of the guest, this data must be explicitly copied into a shared data page.

Note that while the guest may choose to set the C-bit explicitly on instruction pages and page table addresses, the value of this bit is a don't-care in such situations as hardware always performs these as private accesses.

15.34.6 Page Table Support

An SEV-enabled guest controls encryption in its own guest page tables using the C-bit defined by CPUID 8000_001F[EBX]. This location is the same C-bit location as defined under SME (Section 7.10, “Secure Memory Encryption,” on page 228) in non-virtualized mode. If the C-bit is an address bit, this bit is masked from the guest physical address when it is translated through the nested page tables. Consequently, the hypervisor does not need to be aware of which pages the guest has chosen to mark private.

For example if the C-bit is address bit 47, when a guest accesses virtual address 0x54321, it might be translated to guest physical address 0x8000_00AB_C321, indicating the page should be encrypted with the private guest key. When this guest physical address is translated through the nested page tables, host virtual address 0xAB_C321 is used for translation. The C-bit value from the guest physical address is saved and used on the final system physical address after the nested table translation as shown in Figure 15-28.

Note that because guest physical addresses are always translated through the nested page tables, the size of the guest physical address space is not impacted by any physical address space reduction indicated in CPUID 8000_001F[EBX]. If the C-bit is a physical address bit however, the guest physical address space is effectively reduced by 1 bit.

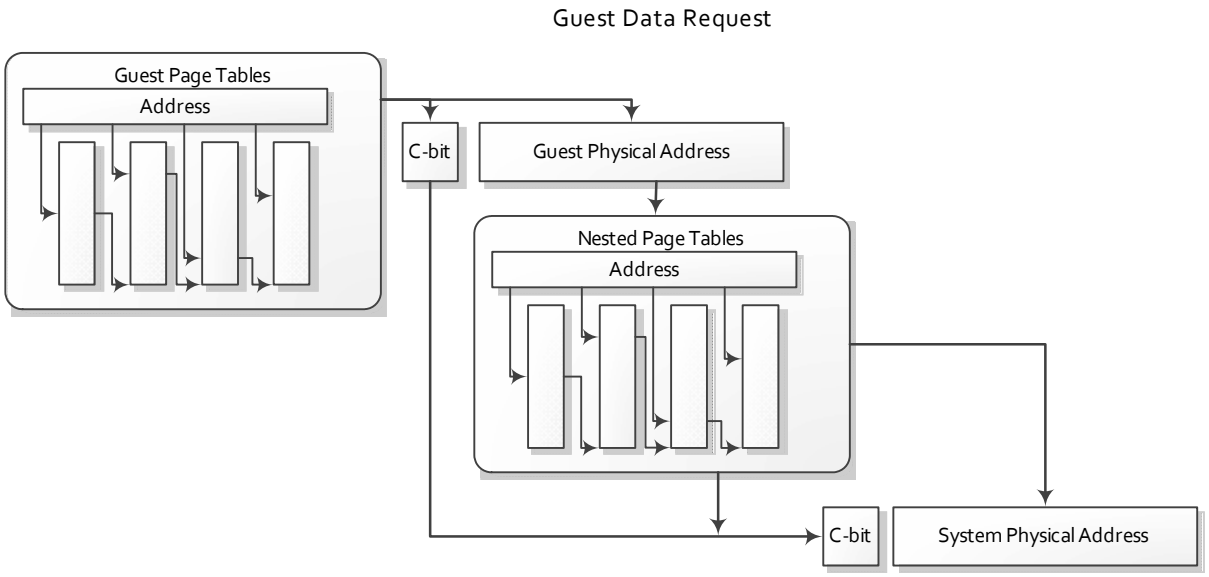

Figure 15-28. Guest Data Request

15.34.7 Restrictions

As with SME, some hardware implementations may not enforce coherency between mappings of the same physical page with different encryption enablement or keys. In such a system, when the encryption enablement or key for a particular memory page is to be changed, software must first ensure the page is flushed from all CPU caches. Certain conventional cache flushing techniques may not work however; see Section 15.34.9 for further details.

Note that if the hardware implementation enforces coherency across encryption domains as indicated by CPUID Fn8000_001F_EAX[10] then this flush is not required.

15.34.8 SEV Interaction with SME

SEV may be used in conjunction with SME mode. In this scenario, the guest page tables control encryption for guest memory, and the host (nested) page tables control encryption for shared memory. This behavior is summarized in Table 15-32. SEV is considered active when the CPU is in guest mode and the guest has SEV enabled in the VMCB.

Table 15-32. Encryption Control

Type of Access	MemEncryptionModEn	Guest Mode	SEV Mode Active	Encrypted	Encryption Key	Notes
Legacy Mode (memory encryption disabled)						
All	0	X	X	No	N/A	
Secure Memory Encryption Mode						
All	1	0	X	Optional	Host Key	Determined by page tables (CR3)
All	1	1	0	Optional	Host Key	Determined by nested page tables (hCR3)
Secure Encrypted Virtualization Mode						
Instruction Fetch	1	1	1	Yes	Guest Key	
Guest Page Table Access	1	1	1	Yes	Guest Key	
Nested Page Table Access	1	1	1	Optional	Host Key	Determined by nested page tables (hCR3)
Data Access	1	1	1	Optional[1]	See Table 15-33: SEV/SME Interaction	Determined by guest page tables (gCR3) and nested page tables (hCR3)

Note:

1. Encryption is guest-controlled in long mode and legacy PAE mode only. In all other modes, these accesses are always considered private and are encrypted with the guest key

Note that during a nested page table walk, it is possible for both the guest page tables to be encrypted and the nested page tables to be encrypted. In this scenario, the guest page tables are decrypted using the guest private encryption key, and the nested page tables are decrypted using the host (SME) encryption key.

Guest data accesses that are marked shared (C=0) by the guest may still be optionally encrypted using the host (SME) key if the pages are marked encrypted in the nested tables. If a page is marked encrypted in both the guest and nested tables, the guest tables have priority and the page will be encrypted using the guest key. This behavior is summarized in Table 15-33.

Table 15-33. SEV/SME Interaction

		Nested Page Table	
		C=0	C=1
Guest Page Table	C=0	Unencrypted	Encrypted with host key
	C=1	Encrypted with guest key	Encrypted with guest key

15.34.9 Page Flush MSR

If coherency across encryption domains is not supported (see “Restrictions” on page 575), and the hypervisor wishes to read an encrypted page, it must first flush the guest view of that page from all CPU caches to ensure it is able to view the most recent copy of that data. This may be accomplished by issuing a WBINVD instruction on all cores on which the guest has run, or by using the VMPAGE_FLUSH MSR (C001_011E). Support for the VMPAGE_FLUSH MSR is indicated in CPUID 8000_001F[EAX] bit 2.

The VMPAGE_FLUSH MSR is a write-only register that may be used to flush 4KB of data on behalf of a guest. The hypervisor writes the host linear address of the page and guest ASID to the MSR, and hardware will then perform a write-back invalidation of the page causing any dirty data present in any CPU caches throughout the system to be encrypted and written to DRAM. Note that the VMPAGE_FLUSH MSR uses the standard host page tables to perform the page translation. The Page Flush MSR operation will hit on and evict guest-cached instances of the memory, whereas CLFLUSH instructions using this same translation will not.

Bit[s]	Description
63:12	**VirtualAddr:** Write-only. Host virtual address of page to flush
11:0	**ASID:** Write-only. Guest ASID to use for the flush

The VMPAGE_FLUSH MSR will only flush memory pages marked private by the guest. If the hypervisor does not know if the memory page was marked private but wishes to evict the page from the cache, it should perform a standard CLFLUSH in addition to using the VMPAGE_FLUSH MSR.

Attempts to flush a host virtual address that is not mapped into a physical address or use of an ASID=0 will cause a #GP(0) fault.

15.34.10 SEV_STATUS MSR

Guests can determine what SEV features are currently active by reading the SEV_STATUS MSR (C001_0131). This MSR indicates which SEV features (if any) were enabled by the hypervisor in the last VMRUN for that guest as shown in Table 15-34. The SEV_STATUS MSR is read-only and accesses to the SEV_STATUS MSR cannot be intercepted by the hypervisor. The SEV_STATUS MSR is available on all platforms that support SEV. Bits 9:2 of SEV_STATUS reflect the enablement of various SEV-SNP security features as described in section 15.36.

Table 15-34. SEV_STATUS MSR Fields

Bit[s]	Description
63:17	**Reserved**
16	**VmsaRegProt_Enabled:** The guest was run with the VMSA Register Protection feature enabled in SEV_FEATURES[14]
15:12	**Reserved**
11	**SecureTsc_Enabled:** The guest was run with the Secure TSC feature enabled in SEV_FEATURES[9]
10	**Reserved**
9	**SNPBTBIsolation_Enabled:** The guest was run with the BTB isolation feature enabled in SEV_FEATURES[7]
8	**PreventHostIBS_Enabled:** This guest was run with the PreventHostIBS feature enabled in SEV_FEATURES[6].
7	**DebugSwap_Enabled:** This guest was run with debug register swapping enabled in SEV_FEATURES[5].
6	**AlternateInjection_Enabled:** The guest was run with the Alternate Injection feature enabled in SEV_FEATURES[4]
5	**RestrictedInjection_Enabled:** The guest was run with the Restricted Injection feature enabled in SEV_FEATURES[3]
4	**ReflectVC_Enabled:** The guest was run with the ReflectVC feature enabled in SEV_FEATURES[2]
3	**vTOM_Enabled:** The guest was run with the Virtual TOM feature enabled in SEV_FEATURES[1]
2	**SNP_Active:** The guest was run in SNP-Active mode as selected by SEV_FEATURES[0]
1	**SEV_ES_Enabled:** The guest was run with the SEV-ES feature enabled in VMCB offset 90h
0	**SEV_Enabled:** The guest was run with the SEV feature enabled in VMCB offset 90h

15.34.11 Virtual Transparent Encryption (VTE)

The Virtual Transparent Encryption feature can be enabled to force all memory accesses within an SEV guest to be encrypted with the guest's key. Support for this feature is indicated in CPUID Fn8000_001F[EAX] bit 16.

To enable this feature, the hypervisor must set VMCB offset 90h bit 5. Bit 5 is only observed when SEV (bit 1) is also set to 1 and SEV-ES (bit 2) is cleared to 0. In all other configurations of these bits (namely SEV disabled or SEV-ES enabled), bit 5 is ignored by hardware.

When this feature is enabled, CPU hardware treats the guest C-bit as 1 for all guest memory references. The actual C-bit in the guest page tables is ignored by hardware.

Guest address translation is unchanged, so the guest physical address (without the C-bit) is used for translation in the nested page tables.

15.35 Encrypted State (SEV-ES)

Encrypted VMs that use the SEV feature described in Section 15.34 may additionally use the SEV-ES feature to protect guest register state from the hypervisor. An SEV-ES VM's CPU register state is

encrypted during world switches and cannot be directly accessed or modified by the hypervisor. This is designed to protect against attacks such as exfiltration (unauthorized reading of VM state) and control flow attacks (modifying VM state) including rollback attacks (restoring an earlier VM register state).

SEV-ES includes architectural support for notifying a VM's operating system when certain types of world switches are about to occur, allowing the VM to selectively share information with the hypervisor when needed for functionality.

15.35.1 Determining Support for SEV-ES

SEV-ES support can be determined by reading CPUID Fn8000_001F[EAX] as described in Section 15.34.1. Bit 3 of EAX indicates support for SEV-ES.

15.35.2 Enabling SEV-ES

SEV-ES may be enabled on a per-VM basis by setting bit 2 in offset 90h of the VMCB. When enabling SEV-ES, the hypervisor must also enable SEV (offset 90h bit 1) and LBR virtualization (offset B8h bit 0). Additionally, all other programming requirements related to enabling SEV (see Section 15.34.3) must be satisfied when running an SEV-ES guest.

On some systems, there is a limitation on which ASID values can be used on SEV guests that are run with SEV-ES disabled. While SEV-ES may be enabled on any valid SEV ASID (as defined by CPUID Fn8000_001F[ECX]), there are restrictions on which ASIDs may be used for SEV guests with SEV-ES disabled. CPUID Fn8000_001F[EDX] indicates the minimum ASID value that must be used for an SEV-enabled, SEV-ES-disabled guest. For example, if CPUID Fn8000_001F[EDX] returns the value 5, then any VMs which use ASIDs 1-4 and which enable SEV must also enable SEV-ES.

Note that prior to running an SEV-ES VM for the first time, the hypervisor must coordinate with the AMD Secure Processor to create the initial encrypted state image for the guest VM.

15.35.3 SEV-ES Overview

The SEV-ES architecture is designed to protect guest VM register state by default, and only allow the guest VM itself to grant selective access as required. This additional security protection functionality is accomplished in two ways. First, all VM register state is saved and encrypted when a VM exit event (#VMEXIT) occurs. This state is decrypted and restored on a VMRUN only. Second, certain types of #VMEXIT events cause a new exception to be taken within the guest VM. This new exception (#VC, see Section 15.35.5) indicates that the guest VM performed some action which requires hypervisor involvement, an example of which would be an IO access by the VM. The guest #VC handler is responsible for determining what register state is necessary to expose to the hypervisor for the purpose of emulating this operation. The #VC handler also inspects the returned values from the hypervisor and updates the guest state if the output is deemed acceptable.

Register state that needs to be exposed utilizes a new structure called the Guest-Hypervisor Communication Block (GHCB). The GHCB location is chosen by the guest who maps the page as a shared memory page, thus allowing direct hypervisor access. Only state located in the GHCB can be

read by the hypervisor as all state stored in the traditional VMCB save state structure is encrypted using the guest memory encryption key and integrity protected.

In the #VC handler, the guest may utilize a new instruction (Section 15.35.6) to perform a world switch and invoke the hypervisor. In response to this, the hypervisor can inspect the GHCB and determine the services requested by the guest.

15.35.4 Types of Exits

When SEV-ES is enabled, all #VMEXIT events are classified as either Automatic Exits (AE) or Non-Automatic Exits (NAE). AE events are generally events that occur asynchronously with respect to the guest execution (e.g. interrupts) or events that need not involve exposing any guest register state. All other #VMEXIT events are classified as NAE events, and with NAE events the guest is allowed to determine what register state (if any) to expose in the GHCB. During guest execution, #VMEXIT events (both AE and NAE) are only taken if the corresponding intercept bit in the VMCB control area is set.

The hypervisor is informed of specific AE events exclusively via the #VMEXIT codes within the EXITCODE field of the VMCB control area. NAE events result in a #VC exception which is handled by the guest. Table 15-35 lists the possible AE events, all other events are considered NAE events.

Table 15-35. AE Exitcodes

Code	Name	Notes	HW Advances RIP
52h	VMEXIT_MC	Machine check exception	No
60h	VMEXIT_INTR	Physical INTR	No
61h	VMEXIT_NMI	Physical NMI	No
62h	VMEXIT_SMI	Physical SMI	No
63h	VMEXIT_INIT	Physical INIT	No
64h	VMEXIT_VINTR	Virtual INTR	No
77h	VMEXIT_PAUSE	PAUSE instruction	Yes
78h	VMEXIT_HLT	HLT instruction	Yes
7Fh	VMEXIT_SHUTDOWN	Shutdown	No
8Fh	VMEXIT_EFER_WRITE_TRAP	See section 15.35.10	Yes
90h -9Fh	VMEXIT_CR[0-15]_WRITE_TRAP	See section 15.35.10	Yes
400h	VMEXIT_NPF	Only if PFCODE[3]=0 (no reserved bit error)	No
403h	VMEXIT_VMGEXIT	VMGEXIT instruction	Yes
–1	VMEXIT_INVALID	Invalid guest state	–
–2	VMEXIT_BUSY	Busy bit was set in guest state (see Section 15.36.16)	–

In the case of exits due to specific instructions, the CPU will automatically advance the guest RIP in response to the AE so that execution will resume at the next instruction on a subsequent VMRUN.

In the case of nested page faults, these are treated as AEs only if there was no reserved bit error. This is intended to be used to help distinguish nested page faults due to demand misses (hypervisor needs to allocate a page) vs MMIO emulation (hypervisor needs to emulate a device). Consequently, the hypervisor should set a reserved page table bit, such as a reserved address bit, on all MMIO pages that it intends to emulate. (This can include address bits that may become reserved when SEV is enabled; see Section 15.34.1.) This will ensure that MMIO page faults become NAE events, which is critical so the guest #VC handler can be invoked to assist in the MMIO emulation. Nested page faults that are AE events do not invoke any guest handler and the hypervisor is intended to allocate memory as needed and then resume the guest.

Note that when a guest is running with SEV-ES enabled, instruction bytes (VMCB offset D0h) are never saved to the VMCB on a nested page fault.

15.35.5 #VC Exception

The VMM Communication Exception (#VC) is always generated by hardware when an SEV-ES enabled guest is running and an NAE event occurs. The #VC exception is a precise, contributory, fault-type exception utilizing exception vector 29. This exception cannot be masked. The error code of the #VC exception is equal to the #VMEXIT code (see Appendix C) of the event that caused the NAE.

In response to a #VC exception, a typical flow would involve the guest handler inspecting the error code to determine the cause of the exception and deciding what register state must be copied to the GHCB for the event to be handled. The handler should then execute the VMGEXIT instruction to create an AE and invoke the hypervisor. After a later VMRUN, guest execution will resume after the VMGEXIT instruction where the handler can view the results from the hypervisor and copy state from the GHCB back to its internal state as needed. This flow is shown in Figure 15-29.

Note that it is inadvisable for the hypervisor to set the VMCB intercept bit for the #VC exception as this would prevent proper handling of NAEs by the guest. Similarly, the hypervisor should avoid setting intercept bits for events that would occur in the #VC handler (such as IRET).

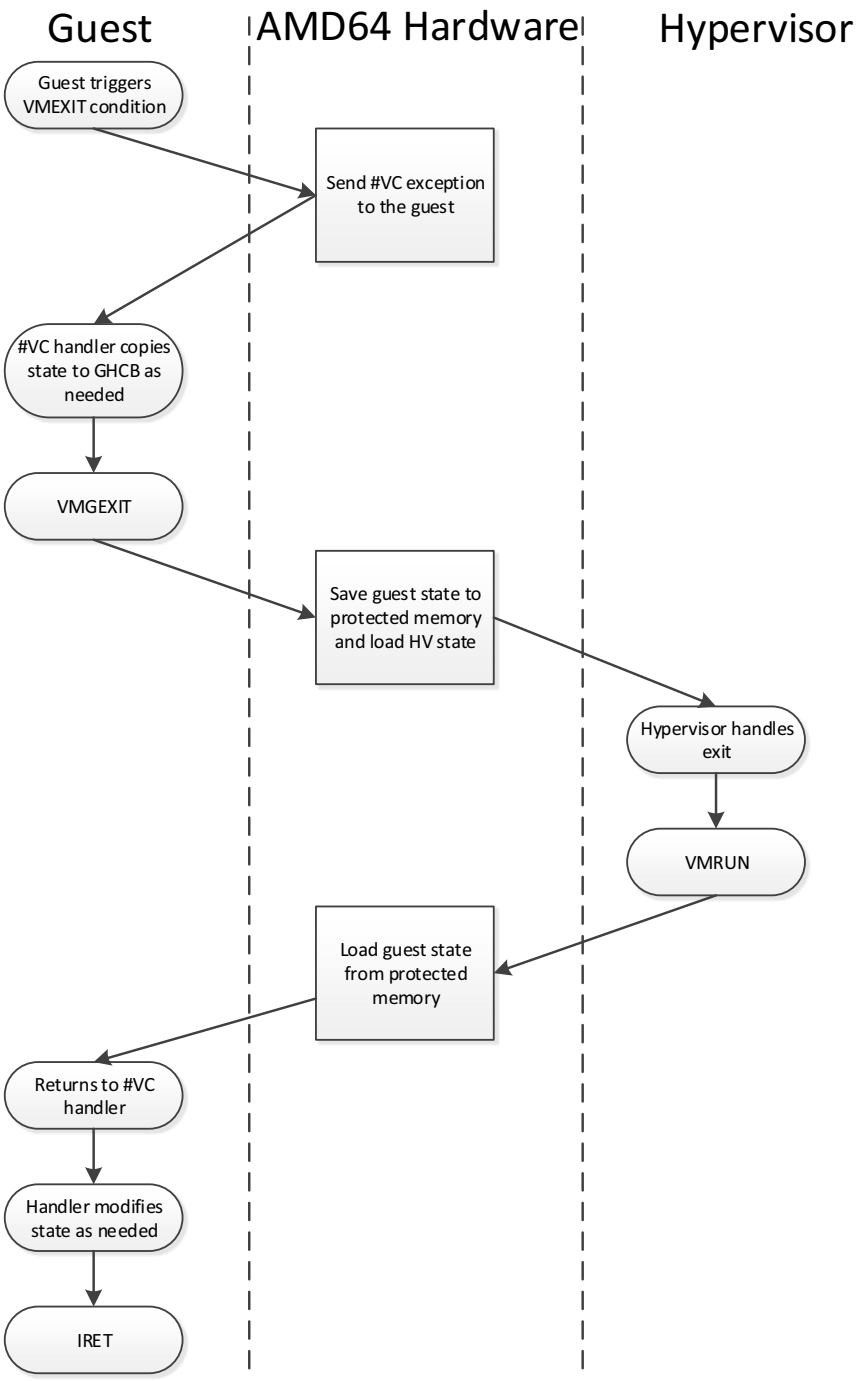

Figure 15-29. EXAMPLE #VC FLOW

15.35.6 VMGExit

The VMGEXIT instruction creates an AE and is intended to allow a guest #VC handler to invoke the hypervisor when needed. VMGEXIT causes an AE with the VMEXIT_VMGEXIT code and behaves like a trap so that upon a subsequent VMRUN, execution resumes following the VMGEXIT. There is no hypervisor intercept bit for VMGEXIT as the instruction unconditionally causes an AE when executed in an SEV-ES guest.

The VMGEXIT opcode is only valid within a guest when run with SEV-ES mode active. If the guest is not run with SEV-ES mode active, the VMGEXIT opcode will be treated as a VMMCALL opcode and will behave exactly like a VMMCALL.

15.35.7 GHCB

The GHCB is an unencrypted memory page used to communicate register state between the SEV-ES guest and the hypervisor. The guest VM is able to set the location of the GHCB via the GHCB MSR (C001_0130). This value is also included in the VMCB and is saved/restored on VMRUN/#VMEXIT respectively.

The GHCB MSR is used to set up the location of the GHCB memory page. The format of this MSR is defined below:

Bit	Function
63:0	Guest physical address of GHCB

The value of this MSR is saved/restored from the VMCB offset 0A0h. It is recommended software write this MSR with a page-aligned address. The GHCB MSR can be read/written only in guest mode, attempts to access this MSR in host mode will result in a #GP.

Hardware never accesses the GHCB directly, and as a result the format of the GHCB is not fixed.

15.35.8 VMRUN

When SEV-ES is enabled, the VM save state area does not reside at offset 400h in the VMCB page. Instead it resides starting at offset 0h in a separate page called the VM Save Area (VMSA) as indicated by the VMSA Pointer at offset 108h. The VMSA Pointer value is stored as a host physical address. Hardware always accesses the VMSA save state area using encrypted memory accesses utilizing the guest's memory encryption key.

When hardware executes a VMRUN instruction and the VMCB indicates SEV-ES is enabled for the guest, the hardware loads guest state from the encrypted save state area indicated by the VMSA Pointer. Also, the VMRUN instruction will perform the following actions in addition to the standard VMRUN behavior:

- Calculate a checksum over guest state to verify integrity
- Perform a VMLOAD to load additional guest register state
- Load guest GPR state

- Load guest FPU state

When a guest has SEV-ES enabled, the encrypted VM state save area definition is expanded to include all GPR and FPU state (see Appendix B). If any part of the VMRUN flow faults or if the integrity checksum fails to match, a #VMEXIT(VMEXIT_INVALID) is generated.

Note that if SEV-ES is enabled, the VMRUN instruction ignores bits 10:5 of the VMCB clean bits and always reloads the full guest state.

Also note that for SEV-ES guests, while the full guest state is loaded on VMRUN only the minimal hypervisor state defined by the legacy VMRUN instruction (see Section 15.5.1) is saved to the host save area. The hypervisor itself should save its desired additional segment state and GPR values to the host save area since these values will be restored by hardware on a subsequent VMEXIT. Hardware does not automatically save host state such as FS, STAR, or GPR values from the hypervisor on a VMRUN. See Appendix B for a detailed breakdown of each piece of VMCB state.

Finally, note that event injection for SEV-ES guests is restricted. Software interrupts and exception vectors 3 and 4 may not be injected. If this is attempted, the VMRUN will fail with a VMEXIT_INVALID error code.

15.35.9 Automatic Exits

When an automatic exit event occurs while an SEV-ES enabled guest is executing, hardware automatically saves guest state to the encrypted save state area and restores hypervisor state from the host save area. Specifically, in addition to the standard state saved/restored by the VMEXIT flow, hardware will also perform the following steps:

- Perform a VMSAVE to save additional guest register state
- Save guest GPR state
- Save guest FPU state
- Calculate and store a checksum over the guest state for use in a subsequent VMRUN
- Perform a VMLOAD to load additional host register state
- Load host GPR state
- Re-initialize FPU state to their reset values

The loading of host GPR state from the host save area is done using the format of the expanded VMCB described in Appendix B. All register state is either loaded from this location or re-initialized to default values so no guest register state is visible to the hypervisor.

15.35.10 Control Register Write Traps

The use of CR[0-15]_WRITE intercepts are discouraged for guests that are run with SEV-ES. These intercepts occur prior to the control register being modified, and the hypervisor is not able to modify the control register itself since the register is located in the encrypted state image. Hypervisors are encouraged to use the new CR[0-15]_WRITE_TRAP and EFER_WRITE_TRAP intercept bits instead which cause an AE after a control register has been modified. These intercepts enable the

hypervisor to track the guest mode and verify if desired features are being enabled. When these traps are taken, the new value of the control register is saved in EXITINFO1. CR write traps are only supported for SEV-ES guests.

Note that writes by SEV-ES guests to EFER.SVME are always ignored by hardware.

15.35.11 Interaction with SMI and #MC

If an SMI occurs while an SEV-ES guest is executing, the platform SMI handler is not immediately executed. Instead, the SMI will remain pending and a #VMEXIT(SMI) is generated. The SMI will then be taken in hypervisor context after STGI is executed. Note that this behavior occurs regardless of the value of the SMI intercept bit in the VMCB.

In some systems, machine check errors are first delivered as an SMI. If this occurs while an SEV-ES guest is executing, #VMEXIT(SMI) will be generated and EXITINFO1[MCREDIR] will be set to 1 (“SMI Intercept” on page 507). As described above, the SMI will be held pending until STGI is executed. After the platform SMI handler executes following STGI, the hypervisor should check the MCREDIR bit to determine if the #VMEXIT(SMI) was due to a machine check error in the guest and handle it appropriately.

15.36 Secure Nested Paging (SEV-SNP)

The SEV-SNP features enable additional protection for encrypted VMs designed to achieve stronger isolation from the hypervisor. SEV-SNP is used with the SEV and SEV-ES features described in Section 15.34 and Section 15.35 respectively and requires the enablement and use of these features.

Primarily, SEV-SNP provides integrity protection of VM memory to help prevent hypervisor-based attacks that rely on guest data corruption, aliasing, replay, and various other attack vectors. To achieve this, a new system-wide data structure called the Reverse Map Table (RMP) is used to perform additional security checks on memory access as described in Section 15.36.3.

In addition to memory protection, SEV-SNP also includes several security features including a new Virtual Machine Privilege Level (VMPL) architecture, interrupt injection restrictions, and side-channel protection. These features are designed to enable additional use models and enhanced security protections.

While this chapter describes the CPU hardware behavior of SEV-SNP, the technology also requires the use of the AMD Secure Processor (AMD-SP) SEV-SNP Application Binary Interface (ABI) to manage the lifecycle events of SEV-SNP VMs. See the SEV-SNP ABI specification (PID#56860) on AMD’s website for more details.

15.36.1 Determining Support for SEV-SNP

Support for SEV-SNP can be determined by reading CPUID Fn8000_001F[EAX] as described in Section 15.34.1. Bit 4 indicates support for SEV-SNP, while bit 5 indicates support for VMPLs. The

number of VMPLs available in an implementation is indicated in bits [15:12] of CPUID Fn8000_001F[EBX].

CPUID Fn8000_001F[EAX] also indicates support for additional security features used with SEV-SNP guests, which are described in the following sections.

15.36.2 Enabling SEV-SNP

SEV-SNP depends on SEV for confidentiality protection. Before enabling SEV-SNP, the MemEncryptionModEn bit in MSR C001_0010 (SYSCFG) must be set, and all programming requirements described in Section 15.34.3 must be satisfied. After SecureNestedPagingEn is set to 1 in MSR C001_0010, certain MSRs may no longer be modified. This includes the fixed range MTRR registers (see Section 7.7.2), the IORR registers (see Section 7.9.2), the TOP_MEM and TOP_MEM2 registers (see Section 7.9.4), as well as the SYS_CFG MSR. Attempts to write the SYS_CFG MSR via WRMSR after SecureNestedPagingEn is set to 1 will be ignored while attempts to write the other MSRs mentioned will result in #GP(0).

Enabling SEV-SNP requires a two-step initialization procedure:

1. Construct the Reverse Map Table (RMP) as described in Section 15.36.4.
2. Set VMPLEn and SecureNestedPagingEn in MSR C001_0010 (SYSCFG) on every core in the system.

After the SEV-SNP feature has been globally enabled, SEV-SNP can be activated on a per-VM basis by setting bit 0 of the SEV_FEATURES field at offset 3B0h of the VMSA during VM creation. SEV-SNP activated VMs must also enable SEV-ES as described in Section 15.35.2 and SEV as described in Section 15.34.3.

In this chapter, the term *SNP-enabled* indicates that SEV-SNP is globally enabled in the SYSCFG MSR. The term *SNP-active* indicates that SEV-SNP is enabled for a specific VM in the SEV_FEATURES field of its VMSA. While SNP-enabled systems support both SNP-active and non-SNP-active VMs, SNP-active VMs can only run on SNP-enabled systems.

15.36.3 Reverse Map Table

The Reverse Map Table (RMP) is a structure shared globally by all logical processors that resides in system memory and is used to ensure a one-to-one mapping between system physical addresses and guest physical addresses. Each page of physical memory that is potentially assignable to guests has one entry within the RMP. RMP entries contain the security attributes of the system physical page as described in Table 15-36.

Table 15-36. Fields of an RMP Entry

Name	Notes
Assigned	Flag indicating that the system physical page is assigned to a guest or to the AMD-SP. 0: Owned by the hypervisor 1: Owned by a guest or the AMD-SP
Page_Size	Encoding of the page size. 0: 4KB page 1: 2MB page
Immutable	Flag indicating that software can alter the entry via x86 RMP manipulation instructions. 0: RMP entry can be altered by software 1: RMP entry cannot be altered by software
Guest_Physical_Address	Guest physical address associated with the page
ASID	ASID of guest to which page is assigned
VMSA	Flag indicating that the page is a VMSA page. 0: Non-VMSA page 1: VMSA page
Validated	Flag indicating that the guest has validated the page. See Section 15.36.6 for details. 0: The guest has not yet validated the page 1: The guest validated the page with PVALIDATE
Permissions[0]	VMPL permission masks for the page. See Section 15.36.7 for details.
...	
Permissions[n-1]	

The integrity of the RMP is maintained by restricting software manipulation of it to the following special-purpose instructions:

- RMPUPDATE: Available to the hypervisor to alter the Guest_Physical_Address, Assigned, Page_Size, Immutable, and ASID fields of an RMP entry. See Section 15.36.5 for details.
- PSMASH: Allows the hypervisor to split a 2MB entry in the RMP into 512 4KB entries in the RMP. See Section 15.36.11 for details.
- RMPADJUST: Allows a guest to alter the VMPL permission masks of the RMP entry. See Section 15.36.7 for details.
- PVALIDATE: Allows a guest to write to the Validated flag in the RMP entry. See Section 15.36.6 for details.

When SEV-SNP is globally enabled, it adds more restrictions to page access controls. The hypervisor and the guests use the above instructions to enforce these restrictions on memory accesses. A violation

of memory access restrictions indicated by the RMP will result in an exception. See Section 15.36.10 for details.

15.36.4 Initializing the RMP

MSR C001_0132 (RMP_BASE) defines the system physical address of the first byte of the RMP. The MSR C001_0133 (RMP_END) defines the system physical address of last byte of the RMP. Software must program RMP_BASE and RMP_END identically for each core in the system and before enabling SEV-SNP globally.

RMP_BASE and (RMP_END+1) must be 8KB aligned. The AMD-SP may place further alignment requirements on these registers. Refer to the latest AMD-SP specifications to determine the required alignment.

The region of memory between RMP_BASE and RMP_END contains a 16KB region used for processor bookkeeping followed by the RMP entries, which are each 16B in size. The size of the RMP determines the range of physical memory that the hypervisor can assign to SNP-active virtual machines at runtime. The RMP covers the system physical address space from address 0h to the address calculated by:

((RMP_END + 1 – RMP_BASE – 16KB) / 16B) x 4KB

For example, if the RMP_BASE is equal to 10_0000h, then to cover the first 4GB of physical memory, RMP_END must be set to 110_3FFFh, which makes the RMP just over 16MB.

Once SEV-SNP is globally enabled, memory accesses are restricted by RMP checks. To ensure that the RMP starts in a known and non-restrictive state, software should write zeros to all memory from RMP_BASE to RMP_END before setting the SecureNestedPagingEn bit in the SYSCFG MSR. The hypervisor then requests the AMD-SP to finalize the initialization of the RMP. The AMD-SP initializes the RMP to prevent all software from directly writing to the memory between RMP_BASE and RMP_END. All subsequent RMP entry manipulation must occur either via the x86 RMP manipulation instructions or through interactions with the AMD-SP.

15.36.5 Hypervisor RMP Management

The hypervisor manages the SEV-SNP security attributes of pages assigned to SNP-active guests by altering the RMP entries of those pages. Because the RMP is initialized by the AMD-SP to prevent direct access to the RMP, the hypervisor must use the RMPUPDATE instruction to alter the entries of the RMP. RMPUPDATE allows the hypervisor to alter the Guest_Physical_Address, Assigned, Page_Size, Immutable, and ASID fields of an RMP entry.

SEV-SNP associates an owner with each system physical page through settings of the Assigned, ASID, and Immutable fields of the page's RMP entry according to Table 15-37. A page can be owned by the hypervisor, a guest, or the AMD-SP.

Table 15-37. RMP Page Assignment Settings

Owner	Assigned	ASID	Immutable
Hypervisor	0	0	-
Guest	1	ASID of the guest	-
AMD-SP	1	0	1

When the hypervisor assigns a page to a guest, it must also set the Guest_Physical_Address and Page_Size to match the nested page table mapping for the guest. If not, access to the page by the guest will result in a fault. See Section 15.36.10 for details on the RMP access checks.

The hypervisor may transition any page that has Immutable set to 0 into a hypervisor-owned page by using RMPUPDATE to set Assigned to 0 and ASID to 0. To transition a page that has Immutable set to 1, the hypervisor must request the AMD-SP to transition the page.

The RMP initialization requirement to write zeros to the RMP (see Section 15.36.4) results in all pages in the system initially belonging to the hypervisor. Any memory pages which are not covered by the RMP are considered permanent hypervisor pages. For example, if the RMP is configured to only cover the first 4GB of memory then all memory above 4GB is considered hypervisor memory for the purpose of RMP access checks.

15.36.6 Page Validation

Each page assigned to a VM is either validated or unvalidated, as indicated by the Validated flag in the page's RMP entry. Memory accesses by the VM to private pages that are unvalidated generate a #VC. All pages are initially assigned as unvalidated.

The VM may use the PVALIDATE instruction to either set or clear the Validated flag of a page. It is expected that VMs would use PVALIDATE to set the Validated flag during VM startup to gain access to the memory the hypervisor has assigned. The VM may later use PVALIDATE to clear the Validated flag if its memory space is being reduced, such as after a memory hot-plug event.

Page validation allows a VM to detect an unexpected remapping of its pages by the hypervisor. Before accessing a page, the VM must validate the page. Once validated, any use of RMPUPDATE by the hypervisor to unassign, reassign, or remap the page will cause the page to become unvalidated. The VM can then detect tampering with the page mapping via the #VC that occurs from accessing unvalidated pages.

PVALIDATE takes a page size as an input parameter indicating that either a 4KB or 2MB page should be validated. If the VM attempts to use PVALIDATE on a 4KB page that is mapped to a 2MB or 1GB page in the nested page table, PVALIDATE generates an #VMEXIT(NPF). In this case, the hypervisor can smash the larger page into 4KB pages using the PSMASH instruction as described in Section 15.36.11. If the VM attempts to use PVALIDATE on a 2MB guest page that is mapped to 4KB nested pages, PVALIDATE returns an error indication to the VM. The VM can instead attempt to execute PVALIDATE for each of the 4KB pages individually.

15.36.7 Virtual Machine Privilege Levels

A typical guest VM may consist of multiple vCPUs. SEV-SNP expands on this capability by enabling the vCPUs to run at distinct Virtual Machine Privilege Levels (VMPLs). Within a vCPU, the different VMPLs are represented by unique VMSAs and are expected to be run in a mutually exclusive manner. Each VMSA is assigned a VMPL as indicated by the VMPL field in the VMSA.

VMPLs are identified numerically starting at 0 with VMPL0 being the most privileged. The number of VMPLs available in an implementation is indicated in bits [15:12] of CPUID Fn8000_001F[EBX]. The VMPL feature enables a guest to sub-divide its address space and implement vCPU-specific access controls on a page-by-page basis.

The processor restricts guest memory accesses based on VMPL permission masks in RMP entries. Each RMP entry contains a set of permission masks, one mask for each implemented VMPL. On memory accesses, the processor checks the current VMPL permission mask of the page to determine whether the access is allowed. The permission mask bits are defined in Table 15-38.

Table 15-38. VMPL Permission Mask Definition

Bit	Name	Settings
0	Read	0: Reads cause #VMEXIT(NPF) 1: Reads are allowed
1	Write	0: Writes cause #VMEXIT(NPF) 1: Writes are allowed
2	Execute-User	0: Execution at CPL 3 causes #VMEXIT(NPF) 1: Execution at CPL 3 is allowed
3	Execute-Supervisor	0: Execution at CPL < 3 causes #VMEXIT(NPF) 1: Execution at CPL < 3 is allowed
4-7	Reserved	SBZ

When a guest access results in a #VMEXIT(NPF) due to a VMPL permission violation, an error code bit in EXITINFO1 is set as described in Section 15.36.10. It is illegal to configure a page with VMPL write permissions but not read permissions. A data access to such a page will result in a #VMEXIT(NPF).

When the hypervisor assigns a page to a guest using RMPUPDATE, full permissions are enabled for VMPL0 and are disabled for all other VMPLs. A VM can then use the RMPADJUST instruction to modify the permissions of VMPLs numerically higher than its own. For example, a vCPU executing at VMPL0 could use RMPADJUST to restrict a page of memory to be only read-write but not executable at VMPL1. However, the vCPU executing at VMPL1 could not alter its own permissions or the permissions of VMPL0.

Further, RMPADJUST cannot be used to grant greater permissions than what is allowed by the permission mask for the current VMPL. For example, if VMPL1 attempts to grant write permission to a page to VMPL2, but VMPL1 does not have write permission to the page, RMPADJUST will fail.

15.36.8 Virtual Top-of-Memory

In the VMSA of an SNP-active guest, the VIRTUAL_TOM field designates a 2MB aligned guest physical address called the virtual top of memory. When bit 1 (vTOM) of SEV_FEATURES is set in the VMSA of an SNP-active VM, the VIRTUAL_TOM field is used to determine the C-bit for data accesses instead of the guest page table contents. All data accesses below VIRTUAL_TOM are accessed with an effective C-bit of 1 and all addresses at or above VIRTUAL_TOM are accessed with an effective C-bit of 0. Note that page table accesses and instruction fetches always have an effective C-bit of 1, regardless of the value of VIRTUAL_TOM or whether the feature is enabled.

When virtual top of memory is enabled in SEV_FEATURES, the C-bit in the guest page table entries must be zero for all accesses. Any guest memory accesses with the C-bit set to 1 in the guest page tables will result in a #PF due to a reserved bit error.

15.36.9 Reflect #VC

When running an SEV-SNP VM, the CPU generates #VC exceptions in response to events that may require hypervisor interaction. #VC exceptions and the events that may lead to them are discussed in Section 15.35.5. SEV-SNP VMs may either chose to handle #VC exceptions directly in their current guest context or turn #VC exceptions into Automatic Exits. This behavior is controlled by bit 2 (ReflectVC) of SEV_FEATURES. If this bit is set to 1, then any event that would otherwise lead to a #VC exception is instead turned into an Automatic Exit.

When a #VC is turned into an Automatic Exit, the guest VM terminates with an exit code of VMEXIT_VC. The error code for the #VC, which reflects the event which led to the #VC (e.g., VMEXIT_CPUID), is saved to the GUEST_EXITCODE field in the VMSA. Additional information about the event that caused the #VC is saved to the GUEST_EXITINFO1, GUEST_EXITINFO2, GUEST_EXITINTINFO, and GUEST_NRIP fields in the VMSA. The information saved to these fields is the same as the standard exit information provided for the event that occurred. For example, if the VM performs a port I/O instruction which is marked for interception, the GUEST_EXITCODE field will be set to VMEXIT_IOIO and the GUEST_EXITINFO1 field will contain information about the I/O port access, as defined in Section 15.10.2.

The Reflect #VC feature enables #VC events to be handled by a vCPU at a VMPL other than the one that initiated them. For example, a guest may contain a vCPU which consists of two different VMSAs. One VMSA is defined to execute at VMPL0, while the other has ReflectVC enabled and is defined to execute at VMPL3. When the vCPU running at VMPL3 encounters a #VC condition, the information is saved to its VMSA and control is returned to the hypervisor. The hypervisor may then run the vCPU at VMPL0 which can read the exit information saved to the VMPL3 VMSA, interact with the hypervisor as required, write appropriate response data back into the VMPL3 VMSA, and instruct the hypervisor to resume execution of the vCPU at VMPL3.

If the #VC event occurred during the processing of an interrupt or exception, the GUEST_EXITINTINFO.V bit will be set. If the Alternate Injection feature is enabled (see Section 15.36.15), hardware will automatically set the VINTR_CTL[BUSY] bit in the VMSA. This enables a higher privileged VMPL to re-inject the event that caused the #VC.

The GUEST_EXITCODE, GUEST_EXITINFO1, GUEST_EXITINFO2, GUEST_EXITINTINFO, and GUEST_NRIP fields are populated by hardware on every Automatic Exit, regardless of the ReflectVC feature. For Automatic Exits other than reflected #VC's, these fields are set to the same values that are set in the unencrypted VMCB.

15.36.10 RMP and VMPL Access Checks

When SEV-SNP is enabled globally, the processor places restrictions on all memory accesses based on the contents of the RMP, whether the accesses are performed by the hypervisor, a legacy guest VM, a non-SNP guest VM or an SNP-active guest VM. The processor may perform one or more of the following checks depending on the context of the access:

- RMP-Covered: Checks that the target page is covered by the RMP. A page is covered by the RMP if its corresponding RMP entry is below RMP_END. Any page not covered by the RMP is considered a Hypervisor-Owned page.
- Hypervisor-Owned: Checks that if the target page is covered by the RMP then the Assigned bit of the target page is 0. If the page table entry that specifies the sPA indicates that the target page size is 2MB, then all RMP entries for the 4KB constituent pages of the target page must have the Assigned bit set to 0. Accesses to 1GB pages only install 2MB TLB entries when SEV-SNP is enabled, therefore this check treats 1GB accesses as 2MB accesses for purposes of this check.
- Guest-Owned: Checks that the ASID field of the RMP entry of the target page matches the ASID of the current VM.
- Reverse-Map: Checks that the Guest_Physical_Address of the RMP entry of the target page matches the guest physical address of the translation.
- Validated: Checks that the Validated field of the RMP entry of the target page is 1.
- Mutable: Checks that the Immutable field of the RMP entry of the target page is 0.
- Page-Size: Checks that the following conditions are met:
  - If the nested page table indicates a 2MB or 1GB page size, the Page_Size field of the RMP entry of the target page is 1.
  - If the nested page table indicates a 4KB page size, the Page_Size field of the RMP entry of the target page is 0.
- VMPL: Checks that the VMPL permission mask allows access. See Section 15.36.7 for details.

Table 15-39 describes under which conditions each check is performed and what fault is produced on failure.

Table 15-39. RMP Memory Access Checks

Host/Guest	SNP-Active	Type of Access	C-Bit	Check	Fault
Host	-	Data write, Page Table Access	-	Hypervisor-Owned	#PF
Guest	No	Data write, Page Table Access	-	Hypervisor-Owned	#VMEXIT(NPF)
Guest	Yes	Instruction Fetch, Page Table Access	-	RMP-Covered, Guest-Owned, Reverse-Map, Mutable, Page-Size	#VMEXIT(NPF)
				Validated	#VC
				VMPL	#VMEXIT(NPF)
Guest	Yes	Data write	0	Hypervisor-Owned	#VMEXIT(NPF)
Guest	Yes	Data write, Data read	1	RMP-Covered, Guest-Owned, Reverse-Map, Mutable, Page-Size	#VMEXIT(NPF)
				Validated	#VC
				VMPL	#VMEXIT(NPF)

In addition, any memory access that results in an RMP check may result in an RMP violation (#PF or #VMEXIT(NPF)) if the accessed RMP entries are in use by other logical processors. In this case, software should retry the access.

If a memory access results in a modification of the Accessed or Dirty bits in a page table entry, this page table modification is treated similarly to data write accesses by SEV-SNP. For any such page table modification access, the page size of the access is inherently 4KB.

If the virtual TOM feature (see Section 15.36.8) is enabled, then the Virtual TOM setting is used to determine the C-bit for a given guest access. Guest physical addresses below Virtual TOM are considered to have a C-bit set to 1.

The following page-fault error bits are set on an RMP check related #PF:

- Bit 31 (RMP): Set to 1 if the fault was caused due to an RMP check or a VMPL check failure, 0 otherwise. All RMP violations described in this section will set this bit to 1.

Additionally, the following page-fault error bits may be set on a #VMEXIT(NPF) in EXITINFO1:

- Bit 34 (ENC): Set to 1 if the guest's effective C-bit was 1, 0 otherwise.

- Bit 35 (SIZEM): Set to 1 if the fault was caused by a size mismatch between PVALIDATE or RMPADJUST and the RMP, 0 otherwise.
- Bit 36 (VMPL): Set to 1 if the fault was caused by a VMPL permission check failure, 0 otherwise.

The effective C-bit is always a 1 on any guest instruction fetch, page table access, or data write to private (C=1) memory.

All RMP checks described in this section occur after page table and nested page table access checks and have lower priority than existing paging checks. Table 15-39 reflects the relative priority of RMP checks. Namely, VMPL checks have the lowest priority, preceded by page validation checks. For example, if a guest access fails the Page-Size check and the Validated check, a #VMEXIT(NPF) will occur instead of a #VC since the Page-Size check has priority over the page validation check.

A failure of the page validation check results in a #VC with error code PAGE_NOT_VALIDATED (0x404). The faulting guest virtual address is saved to CR2 when this error occurs.

15.36.11 Large Page Management

The hypervisor may need to convert a 2MB page assigned to a guest into 4KB pages. This conversion is called page smashing and requires the hypervisor to alter the RMP. The hypervisor can use RMPUPDATE to alter the size of the page in the RMP, but this will clear the validated bit.

To convert a 2MB page into 4KB pages without altering the validated status of the region, the hypervisor may use the PSMASH instruction. PSMASH takes a 2MB aligned system physical address and smashes the page while preserving the Validated bit in the RMP. After PSMASH successfully completes, the RMP entries of the resulting 4KB pages have the following contents:

- Consecutive values in the Guest_Physical_Address fields
- Page_Size set to 0 indicating 4KB pages
- All other RMP fields copied from the original 2MB page RMP entry

One reason the hypervisor may need to smash a 2MB page is if the guest executes PVALIDATE or RMPADJUST on a 4KB page that is backed by a 2MB page. In that case, the instructions generate a #VMEXIT(NPF) with the SIZEM bit set in EXITINFO1. To resolve this, the hypervisor can smash the page and then have the guest restart the instruction.

If the guest wishes to validate a 2MB aligned region, the guest should first attempt to execute PVALIDATE with a size of 2MB. If the page is backed by 4KB pages, PVALIDATE terminates with a FAIL_SIZEMISMATCH error. In this case, the guest should then execute PVALIDATE on each 4KB page individually. This allows the guest to take advantage of the more efficient 2MB mappings and avoid having the hypervisor unnecessarily smash the page.

Table 15-40 summarizes the potential page size mismatches and how to resolve them.

Table 15-40. PVALIDATE/RMPADJUST Page Size Mismatch Combinations

Requested Page Size	Page Size in RMP	Error Condition	Recommended Handling
4KB	2MB	#VMEXIT(NPF)	PSMASH
2MB	4KB	FAIL_SIZEMISMATCH	Guest retries on each 4KB constituent page

The reverse operation of converting a set of consecutive 4KB pages into a single 2MB page requires assistance from either the guest or the AMD-SP to ensure that the operation is safe to perform.

15.36.12 Running SNP-Active Virtual Machines

As with SEV-ES guests, SNP-active guests are described by a hypervisor controlled VMCB and a guest encrypted VMSA. The initial VMSA for an SNP-active guest must be set up through coordination with the AMD-SP, the details of which are beyond the scope of this manual. This includes the initial configuration of the SEV_FEATURES field in the VMSA which indicates which guest security features are enabled for that particular VM instance. VMRUN to an SNP-active guest will fail with a VMEXIT_INVALID error code if SEV-SNP is not globally enabled.

VMRUN Checks. When SEV-SNP is globally enabled on a system, the VMRUN instruction performs additional security checks on various memory pages. These checks are similar to the ones described in Section 15.36.10. Note that where a check depends on page size, a page size of 4KB is used. In addition to the checks described in that section, an additional check exists:

- VMSA: Checks that the VMSA field in the RMP entry equals 1.

The VMSA field in an RMP entry may be set by the AMD-SP, or by a vCPU running at VMPL0 using the RMPADJUST instruction.

The checks performed on VMRUN are as follows:

Table 15-41. VMRUN Page Checks

Page Type	SNP-Active	Check	Fault
VMCB	-	Hypervisor-Owned	#GP(0)
AVIC Backing Page	-	Hypervisor-Owned	#VMEXIT(VMEXIT_INVALID)
VMSA	No	Hypervisor-Owned	#VMEXIT(VMEXIT_INVALID)
VMSA	Yes	RMP-Covered Guest-Owned Reverse-Map Mutable VMSA	#VMEXIT(VMEXIT_INVALID)

The AVIC Logical Table, AVIC Physical Table, IOPM_BASE_PA, MSRPM_BASE_PA, and nCR3 are not checked by VMRUN as these structures are only read by the hardware.

After a successful VMRUN, the VMCB page, as well as any AVIC Backing Page and VMSA Page are marked as in-use by hardware, and any attempt to modify the RMP entries for these pages via instructions like RMPUPDATE will result in a FAIL_INUSE response. The in-use marking is automatically cleared by hardware after a #VMEXIT event.

Other Checks. In addition to the RMP checks performed by VMRUN, a few other VM-related operations perform special RMP checks.

The address written to the VM_HSAVE_PA MSR, which holds the address of the page used to save the host state on a VMRUN, must point to a hypervisor-owned page. If this check fails, the WRMSR will fail with a #GP(0) exception. Note that a value of 0 is not considered valid for the VM_HSAVE_PA MSR and a VMRUN that is attempted while the HSAVE_PA is 0 will fail with a #GP(0) exception.

The VMSAVE instruction also performs checks to ensure that the target page is hypervisor-owned. The VMSAVE instruction is not expected to be used with SEV-ES and SNP-active guests, as described in Section 15.36.8, but may be used with other guests.

If VMSAVE is executed in host mode and the target page fails the RMP check, a #GP(0) exception is generated. If VMSAVE is executed in a guest when the VMSAVE instruction is virtualized (see Section 15.33.1) and the target page fails the RMP check, then a #VMEXIT(NPF) is generated indicating an RMP permission error. In processors that support SEV-SNP, the execution of the VMSAVE instruction inside an SEV-ES or SNP-active guest is not supported and will result in a #VMEXIT(VMSAVE).

Intercept Behavior. All port I/O (IN, INS, OUT, OUTS) and CPUID instructions executed by an SNP-Active guest are treated as intercepted regardless of the intercept bits set in the VMCB and IOPM. Execution of these instructions in an SNP-Active guest will unconditionally generate a Non-Automatic Exit.

15.36.13 Debug Registers

SEV-ES and SNP-active guests may choose to enable full virtualization of CPU debug registers through SEV_FEATURES bit 5 (DebugSwap).

When enabled, the DR[0-3] registers and DR[0-3]_ADDR_MASK registers are swapped as type ‘B’ state (see Appendix B). Note that the DR6 and DR7 registers are always swapped as type ‘A’ state for any SEV guest.

15.36.14 Memory Types

When an SNP-active guest accesses memory, the hardware forces the use of coherent memory types. This prevents the hypervisor from attempting to corrupt guest memory by the use of non-coherent memory types for accesses by the guest.

If a guest memory access is determined to be non-coherent after the memory type determination logic described in Section 15.25.8, the hardware forces a coherent type as described in Table 15-42.

Table 15-42. Non-Coherent Memory Type Conversion

Non-Coherent Memory Type	Forced Coherent Memory Type
UC	CD
WC	WC+

15.36.15 TLB management

For non-SNP-active guests, when a hypervisor moves a VMSA to a new logical processor it must ensure that the VMSA cannot use any stale (incorrect) TLB translations to prevent corruption of the guest. For SNP-active guests, to avoid any dependency on the hypervisor for correctly managing guest TLB contents, the hardware detects when the VMSA is moved and manages the TLB for that guest automatically. The hardware uses two VMSA fields to track this information: the TLB_ID (byte offset 3D0h) and the PCPU_ID (byte offset 3D8h).

During guest creation, software should initialize the TLB_ID and PCPU_ID by setting both to zero. The hardware subsequently manages the values in both fields throughout the lifetime of that VMSA. During operation, software may explicitly write PCPU_ID to 0 to force a TLB flush on the next VMRUN to that VMSA if desired. If this occurs, the hardware will set the PCPU_ID field to a non-zero value when it flushes the TLB.

For example, when guest software performs an RMPADJUST to alter the permissions of a VMPL, it may need to ensure that the existing TLB entries of all vCPUs executing at the targeted VMPL are not used anymore. The guest software can do this by writing zero to PCPU_ID of the affected VMSAs. When these VMSAs are re-entered with VMRUN, the hardware will ensure existing TLB entries are no longer used and set PCPU_ID to a non-zero value. This value can be checked for non-zero by the guest software to ensure the operation has completed before proceeding.

As with any guest, the hypervisor may use the TLB_CONTROL field in the VMCB to force TLB flushes when desired. When the hypervisor writes 3h or 7h to TLB_CONTROL, both global and non-global TLB entries of the guest are invalidated.

15.36.16 Interrupt Injection Restrictions

SNP-active guests may choose to enable the Restricted Injection or Alternate Injection features through SEV_FEATURES bits 3 and 4 respectively. These features enforce additional interrupt and event injection security protections designed to help protect against malicious injection attacks. The two are mutually exclusive for a specific VMSA and an attempt to enable both will result in a #VMEXIT(VMEXIT_INVALID) when the VMSA is run.

Restricted Injection Operation. This feature disables all hypervisor-based interrupt queuing and event injection of all vectors except a new exception vector, #HV (28), which is reserved for SNP guest use, but never generated by hardware. #HV is only allowed to be injected into VMSAs that

execute with Restricted Injection. #HV is a benign exception and can only be injected as an exception (VMCB.EVENTINJ[Type]=3) and without an error code. Guests running with Restricted Injection are expected to communicate with the hypervisor about events via a software-managed para-virtualization interface. This interface can use #HV injection as a doorbell to inform the guest that new events have been added.

The VMRUN instruction with Restricted Injection enabled will fail with a VMEXIT_INVALID error code if the hypervisor attempts the injection of any unsupported event or attempts to run the guest with AVIC enabled.

Alternate Injection Operation. This feature replaces all hypervisor-based interrupt queuing and event injection with guest-controlled queuing and injection. When this is enabled on a VMSA, event injection information on VMRUN is read from the EventInjCtrl field in the VMSA (offset 3E0h) and interrupt queuing information is read from the VIntrCtrl field in the VMSA (offset 3B8h). This feature is intended to be used in a multi-VMPL architecture where a high privilege VMSA injects events and interrupts directly into a low privilege VMSA by writing to its encrypted VMSA.

When Alternate Injection is enabled, the EventInjCtlr field in the unencrypted VMCB (offset A8h) is ignored on VMRUN. The VIntrCtrl field in the unencrypted VMCB (offset 70h) is processed, but only the V_INTR_MASKING, Virtual GIF Mode, and AVIC Enable bits are used. The AVIC Enable bit must be 0 if the guest is running with Alternate Injection enabled, otherwise the VMRUN will fail with a VMEXIT_INVALID error code.

The remaining fields of VIntrCtrl (V_TPR, V_IRQ, VGIF, V_INTR_PRIO, V_IGN_TPR, V_INTR_VECTOR) are read exclusively from the encrypted version in the VMSA. Additionally, bit 10 of the encrypted VIntrCtrl field is defined as the INT_SHADOW bit and the unencrypted INT_SHADOW bit in VMCB offset 68h bit 0 is ignored. On a VMEXIT, the V_TPR, V_IRQ, and INT_SHADOW values are written back to the encrypted VIntrCtrl only.

In guests that run with Alternate Injection, bit 63 of the encrypted VIntrCtrl field is defined as a BUSY bit. On VMRUN, if VIntrCtrl[BUSY] is set to 1, then the VMRUN fails with a VMEXIT_BUSY error code. The BUSY bit enables a VMSA to be temporarily marked non-runnable while software modifications are in progress.

Additional Intercept Behavior. Additional hardware-forced intercept behavior exists in guests that run with either of these features enabled:

- For either feature, hardware treats physical INTR, NMI, INIT, and #MC events as intercepted regardless of the intercept bit set in the VMCB.
- Under Alternate Injection, any MSR access to the x2APIC MSR range (MSR 0x800-0x8FF) by the guest is intercepted regardless of the MSR_PROT intercept and MSR protection bitmap. In this case, the interception behavior is the same as what would occur if the MSR bitmap indicated an interception of the corresponding MSR.

15.36.17 Side-Channel Protection

SEV-SNP provides optional protections against certain side channel attacks.

Branch Target Buffer Isolation

SNP-active guests may choose to enable the Branch Target Buffer Isolation mode through SEV_FEATURES bit 7 (BTBIsolation). The Branch Target Buffer (BTB) is an internal CPU structure that is used when predicting indirect branches, and SNP-active guests may choose to impose additional restrictions on it in order to help prevent certain types of speculative execution-based side channels.

When executing an SNP-active guest when BTB Isolation is enabled, CPU hardware will ensure that no code outside of that guest context is able to influence the BTB-based predictions performed by hardware within the guest. Hardware tracks the source of prediction information in the BTB and may flush BTB contents when required to maintain this isolation.

In hardware that supports BTB Isolation, new BTB prediction information is never written if SPEC_CTRL[IBRS] is enabled in the current context. Therefore, it is recommended that non-guest software that executes temporarily (e.g., hypervisor exit handling code) run with SPEC_CTRL[IBRS] set to 1. This ensures that indirect branch information from that context is not stored in the BTB and may avoid the need for a BTB flush when guest execution is resumed.

Instruction Based Sampling

SEV-ES and SNP-active guests may choose to disallow the use of Instruction Based Sampling (IBS) by the hypervisor in order to limit the information that may be gathered about their execution. Guests may enable this restriction through SEV_FEATURES bit 6 (PreventHostIBS). When a VMRUN is executed on a guest that has enabled this protection, the IbsFetchCtl[IbsFetchEn] and IbsOpCtl[IbsOpEn] MSR bits must be 0. If either of these bits are not 0 then the VMRUN will fail with a VMEXIT_INVALID error code.

VMSA Register Protection

SNP-active guests may choose to enable the VMSA Register Protection feature through SEV_FEATURES bit 14 (VmsaRegProt). When an Automatic Exit occurs and this feature is enabled, CPU hardware will obfuscate the values of certain registers before they are written to the VMSA. The hardware will then deobfuscate these values on a subsequent VMRUN. This obfuscation may help prevent certain types of side channel attacks on the encrypted VMSA ciphertext.

The obfuscation is performed with a bit-wise XOR operation between the register value and an 8B nonce. The nonce value is stored in the VMSA and is updated in a pseudo-random manner by the CPU hardware on every Automatic Exit. When initializing a new VMSA, it is recommended that the nonce is set to a random value.

The specific VMSA fields which are obfuscated when this feature is enabled may vary by implementation. More information about this may be found in the AMD-SP SEV-SNP ABI specification.

15.36.18 Secure TSC

SNP-active guests may choose to enable the Secure TSC feature through SEV_FEATURES bit 9 (SecureTscEn). When enabled, Secure TSC changes the guest view of the Time Stamp Counter when read by the guest via either the TSC MSR, RDTSC, or RDTSCP instructions. The TSC value is first scaled with the GUEST_TSC_SCALE value from the VMSA and then is added to the VMSA GUEST_TSC_OFFSET value. The P0 frequency, TSC_RATIO (C001_0104h) and TSC_OFFSET (VMCB offset 50h) values are not used in the calculation.

The GUEST_TSC_SCALE is an 8.32 fixed point binary number which is composed of 8 bits of integer and 32 bits of fraction. The AMD-SP SEV-SNP ABI specification provides additional information about the Secure TSC feature and initialization of GUEST_TSC_SCALE.

Guests that run with Secure TSC enabled may read the GUEST_TSC_FREQ MSR (C001_0134h) which returns the effective frequency in MHz of the guest view of TSC. This MSR is read-only and attempting to write the MSR or read it when outside of a guest with Secure TSC enabled causes a #GP(0) exception.

Guests that run with Secure TSC enabled are not expected to perform writes to the TSC MSR (10h). If such a write occurs, subsequent TSC values read are undefined.

15.37 SPEC_CTRL Hypervisor Model

A hypervisor may wish to impose speculation controls on guest execution or a guest may want to impose its own speculation controls. Therefore, the processor implements both host and guest versions of SPEC_CTRL. The presence of this feature is indicated by CPUID Fn8000_000A_EDX[20]=1.

When in host mode, the host SPEC_CTRL value is in effect and writes update only the host version of SPEC_CTRL. On a VMRUN, the processor loads the guest version of SPEC_CTRL from the VMCB. For most guests, processor behavior is controlled by the logical OR of the two registers. When the guest writes SPEC_CTRL, only the guest version is updated. On a VMEXIT, the guest version is saved into the VMCB and the processor returns to only using the host SPEC_CTRL for speculation control.

SNP-active guests with BTB isolation enabled behave differently (see section 15.36.17). For these guests the host value of IBRS does not override the guest value.

16 Advanced Programmable Interrupt Controller (APIC)

The Advanced Programmable Interrupt Controller (APIC) provides interrupt support on AMD64 architecture processors. The local APIC accepts interrupts from the system and delivers them to the local CPU core interrupt handler.

Support for APIC is indicated by CPUID Fn0000_0001_EDX[APIC] = 1. For information on using the CPUID instruction to obtain processor implementation information, see Section 3.3, “Processor Feature Identification,” on page 71.

The APIC block diagram is provided in Figure 16-1.

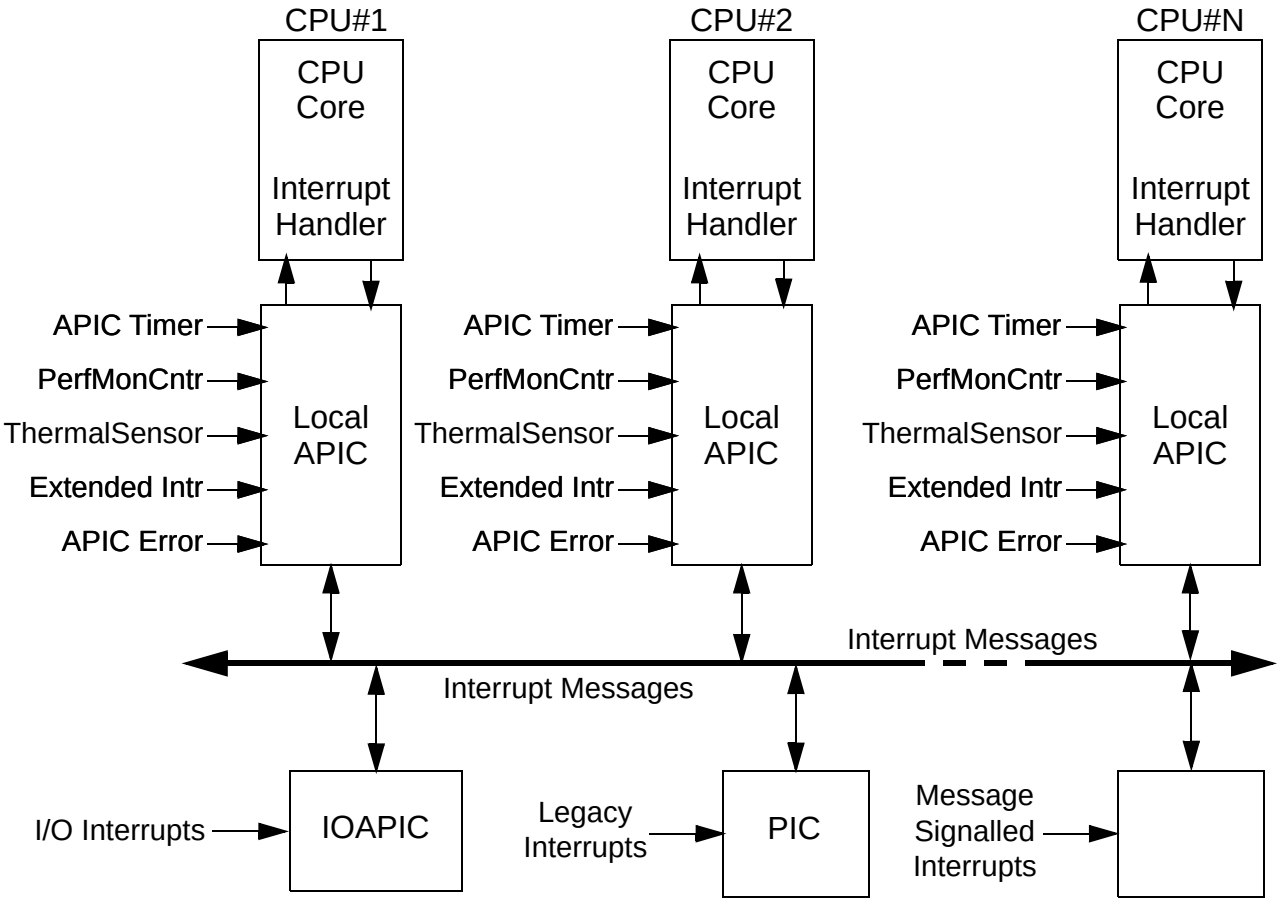

Figure 16-1. Block Diagram of a Typical APIC Implementation

16.1 Sources of Interrupts to the Local APIC

Each CPU core has an associated local APIC which receives interrupts from the following sources:

- I/O interrupts from the IOAPIC interrupt controller (including LINT0 and LINT1)
- Legacy interrupts (INTR and NMI) from the legacy interrupt controller
- Message Signalled Interrupts
- Interprocessor Interrupts (IPIs) from other local APICs. Interprocessor Interrupts are used to send interrupts or to execute system wide functions between CPU cores in the system, including the originating CPU core (self-interrupt).
- Locally generated interrupts within the local APIC. The local APIC receives local interrupts from the APIC timer, Performance Monitor Counters, thermal sensors, APIC errors and extended interrupts from implementation specific sources.

The sources of interrupts for the local APIC are provided in Table 16-1.

Table 16-1. Interrupt Sources for Local APIC

Source	Description	Message Type to Local APIC
I/O interrupts	System interrupts from I/O devices or system hardware received through the I/O APIC and sent to the local APIC as interrupt messages. They may be edge-triggered or level-sensitive.	Fixed, Lowest Priority, SMI, NMI, INIT, STARTUP, External interrupt, LINT0, LINT1
Legacy Interrupts	Legacy interrupts (INT and NMI) from the PIC and sent to the local APIC as interrupt messages.	NMI, INT
Interprocessor (IPI)	Interprocessor interrupts. Used for interrupt forwarding, system-wide functions, or software self-interrupts.	Fixed, lowest priority, SMI, read request, NMI, INIT, STARTUP, External interrupt
APIC Timer	Local interrupt from the programmed APIC timer reaches zero, under control of TIMER_LVT.	Fixed
Performance Monitor Counter	Local interrupt from the performance monitoring counter when it overflows, under control of PERF_CNT_LVT.	Fixed, SMI, or NMI
Thermal Sensor	Local interrupt from internal thermal sensors when it has tripped, under control of THERMAL_LVT.	Fixed, SMI, or NMI
Extended Interrupt[3:0]	Local Interrupts from programmable internal CPU core sources, under the control of the EXTENDED_INTERRUPT[3:0]_LVT.	Fixed, SMI, NMI, or External interrupt
APIC Internal Error	Local interrupt when an error is detected within the local APIC, under control of ERROR_LVT.	Fixed, SMI, or NMI

16.2 Interrupt Control

I/O, legacy, and interprocessor interrupts are sent via interrupt messages. The interrupt messages contain the following information:

- Destination address of the local APIC.
- VECTOR[7:0] indicating interrupt priority of up to 256 interrupt vectors. This information is captured in the IRR register for Fixed and Lowest Priority interrupt message types.
- Trigger Mode indicating edge triggered or level-sensitive (which requires an EOI response to the source).
- Message Type[3:0] indicating the type of interrupt to be presented to the local APIC. For Fixed and Lowest Priority message types, the interrupt is processed through the target local APIC. For all other message types, the interrupt is sent directly to the destination CPU core. There is a 5-line interrupt interface to the CPU core for INTR, SMI, NMI, INIT and STARTUP interrupts. For locally-generated interrupts, control is provided by local vector tables or LVTs. Separate LVTs are provided for each interrupt source, allowing for a unique entry point for each source. The LVT contains the VECTOR[7:0], trigger mode and message type as well as other fields associated with the specific interrupt. The message type may be Fixed, SMI, NMI, or External interrupt. A Mask bit is also provided to mask the interrupt.

16.3 Local APIC

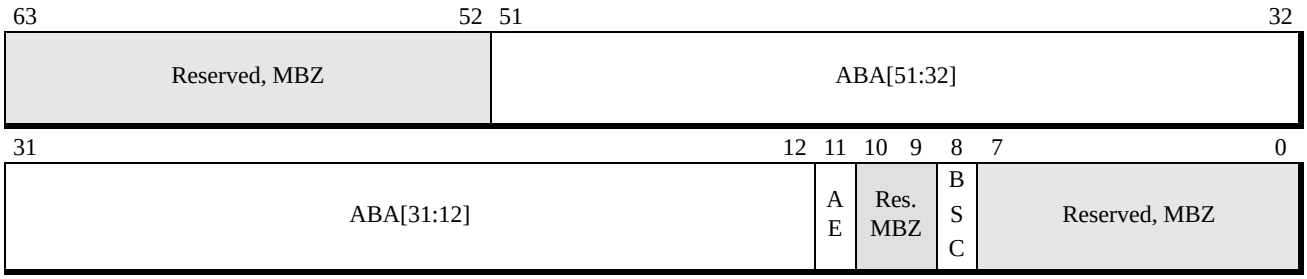
16.3.1 Local APIC Enable

The local APIC is controlled by the APIC enable bit (AE) in the APIC Base Address Register (MSR 0000_001Bh). See Figure 16-2 on page 604.

When AE is set to 1, the local APIC is enabled and all interrupt types are accepted. When AE is cleared to 0, the local APIC is disabled, including all local vector table interrupts.

Software can disable the local APIC, using the APIC_SW_EN bit in the Spurious Interrupt Vector Register (APIC_F0). When this bit is cleared to zero, the local APIC is temporarily disabled:

- SMI, NMI, INIT, Startup, and Remote Read interrupts may be accepted.
- Pending interrupts in the ISR and IRR are held.
- Further fixed, lowest-priority, and ExtInt interrupts are not accepted.
- All LVT entry mask bits are set and cannot be cleared.



Bits	Mnemonic	Description	Access Type
63:52	—	Reserved, MBZ	
51:12	ABA	APIC Base Address	R/W
11	AE	APIC Enable	R/W
8	BSC	Boot Strap CPU Core	RO
7:0	Reserved	Reserved, Must be Zero	

Figure 16-2. APIC Base Address Register (MSR 0000_001Bh)

The fields within the APIC Base Address register are as follows:

- *Boot Strap CPU Core (BSC)*—Bit 8. The BSC bit indicates that this CPU core is the boot core of the BSP. Each CPU core that is not the boot core of the boot processor is an AP (Application Processor).
- *APIC Enable (AE)*—Bit 11. This is the APIC enable bit. The local APIC is enabled and all interruption types are accepted when AE is set to 1. Clearing AE to 0 disables the local APIC, and no local vector table interrupts are supported.
- *APIC Base Address (ABA)*—Bits 51:12. Specifies the base physical address for the APIC register set. The address is extended by 12 bits at the least-significant end to form the 52-bit physical base address. The reset value of the APIC base address is 0_0000_FEE0_0000h. This address is not affected by INIT.

Note that a given processor may implement a physical address less than 52 bits in length.

16.3.2 APIC Registers

The system programming interface of the local APIC is made up of the registers listed in Table 16-2 below. All APIC registers are memory-mapped into the 4-Kbyte APIC register space, and are accessed with memory reads and writes. The memory address is indicated as:

APIC Register address = APIC Base Address + Offset

where the APIC Base Address must point to an uncacheable memory region, and is located in APIC Base Address Register, MSR 0000_001Bh. See Figure 16-2.

APIC registers are aligned to 16-byte offsets and must be accessed using naturally-aligned DWORD size read and writes. All other accesses cause undefined behavior.

The table includes the value of each register after reset and INIT.

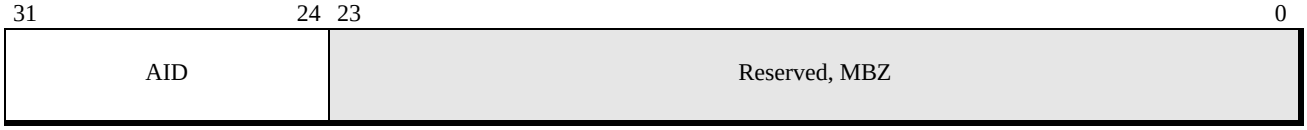
Table 16-2. APIC Registers

Offset	Name	Reset
20h	APIC ID Register	??000000h
30h	APIC Version Register	80??0010h
80h	Task Priority Register (TPR)	00000000h
90h	Arbitration Priority Register (APR)	00000000h
A0h	Processor Priority Register (PPR)	00000000h
B0h	End of Interrupt Register (EOI)	–
C0h	Remote Read Register	00000000h
D0h	Logical Destination Register (LDR)	00000000h
E0h	Destination Format Register (DFR)	FFFFFFFF
F0h	Spurious Interrupt Vector Register	000000FFh
100-170h	In-Service Register (ISR)	00000000h
180-1F0h	Trigger Mode Register (TMR)	00000000h
200-270h	Interrupt Request Register (IRR)	00000000h
280h	Error Status Register (ESR)	00000000h
300h	Interrupt Command Register Low (bits 31:0)	00000000h
310h	Interrupt Command Register High (bits 63:32)	00000000h
320h	Timer Local Vector Table Entry	00010000h
330h	Thermal Local Vector Table Entry	00010000h
340h	Performance Counter Local Vector Table Entry	00010000h
350h	Local Interrupt 0 Vector Table Entry	00010000h
360h	Local Interrupt 1 Vector Table Entry	00010000h
370h	Error Vector Table Entry	00010000h
380h	Timer Initial Count Register	00000000h
390h	Timer Current Count Register	00000000h
3E0h	Timer Divide Configuration Register	00000000h
400h	Extended APIC Feature Register	00040007h
410h	Extended APIC Control Register	00000000h
420h	Specific End of Interrupt Register (SEOI)	–
480-4F0h	Interrupt Enable Registers (IER)	FFFFFFFFh
500-530h	Extended Interrupt [3:0] Local Vector Table Registers	00000000h

16.3.3 Local APIC ID

Unique local APIC IDs are assigned to each CPU core in the system. The value is determined by hardware, based on the number of CPU cores on the processor and the node ID of the processor.

The APIC ID is located in the APIC ID register at APIC offset 20h. See Figure 16-3. It is model dependent, whether software can modify the APIC ID Register. The initial value of the APIC ID (after a reset) is the value returned in CPUID function 0000_0001h_EBX[31:24].



Bits	Mnemonic	Description	R/W
31:24	AID	APIC ID	R/W
23:0	—	Reserved, MBZ	

Figure 16-3. APIC ID Register (APIC Offset 20h)

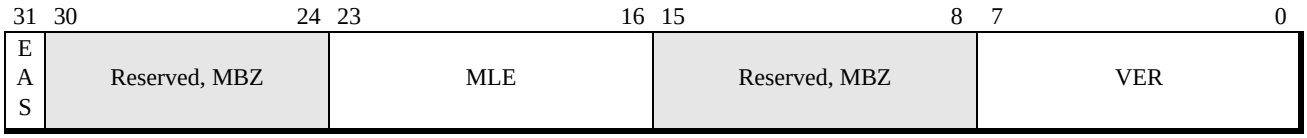
- *APIC ID (AID)*—Bits 31:24. The APIC ID field contains the unique APIC ID value assigned to this specific CPU core. A given implementation may use some bits to represent the CPU core and other bits represent the processor.

16.3.4 APIC Version Register

A version register is provided to allow software to identify which APIC version is used. Bits 7:0 of the APIC Version Register indicate the version number of the APIC implementation.

The number of entries in the local vector table are specified in bits 23:16 of the register as the maximum number minus one.

Bit 31 indicates the presence of extended APIC registers which have an offset starting at 400h.



Bits	Mnemonic	Description	R/W
31	EAS	Extended APIC Register Space Present	RO
30:24	—	Reserved, MBZ	
23:16	MLE	Max LVT Entries	RO
15:8	—	Reserved, MBZ	
7:0	VER	Version	RO

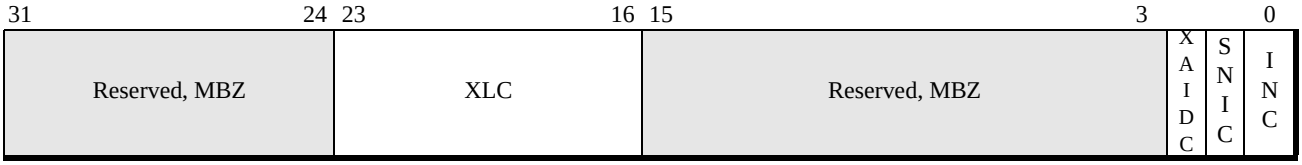
Figure 16-4. APIC Version Register (APIC Offset 30h)

The fields within the APIC Version register are as follows:

- *Version (VER)*—Bits 7:0. The VER field indicates the version number of the APIC implementation. The local APIC implementation is identified with a value=1Xh (20h-FFh are reserved).
- *Max LVT Entries (MLE)*—Bits 23:16. The MLE field specifies the number of entries in the local vector table minus one.
- *Extended APIC Register Space Present (EAS)*—Bit 31. The EAS bit when set to 1 indicates the presence of an extended APIC register space, starting at offset 400h.

16.3.5 Extended APIC Feature Register

The Extended APIC Feature Register indicates the number of extended Local Vector Table registers in the local APIC, whether the Interrupt Enable Registers are present, and whether the 8-bit Extended APIC ID and Specific End Of Interrupt (SEOI) Register are supported.



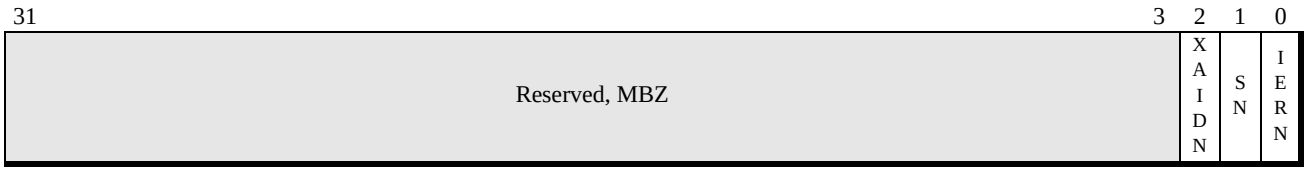
Bits	Mnemonic	Description	R/W
31:24	Reserved	Reserved, Must be Zero	
23:16	XLC	Extended LVT Count	RO
15:3	Reserved	Reserved, Must be Zero	
2	XAIDC	Extended APIC ID Capable	RO
1	SNIC	Specific End of Interrupt Capable	RO
0	INC	Interrupt Enable Register Capable	RO

Figure 16-5. Extended APIC Feature Register (APIC Offset 400h)

- Extended LVT Count (XLC)—(Bits 23:16) Specifies the number of extended local vector table registers in the local APIC.
- Extended APIC ID Capability (XAIDC)—(Bit 2) Indicates that the processor is capable of supporting an 8-bit APIC ID.
- Specific End of Interrupt Capable—(Bit 1) Indicates that the Specific End Of Interrupt Register is present.
- Interrupt Enable Register Capable—(Bit 0) Read-only. Indicates that the Interrupt Enable Registers are present.

16.3.6 Extended APIC Control Register

This bit enables writes to the interrupt enable registers.



Bits	Mnemonic	Description	R/W
31:3	—	Reserved, MBZ	
2	XAIDN	Extended APIC ID Enable.	R/W
1	SN	Enable SEOI Generation	R/W
0	IERN	Enable Interrupt Enable Registers	R/W

Figure 16-6. Extended APIC Control Register (APIC Offset 410h)

- Extended APIC ID Enable (XAIDN)—Bit 2. Setting XAIDN to 1 enables the upper four bits of the APIC ID field described in “APIC ID Register (APIC Offset 20h)” on page 606. Clearing this bit, specifies a 4-bit APIC ID using only the lower four bits of the APIC ID field of the APIC ID register.
- Enable SEOI Generation (SN)—Bit 1. Read-write. This bit enables Specific End of Interrupt (SEOI) generation when a write to the specific end of interrupt register is received.
- Enable Interrupt Enable Registers (IERN)—Bit 0. This bit enables writes to the interrupt enable registers.

16.4 Local Interrupts

The local APIC handles the following local interrupts:

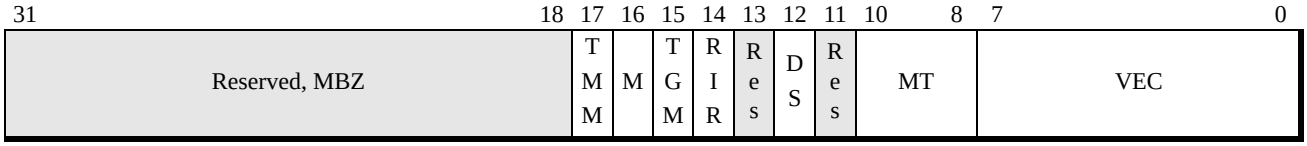
- APIC Timer
- Local Interrupt 0 (LINT0)
- Local Interrupt 1 (LINT1)
- Performance Monitor Counters
- Thermal Sensors
- APIC internal error
- Extended (Implementation dependent)

A separate entry in the local vector table is provided for each interrupt to allow software to specify:

- Whether the interrupt is masked or not.
- The delivery status of the interrupt.
- The message type.
- The unique address vector.
- For LINT0 and LINT1 interrupts, the trigger mode, remote IRR, and input pin polarity.

- For the APIC timer interrupt, the timer mode.

The general format of a Local Vector Table Register is shown in Figure 16-7.



Bits	Mnemonic	Description	R/W
31:18	—	Reserved, MBZ	
17	TMM	Timer Mode	R/W
16	M	Mask	R/W
15	TGM	Trigger Mode	R/W
14	RIR	Remote IRR	RO
13	—	Reserved, MBZ	
12	DS	Delivery Status	RO
11	—	Reserved, MBZ	
10:8	MT	Message Type	R/W
7:0	VEC	Vector	R/W

Figure 16-7. General Local Vector Table Register Format

The fields within the General Local Vector Table register are as follows:

- *Vector (VEC)*—Bits 7:0. The VEC field contains the vector that is sent for this interrupt source when the message type is fixed. It is ignored when the message type is NMI and is set to 00h when the message type is SMI. Valid values for the vector field are from 16 to 255. A value of 0 to 15 when the message type is fixed results in an illegal vector APIC error.
- *Message Type (MT)*—Bits 10:8. The MT field specifies the delivery mode sent to the CPU core interrupt handler. The legal values are:
  - 000b = Fixed - The vector field specifies the interrupt delivered.
  - 010b = SMI - An SMI interrupt is delivered. In this case, the vector field should be set to 00h.
  - 100b = NMI - A NMI interrupt is delivered with the vector field being ignored.
  - 111b = External interrupt is delivered.
- *Delivery Status (DS)*—Bit 12. The DS bit indicates the interrupt delivery status. The DS bit is set to 1 when the interrupt is pending at the CPU core interrupt handler. After a successful delivery of the interrupt, the associated bit in the IRR is set and this bit is cleared to zero. See Section 16.6.2, “Lowest Priority Messages and Arbitration,” on page 620 for details. The bit is cleared to 0 when the interrupt is idle.
- *Remote IRR (RIR)*—Bit 14. The RIR bit is set to 1 when the local APIC accepts an LINT0 or LINT1 interrupt with the trigger mode=1 (level sensitive). The bit is cleared to 0 when the interrupt completes, as indicated when an EOI is received.

- *Trigger Mode (TGM)*—Bit 15. Specifies how interrupts to the local APIC are triggered. The TGM bit is set to 1 when the interrupt is level-sensitive. It is cleared to 0 when the interrupt is edge-triggered. When the message type is SMI or NMI, the trigger mode is edge triggered.
- *Mask (M)*—Bit 16. When the M bit is set to 1, reception of the interrupt is disabled. When the M bit is cleared to 0, reception of the interrupt is enabled.
- *Timer Mode (TMM)*—Bit 17. Specifies the timer mode for the APIC Timer interrupt. The TMM bit set to 1 indicates periodic timer interrupts. The TMM bit cleared to 0 indicates one-shot operation.

16.4.1 APIC Timer Interrupt

The APIC timer is a programmable 32-bit counter used by software to time operations or events. The timer can operate in two modes, periodic and one-shot, under the control of bit 17 (Timer Mode) in APIC Timer Local Vector Table Register (see Figure 16-8). In both modes, the APIC timer is set to a programmable initial value and starts to decrement at a programmable clock rate. When the Initial Count Register is written to a non-zero value, the APIC timer is initialized to the value just written and starts decrementing. When the Initial Count Register is written to zero, the APIC timer is initialized to zero and stops decrementing. In one-shot mode, the APIC timer stops counting when the timer reaches zero. In periodic mode, the APIC timer is initialized again when it reaches zero, and it starts to decrement again. Whenever the timer value is decremented to zero, an APIC timer interrupt is generated under the control of bit 16 (Mask) in the APIC Timer Local Vector Table Register.

To avoid race conditions, software should initialize the Divide Configuration Register and the Timer Local Vector Table Register prior to writing the Initial Count Register to start the timer.

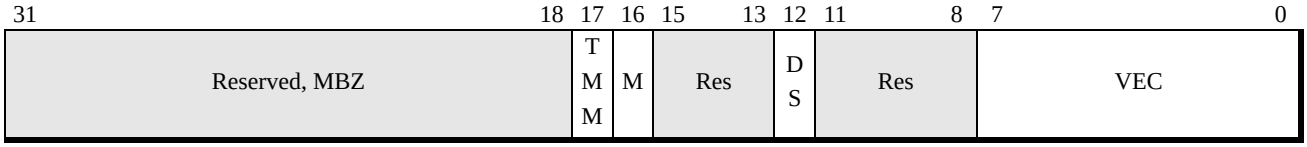


Figure 16-8. APIC Timer Local Vector Table Register (APIC Offset 320h)

Three APIC registers are defined for the APIC timer function:

- Current Count Register (CCR) is the actual APIC timer. Whenever the ICR is written to a non-zero value, or when the CCR reaches zero while in periodic mode, it is initialized to a start count loaded from the ICR and then decrements. The APIC timer interrupt is generated when the CCR value reaches zero. The counting rate is controlled by the DCR. See Figure 16-9.
- Initial Count Register (ICR) provides the initial value for the APIC timer. See Table 16-10.
- Divide Configuration Register (DCR) controls the counting rate of the APIC timer by dividing the CPU core clock by a programmable amount. See Figure 16-11. For the specific details on the implementation of the APIC timer base clock rate, see the *BIOS and Kernel Developer's Guide (BKDG)* or *Processor Programming Reference Manual* applicable to your product.

Bits	Mnemonic	Description	R/W
31:0	APICTCC	APIC Timer Current Count	RO

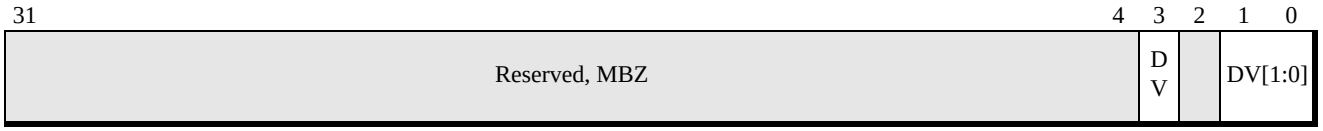
Figure 16-9. Timer Current Count Register (APIC Offset 390h)

- *APIC Timer Current Count (APICTCC)*—Bits 31:0. The APICTCC field contains the current value of the APIC timer.

Bits	Mnemonic	Description	R/W
31:0	APICTIC	APIC Timer Initial Count	R/W

Figure 16-10. Timer Initial Count Register (APIC Offset 380h)

- *APIC Timer Initial Count (APICTIC)*—Bits 31:0. The APICTIC field contains the value that is loaded into the APIC Timer Current Count Register when the APIC timer is initialized.



Bits	Mnemonic	Description	R/W
31:4	—	Reserved, MBZ	
3	DV[2]	Divide Value[2]	R/W
2	—	Reserved, MBZ	
1:0	DV[1:0]	Divide Value[1:0]	R/W

Figure 16-11. Divide Configuration Register (APIC Offset 3E0h)

- *Divide Value (DV)*—Bits 3, 1:0. The DV field specifies the value of the CPU core clock divisor. Table 16-3 lists the allowable values.

Table 16-3. Divide Values

Bits 3, 1:0	Resulting Timer Divide
000b	Divide by 2
001b	Divide by 4
010b	Divide by 8
011b	Divide by 16
100b	Divide by 32
101b	Divide by 64
110b	Divide by 128
111b	Divide by 1

16.4.2 Local Interrupts LINT0 and LINT1

When the target local APIC receives an interrupt message from an IOAPIC with the LINT0 or LINT1 message type, the appropriate local interrupt is generated under the control of bit 16 (Mask) in the APIC LINT0 or LINT1 Local Vector Table Register. See Figure 16-12.

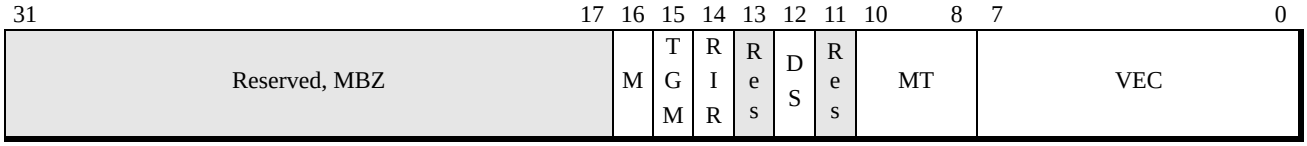


Figure 16-12. Local Interrupt 0/1 (LINT0/1) Local Vector Table Register (APIC Offset 350h/360h)

In addition to the normal LVT control bits (mask, delivery status and vector offset), the LINT0/LINT1 interrupts provide the following controls:

- Trigger Mode - indicates whether the interrupt pin is edge triggered or level sensitive when the message type is fixed.
- Remote IRR - When the trigger mode indicates level, this flag is set when the local APIC accepts the interrupt, and is reset when the local APIC receives an EOI. When the flag is set, no additional local interrupt requests are sent to the local APIC, and they remain pending.

16.4.3 Performance Monitor Counter Interrupts

When a performance monitor counter overflows, an APIC interrupt is generated under the control of bit 16 (Mask) in the APIC Performance Monitor Counter Local Vector Table Register. See Figure 16-13 on page 613.

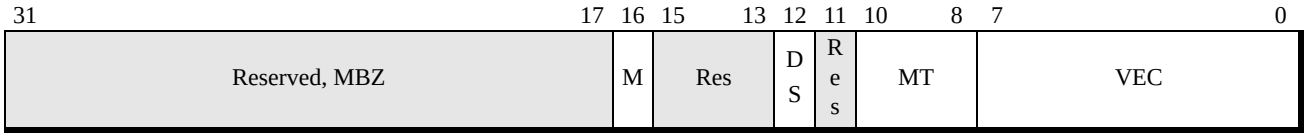

Figure 16-13. Performance Monitor Counter Local Vector Table Register (APIC Offset 340h)

16.4.4 Thermal Sensor Interrupts

When a thermal event occurs, an APIC interrupt is generated under the control of bit 16 (Mask) in the APIC Thermal Sensor Local Vector Table Register. See Figure 16-14. See the *BIOS and Kernel Developer's Guide (BKDG)* or *Processor Programming Reference Manual* applicable to your product for more information on thermal events. This interrupt may not be supported in all implementations.

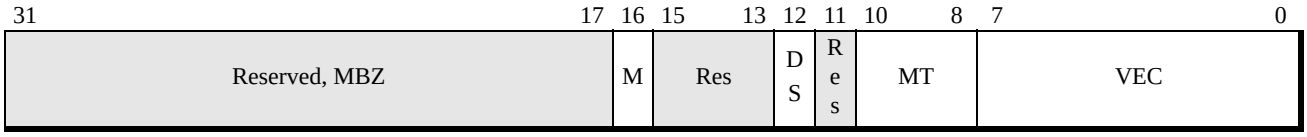

Figure 16-14. Thermal Sensor Local Vector Table Register (APIC Offset 330h)

16.4.5 Extended Interrupts

The local interrupts are extended to include more LVT registers, to allow additional interrupt sources. The additional sources are model dependent and can include:

- Counter overflow from the Machine Check Miscellaneous Threshold Register. See "Machine-Check Miscellaneous-Error Information Register 0 (MC*i*_MISC0)" on page 302 for details.
- ECC Error Count Threshold in memory system.
- Instruction Sampling.

The LVT register used for each interrupt source is specified by the control register associated with the source.

The Extended LVT Count field (bits 23:16) of the Extended APIC Feature Register specifies the number of extended LVT registers. Currently there are four additional LVT registers defined, Extended Interrupt [3:0], Local Vector Table Register, located at APIC offsets 500h–530h. (See Section 16.7.1, "Specific End of Interrupt Register," on page 627 and Figure 16-5 on page 607.)

16.4.6 APIC Error Interrupts

Errors that are detected while handling interrupts cause an APIC error interrupt to be generated under the control of bit 16 (Mask) in the APIC Error Local Vector Table Register. See Figure 16-15 on page 614.

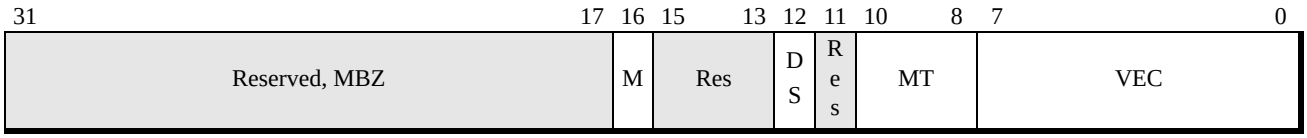

Figure 16-15. APIC Error Local Vector Table Register (APIC Offset 370h)

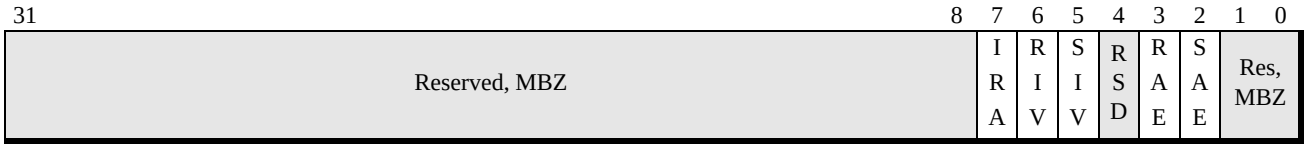
The error information is recorded in the APIC Error Status Registers. The APIC Error Status Register is a read-write register. Writes to the register cause the internal error state to be recorded in the register, clearing the original error. See Figure 16-16.



Bits	Mnemonic	Description	R/W
31:8	—	Reserved, MBZ	
7	IRA	Illegal Register Address	R/W
6	RIV	Received Illegal Vector	R/W
5	SIV	Sent Illegal Vector	R/W
4	—	Reserved, MBZ	
3	RAE	Receive Accept Error	R/W
2	SAE	Sent Accept Error	R/W
1:0	—	Reserved, MBZ	

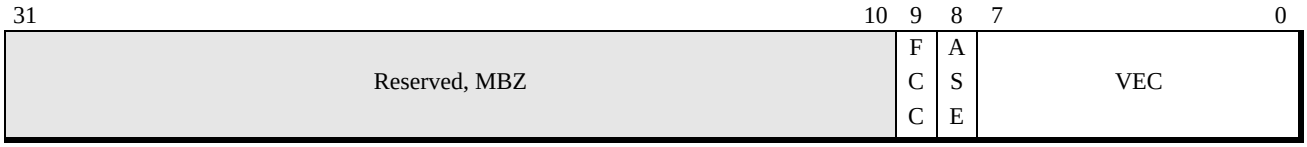
Figure 16-16. APIC Error Status Register (APIC Offset 280h)

The fields within the APIC Error Status register are as follows:

- *Sent Accept Error (SAE)*—Bit 2. The SAE bit when set to 1 indicates that a message sent by the local APIC was not accepted by any other APIC.
- *Receive Accept Error (RAE)*—Bit 3. The RAE bit when set to 1 indicates that a message received by the local APIC was not accepted by this or any other APIC
- *Sent Illegal Vector (SIV)*—Bit 5. The SIV bit when set to 1 indicates that the local APIC attempted to send a message with an illegal vector value.
- *Receive Illegal Vector (RIV)*—Bit 6. The RIV bit when set to 1 indicates that the local APIC has received a message with an illegal vector value.
- *Illegal Register Address (IRA)*—Bit 7. The IRA bit when set to 1 indicates that an access to an unimplemented register location within the local APIC register range (APIC Base Address + 4 Kbytes) was attempted.

16.4.7 Spurious Interrupts

A timing issue exists between software and hardware that, though rare, results in spurious interrupts. In the event that the task priority is set to or above the level of the interrupt to be serviced while the interrupt is being acknowledged, the local APIC delivers a spurious interrupt to the CPU core instead, with the vector number specified by the Vector field of the Spurious Interrupt Register. The ISR is unaffected by the spurious interrupt, so the interrupt handler completes without sending an EOI back to the issuing local APIC.



Bits	Mnemonic	Description	R/W
31:10	Reserved	Reserved, Must be Zero	
9	FCC	Focus CPU Core Checking	R/W
8	ASE	APIC Software Enable	R/W
7:0	VEC	Vector	R/W

Figure 16-17. Spurious Interrupt Register (APIC Offset F0h)

The fields within the Spurious Interrupt register are as follows:

- *Vector (VEC)*—Bits 7:0. The VEC field contains the vector that is sent to the CPU core in the event of a spurious interrupt.
- *APIC Software Enable (ASE)*—Bit 8. The ASE bit when set to 0 disables the local APIC temporarily. When the local APIC is disabled, SMI, NMI, INIT, Startup, and Remote Read may be accepted; pending interrupts in the ISR and IRR are held, but further fixed, lowest-priority, and ExtInt interrupts are not accepted. All LVT entry mask bits are set and cannot be cleared. Setting the ASE bit to 1, enables the local APIC.
- *Focus CPU Core Checking (FCC)*—Bit 9. The FCC bit when set to 1 disables focus CPU core checking when the lowest-priority message type is used. A CPU core is the focus of an interrupt if it is already servicing that interrupt (ISR=1) or if it has a pending request for that interrupt (IRR=1). Clearing the FCC bit to 0 disables focus CPU core checking.

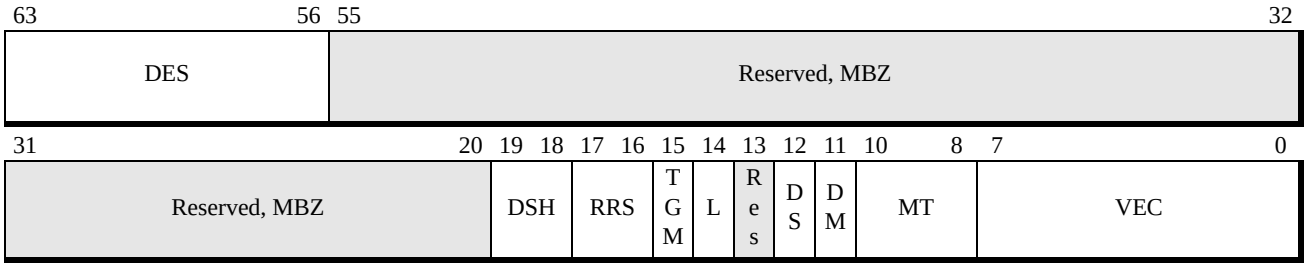
16.5 Interprocessor Interrupts (IPI)

A local APIC can send interrupts to other local APICs (or itself) using software-initiated Interprocessor Interrupts (IPIs) using the Interrupt Command Register (ICR). Writing into the low order doubleword of the ICR causes the IPI to be sent.

The ICR can issue the following types of interrupt messages:

- basic interrupt message to another local APIC, including forwarding an interrupt that was received but not serviced
- basic interrupt message to the same local APIC (self-interrupt)
- system management interrupt (SMI)
- remote read message to another local APIC to read one of its APIC registers.
- non-maskable interrupt (NMI) delivered to another local APIC
- initialization message (INIT) to a target local APIC to be reset to their INIT state and await a STARTUP IPI.
- startup message (SIPI) to the target local APICs, pointing to a start-up routine.

The format of the Interrupt Command Register is shown in Figure 16-18.



Bits	Mnemonic	Description	R/W
63:56	DES	Destination	R/W
55:20	—	Reserved, MBZ	
19:18	DSH	Destination Shorthand	R/W
17:16	RRS	Remote Read Status	RO
15	TGM	Trigger Mode	R/W
14	L	Level	R/W
13	—	Reserved, MBZ	
12	DS	Delivery Status	RO
11	DM	Destination Mode	R/W
10:8	MT	Message Type	R/W
7:0	VEC	Vector	R/W

Figure 16-18. Interrupt Command Register (APIC Offset 300h–310h)

The fields within the Interrupt Command register are as follows:

- *Vector (VEC)*—Bits 7:0. The function of this field varies with the Message Type field. The VEC field contains the vector that is sent for this interrupt source for fixed and lowest priority message types.
- *Message Type (MT)*—Bits 10:8. The MT field specifies the message type sent to the CPU core interrupt handler. The legal values are:
  - 000b = Fixed - The IPI delivers an interrupt to the target local APIC specified in Destination field.

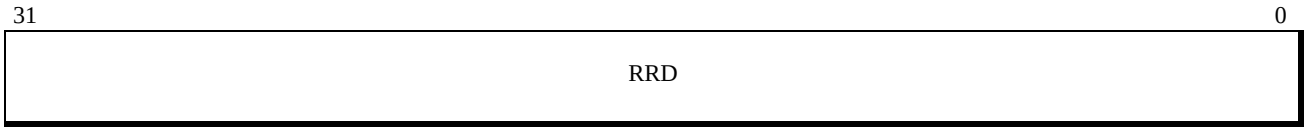
- 001b = Lowest Priority - The IPI delivers an interrupt to the local APIC executing at the lowest priority of all local APICs that match the destination logical ID specified in the Destination field. See Section 16.6.1, “Receiving System and IPI Interrupts,” on page 619.
- 010b = SMI - The IPI delivers an SMI interrupt to target local APIC(s). The trigger mode is edge-triggered and the Vector field must = 00h.
- 011b = Remote read - The IPI delivers a read request to read an APIC register in the target local APIC specified in Destination field. The trigger mode is edge triggered and the Vector field specifies the APIC offset of the APIC register to be read. The Remote Status field provides the current status of the remote read access after it has been issued. Data is returned from the target local APIC and captured in the Remote Read Register of the issuing local APIC. See Figure 16-19 on page 618.
- 100b = NMI - The IPI delivers a non-maskable interrupt to the target local APIC specified in the Destination field. The Vector field is ignored.
- 101b = INIT - The IPI delivers an INIT request to the target local APIC(s) specified in the Destination field, causing the CPU core to assume the INIT state. The trigger mode is edge-triggered, and the Vector field must =00h. In the INIT state, the target APIC is responsive only to the STARTUP IPI. All other interrupts (including SMI and NMI) are held pending until the STARTUP IPI has been accepted.
- 110b = STARTUP - The IPI delivers a start-up request (SIPI) to the target local APIC(s) specified in Destination field, causing the CPU core to start processing the platform firmware boot-strap routine whose address is specified by the Vector field.
- 111b = External interrupt - The IPI delivers an external interrupt to the target local APIC specified in Destination field. The interrupt can be delivered even if the APIC is disabled.

- *Destination Mode (DM)*—Bit 11. The DM bit when set to 1 specifies a logical destination which may be one or more local APICs with a common destination logical ID. When cleared to 0, the DM bit specifies a physical destination which indicates a single local APIC ID.
- *Delivery Status (DS)*—Bit 12. The DS bit indicates the interrupt delivery status. The DS bit is set to 1 when the local APIC has sent the IPI and is waiting for it to be accepted by another local APIC (the ICR is not idle). Clearing the DS bit indicates that the target local APIC is idle. Code may repeatedly write ICRL without polling the DS bit; all requested IPIs will be delivered.
- *Level (L)*—Bit 14. The L bit when set to 1 indicates assert. Clearing the L bit to 0 indicates deassert.
- *Trigger Mode (TGM)*—Bit 15. Specifies how IPIs to the local APIC are triggered. The TGM bit is set to 1 when the interrupt is level-sensitive. It is cleared to 0 when the interrupt is edge-triggered.
- *Remote Read Status (RRS)*—Bits 17:16. The RRS field indicates the current read status of a Remote Read from another local APIC. The encoding for this field is as follows:
  - 00b = Read was invalid
  - 01b = Delivery pending
  - 10b = Delivery done and access was valid. Data available in Remote Read Register.

- 11b = Reserved

- *Destination Shorthand (DSH)*—Bits 19:18. The DSH field indicates whether a shorthand notation is used, and provides a quick way to specify a destination for a message. It replaces the Destination field, when the destination field is not required (DSH > 00b), allowing software to use a single write to the low order ICR. The encoding are as follows:
  - 00b = Destination - The Destination field is required to specify the destination.
  - 01b = Self - The issuing APIC is the only destination.
  - 10b = All including self - The IPI is sent to all local APICs including itself (destination field=FFh).
  - 11b = All excluding self - The IPI is sent to all local APICs except itself (destination field=FFh).

    Note that if the lowest priority is used, the message could end up being reflected back to this local APIC. If DS=1xb, the destination mode is ignored and physical is automatically used.
- *Destination (DES)*—Bits 63:56. The DES field identifies the target local APIC(s) for the IPI and contains the destination encoding used when the Destination Shorthand field=00b. The field indicates the target local APIC when the destination mode=0 (physical), and the destination logical ID (as indicated by LDR and DFR) when the destination mode=1 (logical).



Bits	Mnemonic	Description	R/W
31:0	RRD	Remote Read Data	RO

Figure 16-19. Remote Read Register (APIC Offset C0h)

- *Remote Read Data (RRD)*—Bits 31:0. The RRD field contains the data resulting from a valid completion of a remote read interprocessor interrupt.

Not all combinations of ICR fields are valid. Only the combinations indicated in Table 16-4 are valid.

Table 16-4. Valid ICR Field Combinations

Message Type	Trigger Mode	Level	Destination Shorthand
Fixed	Edge	x	x
	Level	Assert	x
Lowest Priority, SMI, NMI, INIT	Edge	x	Destination or all excluding self.
	Level	Assert	Destination or all excluding self
Startup	x	x	Destination or all excluding self

Note: *x indicates a don't care.*

16.6 Local APIC Handling of Interrupts

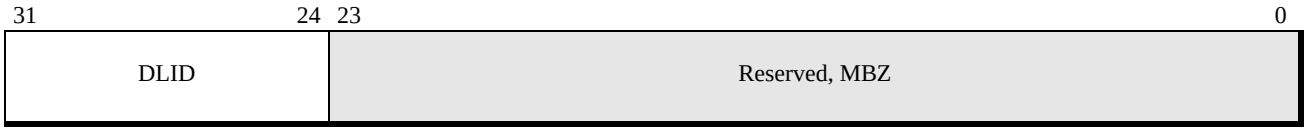
16.6.1 Receiving System and IPI Interrupts

Each local APIC verifies the destination ID, the destination mode and the message type of an APIC interrupt to determine if it is the target of the interrupt.

The destination mode is either physical or logical. In physical destination mode, the value of the interrupt message destination field is compared with the unique APIC ID value of each local APIC to select the target local APIC. If the destination field of the Interrupt Command Register is set to FFh, the interrupt is broadcasted and accepted by all local APICs. In physical destination mode, the lowest priority message type is not supported.

In logical destination mode, all local APICs use the Logical Destination Register and the Destination Format Register to determine if the interrupt is directed to them. The value of the interrupt message destination field is compared with the value in the Logical Destination Register (see Figure 16-20) of all local APICs.

The logical APIC ID must be unique. Since the comparison with the interrupt message destination field is on a bit-basis, there are only 8 unique logical IDs (01h, 02h, 04h, 08h, 10h, 20h, 40h, and 80h). For flat mode, the logical ID must be one of these values (for a total of eight local APICs supported). In cluster mode, the value of the logical ID is constrained to be *xy*h, where $0 \leq x \leq$ Eh and *y* = either 1,2,4, or 8, for a total of (15 × 4) possible unique logical IDs.

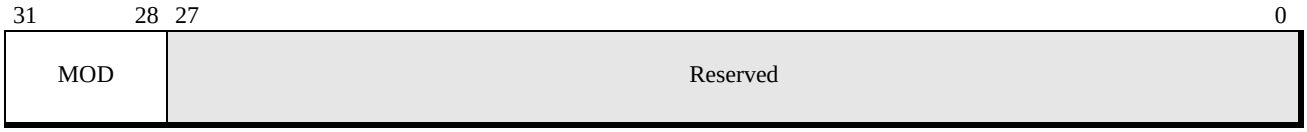


Bits	Mnemonic	Description	R/W
31:24	DLID	Destination Logical ID	R/W
23:0	—	Reserved, MBZ	

Figure 16-20. Logical Destination Register (APIC Offset D0h)

- *Destination Logical ID (DLID)*—Bits 31:24. The DLID field contains the logical APIC ID assigned to this specific CPU core. The logical APIC ID must be unique.

Two interrupt models are defined for the logical destination mode, the flat model and the cluster model, under the control of the Destination Format Register. See Figure 16-21.



Bits	Mnemonic	Description	R/W
31:28	MOD	Model	R/W
27:0	—	Reserved (all ones)	R

Figure 16-21. Destination Format Register (APIC Offset E0h)

- *Model (MOD)*—Bits 31:28. The MOD field controls which format to use when accepting interrupts in logical destination mode. The allowable values are 0h = cluster model and Fh = flat model.

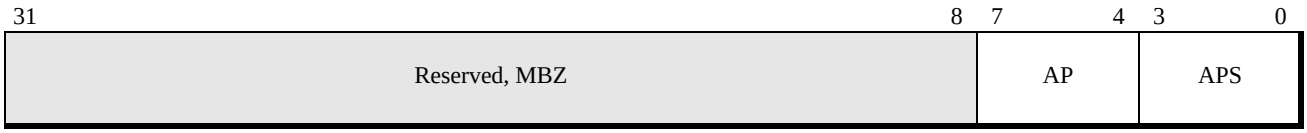
With the flat model, up to eight unique logical APIC ID values can be provided by software by setting a different bit in the LDR. When the logical ID of the destination is compared with the LDR, if any bit position is set in both fields, this local APIC is a valid destination. A broadcast to all local APICs occurs when the LDR is set to all ones.

In the cluster model, bits 31:28 of the logical ID of the destination are compared with bits 31:28 of the LDR. If there is a match, then bits 27:24 are tested for matching ones, similar to the flat model. If bits 31:28 match, and any of bits 27:24 are set in both fields, this local APIC is a valid destination. The cluster model allows for 15 unique clusters to be defined, with each cluster having four unique logical APIC values to be addressed. In cluster logical destination mode, lowest priority message type is not supported.

In both the flat model and the cluster model, if the destination field = FFh, the interrupt is accepted by all local APICs.

16.6.2 Lowest Priority Messages and Arbitration

In the case where the interrupt is valid for several local APICs in logical destination mode with a lowest priority message type, the interrupt is accepted by the local APIC with the lowest arbitration priority, as indicated by the *Arbitration Priority* field in the Arbitration Priority Register (APR). The value in the *Arbitration Priority* field indicates the current priority for a pending interrupt or task, or an interrupt being serviced by the CPU core. See Figure 16-22.



Bits	Mnemonic	Description	R/W
31:8	—	Reserved, MBZ	
7:4	AP	Arbitration Priority	RO
3:0	APS	Arbitration Priority Sub-class	RO

Figure 16-22. Arbitration Priority Register (APIC Offset 90h)

The fields within the Arbitration Priority register are as follows:

- *Arbitration Priority Sub-class (APS)*—Bits 3:0. The APS field indicates the current sub-priority to handle arbitrated interrupts to be serviced by the CPU core.
- *Arbitration Priority (AP)*—Bits 7:4. The AP field indicates the current priority to handle arbitrated interrupts to be serviced by the CPU core. The priority is used to arbitrate between CPU cores to determine which core accepts a lowest-priority interrupt request.

The value in the Arbitration Priority field is equal to the highest priority of the Task Priority field of the Task Priority Register (TPR), the highest bit set in the In-Service Register (ISR) vector, or the highest bit set in the Interrupt Request Register (IRR) vector. The value in the Arbitration Priority Sub-class field is equal to the Task Priority Sub-class if the APR is equal to the TPR, and zero otherwise.

If focus CPU core checking is enabled (Spurious Interrupt Register bit 9=0), the focus CPU core for an interrupt can always accept the interrupt. A CPU core is the focus of an interrupt if it is already servicing that interrupt (corresponding ISR bit is set) or if it already has a pending request for that interrupt (corresponding IRR bit is set). If there is no focus CPU core for an interrupt or if focus CPU core checking is disabled (Spurious Interrupt Register bit 9=1), all target local APICs identified as candidates for the interrupt arbitrate to determine which is executing with the lowest arbitration priority. If there is a tie for lowest priority, the local APIC with the highest APIC ID is selected.

16.6.3 Accepting System and IPI Interrupts

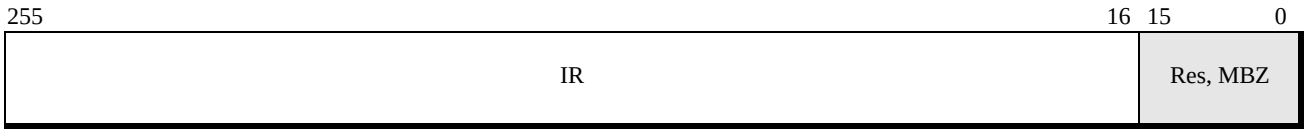
If the local APIC accepting the interrupt determines that the message type for the interrupt request indicates SMI, NMI, INIT, STARTUP or ExtINT, it sends the interrupt directly to the CPU core for handling. If the message type is fixed or lowest priority, the accepting local APIC places the interrupt into an open slot in either the IRR or ISR registers. If there is no free slot, the interrupt is rejected and sent back to the sender with a retry request.

Three 256-bit acceptance registers support interrupts accepted by the local APIC. Bits 255:16 correspond to interrupt vectors 255:16 with 255 being the highest priority; bits 15:0 are reserved.

- Interrupt Request Register (IRR), which contains interrupt requests that have been accepted but have not been sent to the CPU core for interrupt handling. When a system interrupt is accepted, the associated bit corresponding to the interrupt vector is set in the IRR. When the CPU core requests a

new interrupt, the local APIC selects the highest priority IRR interrupt and sends it to the CPU core. The local APIC then sets the corresponding bit in the ISR and resets the associated IRR bit. See Figure 16-23 on page 622.

- In-Service Register (ISR) contains the bit map of the interrupts that have been sent to the CPU core and are still being serviced. When the CPU core writes to the EOI register indicating completion of the interrupt processing, the associated ISR bit is reset and a new interrupt is selected from the IRR register. If a higher priority interrupt is accepted by the local APIC while the CPU core is servicing another interrupt, the higher priority interrupt is sent directly to the CPU core (before the current interrupt finishes processing) and the associated IRR bit is set. The CPU core interrupts the current interrupt handler to service the higher priority interrupt. When the interrupt handler for the higher priority interrupt completes, the associated IRR bit is reset and the interrupt handler returns to complete the previous interrupt handler routine. If a second interrupt with the same interrupt vector number is received by the local APIC while the ISR bit is set, the local APIC sets the IRR bit. No more than two interrupts can be pending for the same interrupt vector number. Subsequent interrupt requests to the same interrupt vector number will be rejected. See Figure 16-24 on page 623.
- Trigger Mode Register (TMR) indicates the trigger mode of the interrupt and determines whether an EOI message is sent to the I/O APIC for level-sensitive interrupts. When the interrupt is accepted by the local APIC and the IRR bit is set, the associated TMR bit is set for level-sensitive interrupts or reset for edge-triggered interrupts. At the end of the interrupt handler routine, when the EOI is received at the local APIC, an EOI message is sent to the I/O APIC if the associated TMR bit is set for a system interrupt. See Figure 16-25 on page 624.

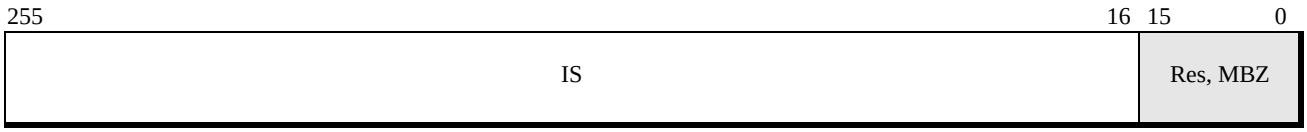


Bits	Mnemonic	Description	R/W
255:16	IR	Interrupt Request bits	RO
15:0	—	Reserved, MBZ	

Figure 16-23. Interrupt Request Register (APIC Offset 200h–270h)

- *Interrupt Request bits (IR)*—Bits 255:16. The corresponding request bit is set when an interrupt is accepted by the local APIC. The interrupt request registers provide a bit per interrupt to indicate that the corresponding interrupt has been accepted by the local APIC. Interrupts are mapped as follows:

Register	Interrupt Number
IRR (APIC offset 200h)	31–16
IRR (APIC offset 210h)	63–32
IRR (APIC offset 220h)	95–64
IRR (APIC offset 230h)	127–96
IRR (APIC offset 240h)	159–128
IRR (APIC offset 250h)	191–160
IRR (APIC offset 260h)	223–192
IRR (APIC offset 270h)	255–224

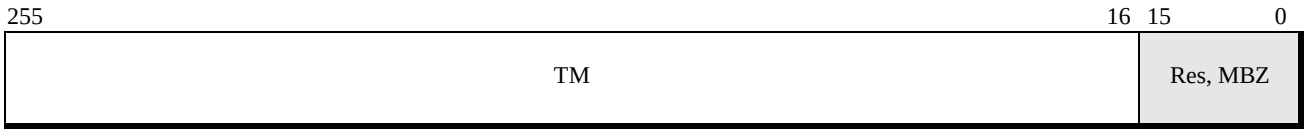


Bits	Mnemonic	Description	R/W
255:16	IS	In Service bits	RO
15:0	—	Reserved, MBZ	

Figure 16-24. In Service Register (APIC Offset 100h–170h)

- *In Service bits (IS)*—Bits 255:16. These bits are set when the corresponding interrupt is being serviced by the CPU core. The in-service registers provide a bit per interrupt to indicate that the corresponding interrupt is being serviced by the CPU core. Interrupts are mapped as follows:

Register	Interrupt Number
ISR (APIC offset 100h)	31–16
ISR (APIC offset 110h)	63–32
ISR (APIC offset 120h)	95–64
ISR (APIC offset 130h)	127–96
ISR (APIC offset 140h)	159–128
ISR (APIC offset 150h)	191–160
ISR (APIC offset 160h)	223–192
ISR (APIC offset 170h)	255–224



Bits	Mnemonic	Description	R/W
255:16	TM	Trigger Mode bits	RO
15:0	—	Reserved, MBZ	

Figure 16-25. Trigger Mode Register (APIC Offset 180h–1F0h)

- *Trigger Mode bits (TM)*—Bits 255:16. These bits provide a bit per interrupt to indicate the assertion mode of each interrupt. Interrupts are mapped as follows:

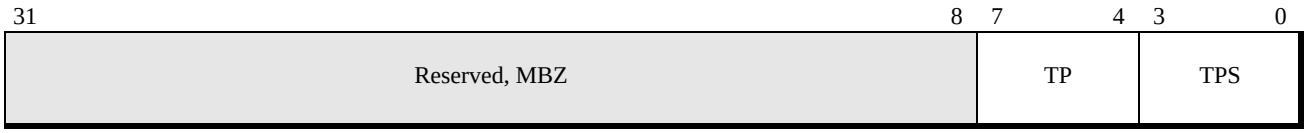
Register	Interrupt Number
TMR (APIC offset 180h)	31–16
TMR (APIC offset 190h)	63–32
TMR (APIC offset 1A0h)	95–64
TMR (APIC offset 1B0h)	127–96
TMR (APIC offset 1C0h)	159–128
TMR (APIC offset 1D0h)	191–160
TMR (APIC offset 1E0h)	223–192
TMR (APIC offset 1F0h)	255–224

16.6.4 Selecting and Handling Interrupts

Interrupts are selected by the local APIC for delivery to the CPU core interrupt handler on a priority determined by the interrupt vector number. Of the 15 priority levels, 15 is the highest and 1 is the lowest. The priority level for an interrupt is equal to the interrupt vector number divided by 16, rounded down to the nearest integer, with vectors 0Fh–00h reserved. Therefore, interrupt vectors 79h and 70h have the same priority level. The high-order hex digit indicates the priority level while the low-order hex digit indicates the priority within the same priority level.

Two registers are used to determine the priority threshold for selecting interrupts to be delivered to the CPU core, the Task Priority Register (TPR) and the Processor Priority Register (PPR). Software uses the TPR to set a priority threshold for interrupts to the CPU core, allowing the OS to block specific interrupts. See Figure 16-26 on page 625 for more details on the TPR.

The value in the *Task Priority* field is set by software to set a threshold priority at which the processor is to be interrupted. The value varies from 0 (all interrupts are allowed) to 15 (all interrupts with fixed delivery mode are inhibited). See Figure 16-26.



Bits	Mnemonic	Description	R/W
31:8	—	Reserved, Must be Zero	
7:4	TP	Task Priority	R/W
3:0	TPS	Task Priority Sub-class	R/W

Figure 16-26. Task Priority Register (APIC Offset 80h)

The fields within the Task Priority register are as follows:

- *Task Priority Sub-class (TPS)*—Bits 3:0. The TPS field indicates the current sub-priority to be used when arbitrating lowest-priority messages. This field is written with zero when TPR is written using the architectural CR8 register.
- *Task Priority (TP)*—Bits 7:4. The TP field indicates the current priority to be used when a core is deciding when to handle interrupts. A value of zero allows all interrupts; a value of Fh disables all interrupts. TP is also used to arbitrate between CPU cores to determine which core accepts a lowest-priority interrupt request. This field can also be written using the architectural CR8 register.

The PPR is set by the CPU core and represents the current priority level at which the CPU core is executing. The PPR determines whether a pending interrupt in the local APIC can be selected for interrupt handling in the CPU core. The value set by hardware is either the interrupt priority level of the highest priority ISR bit set or the value in the TPR, whichever is higher. The PPR is equal to the TPR when the CPU core is not servicing a higher priority interrupt. See Figure 16-27 on page 625.

Bits	Mnemonic	Description	R/W
31:8	—	Reserved, MBZ	
7:4	PP	Processor Priority	RO
3:0	PPS	Processor Priority Sub-class	RO

Figure 16-27. Processor Priority Register (APIC Offset A0h)

The fields within the Processor Priority register are as follows:

- *Processor Priority Sub-class (PPS)*—Bits 3:0. The PPS field is set to the Task Priority sub-class field of the Task Priority Register (TPR) if the PP field is equal to the Task Priority field of the TPR.
- *Processor Priority (PP)*—Bits 7:4. The PP field indicates the CPU core's current priority for servicing a task or interrupt, and is used to determine if any pending interrupts should be serviced.

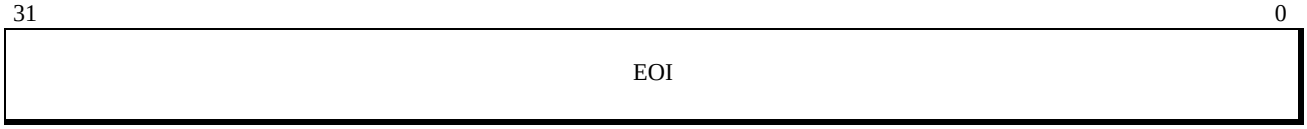
It is the higher value of either the interrupt priority level of the highest priority ISR bit set or the value in the TPR.

Pending interrupts must have a higher priority level than the value in the PPR to be selected by the local APIC for interrupt handling in the core; otherwise, they remain pending in the IRR until the PPR is lowered below the pending interrupt priority level. No pending interrupts are selected by the local APIC when the TPR=15.

The local APIC selects the highest priority pending interrupt (highest priority IRR) when the CPU core is ready, and sends the interrupt (with the IRR vector) to the CPU core. The local APIC resets the highest priority IRR bit and sets the associated ISR bit.

As part of the completion of the interrupt handling routine, software writes a value of zero to the End-of-Interrupt Register (EOI) in the local APIC, which causes the local APIC to reset the associated ISR bit. The EOI register is a write-only register.

If a higher priority interrupt is accepted by the local APIC while the CPU core is servicing another interrupt, the higher priority interrupt is sent directly to the CPU core (before the current interrupt finishes processing) and the associated ISR bit is set. The CPU core interrupts the current interrupt handler to service the higher priority interrupt. When the interrupt handler for the higher priority interrupt completes, the associated ISR bit is reset and the interrupt handler returns to complete the previous interrupt handler routine.



Bits	Mnemonic	Description	R/W
31:0	EOI	End of Interrupt	WO

Figure 16-28. End of Interrupt (APIC Offset B0h)

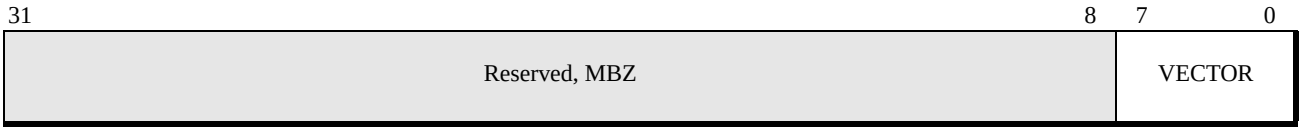
- *End of Interrupt (EOI)*—Bits 31:0. Write-only operation signals end of interrupt processing to source of interrupt.

16.7 SVM Support for Interrupts and the Local APIC

The SVM hypervisor uses the Extended APIC Feature Register, Extended APIC Control Register, Specific End of Interrupt Register (SEOI), and Interrupt Enable Register (IER) to control virtualized interrupts. When guests have direct access to devices, interrupts arriving at the local APIC can usually be dismissed only by the guest that owns the device causing the interrupt. To prevent one guest from blocking other guests' interrupts (by never processing their own), the VMM can mask pending interrupts in the local APIC, so they do not participate in the prioritization of other interrupts.

16.7.1 Specific End of Interrupt Register

Software issues a specific EOI (SEOI) by writing the vector number of the interrupt to the SEOI register in the local APIC. The SEOI register is located at offset 420h in the APIC space. The SEOI register format is shown in Figure 16-29.

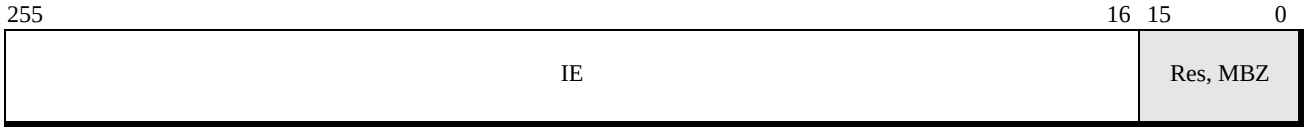


Bits	Mnemonic	Description	R/W
31:8	—	Reserved, MBZ	
7:0	VECTOR	Vector Number of Interrupt	R/W

Figure 16-29. Specific End of Interrupt (APIC Offset 420h)

16.7.2 Interrupt Enable Register

The IER is made available to software by means of eight 32-bit registers in the local APIC; bit *i* of the 256-bit IER is located at bit position (*i* mod 32) in the local APIC register IER[*i* / 32]. The eight IER registers are located at offsets 480h, 490h, ...,4F0h in APIC space. The IER format is shown in Figure 16-30.



Bits	Mnemonic	Description	R/W
255:16	IE	Interrupt Enable	R/W
15:0	—	Reserved, MBZ	

Figure 16-30. Interrupt Enable Register (APIC Offset 480h–4F0h)

- *Interrupt Enable (IE)*—Bits 255:16. Interrupts are mapped as follows:

Register	Interrupt Number
IER (APIC offset 480h)	31–16
IER (APIC offset 490h)	63–32
IER (APIC offset 4A0h)	95–64
IER (APIC offset 4B0h)	127–96
IER (APIC offset 4C0h)	159–128
IER (APIC offset 4D0h)	191–160

Register	Interrupt Number
IER (APIC offset 4E0h)	223–192
IER (APIC offset 4F0h)	255–224

The IER and SEOI registers are located in the APIC Extended Space area. The presence of the APIC Extended Space area is indicated by bit 31 of the APIC Version Register (at offset 30h in APIC space).

The presence of the IER and SEOI functionality is identified by bits 0 and 1, respectively, of the APIC Extended Feature Register (located at offset 400h in APIC space). IER and SEOI are enabled by setting bits 0 and 1, respectively, of the APIC Extended Control Register (located at offset 410h).

Only vectors that are enabled in IER participate in APIC's computation of the highest-priority pending interrupt. The reset value of IER is all ones.

16.8 x2APIC Mode

x2APIC mode is an extension to the local APIC architecture designed to support larger CPU topologies and to enhance delivery of interrupts. When enabled, x2APIC mode adds the following features:

- All APIC and x2APIC registers are accessed via an MSR-based interface.
- The Local APIC ID and Logical APIC ID registers are expanded to 32 bits.
- Logical and physical destinations are extended to 32 bits.
- A new self-IPI register simplifies sending IPIs to self.

In general, x2APIC mode maintains backwards compatibility with the key elements of the local APIC functionality previously described in Section 16. However, the following local APIC functionality is changed in x2APIC mode:

- The Destination Format Register (DFR) is no longer needed and is not supported.
- The two 32-bit Interrupt Command Registers (ICRs) are merged into a single 64-bit ICR.
- Local APIC Base (MSR 01Bh) bit 10, previously reserved, is used to enable x2APIC mode.

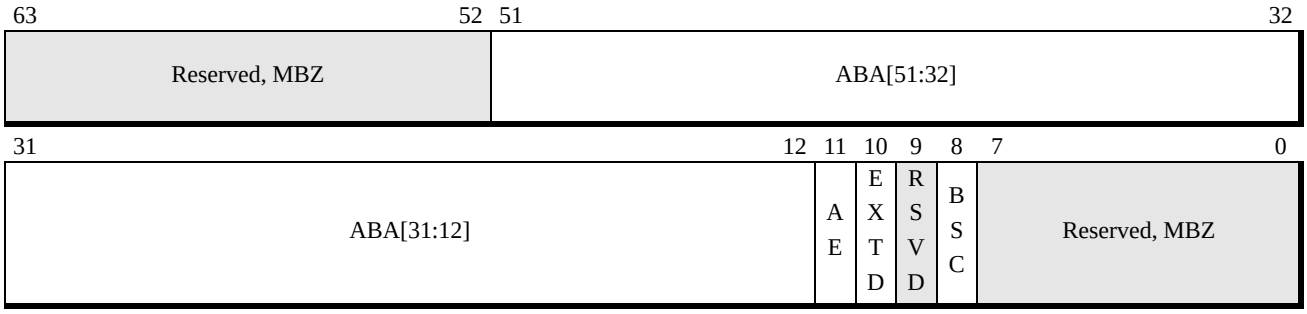
16.8.1 x2APIC Terminology

Although x2APIC is an operational mode of the local APIC, the following sections use the term ‘x2APIC’ as a qualifier to more conveniently identify a given aspect of the local APIC when that mode is enabled. For example, the term ‘x2APIC programming interface’ may be used instead of ‘the programming interface when the local APIC is in x2APIC mode’.

16.9 Detecting and Enabling x2APIC Mode

System software can detect the presence of the x2APIC feature by executing the CPUID instruction. Support for x2APIC mode is indicated by CPUID Fn000_0001_ECX[x2APIC] (bit 21) = 1.

If the feature is present, the local APIC is placed into x2APIC mode by setting bit 10 in the Local APIC Base register (MSR 01Bh). Before entering x2APIC mode, the local APIC must first be enabled (AE=1, EXTD=0). System software can then place the local APIC into x2APIC mode by executing a WRMSR with both AE=1 and EXTD=1. The format of the Local APIC Base register for x2APIC-capable processors is shown in Figure 16-31.



Bits	Mnemonic	Description	R/W
63:52	—	Reserved, MBZ	
51:12	ABA	APIC Base Address	R/W
11	AE	APIC Enable (xAPIC mode)	R/W
10	EXTD	X2APIC Mode Enable	R/W

[7:0]	—	Reserved, MBZ	

Figure 16-31. APIC Base Address Register (MSR 01Bh) support for x2APIC

Not all combinations of the local APIC mode bits are valid. See Table 16-5. Attempting to set the combination of AE=0 and EXTD=1 is invalid and causes the WRMSR instruction to generate a #GP(0) exception.

Table 16-5. Local APIC Operating Modes

AE (bit 11)	EXTD (bit 10)	Local APIC Mode
0	0	local APIC disabled
0	1	Invalid
1	0	local APIC enabled in xAPIC mode
1	1	local APIC enabled in x2APIC mode

Similarly, not all transitions between local APIC states are valid. The valid state transitions are illustrated in Figure 16-2. Once the local APIC has been placed into x2APIC mode, the only valid transition (other than reset) is to “APIC Disabled” mode by simultaneously clearing AE and EXTD to zero. Executing a WRMSR instruction to attempt a transition other than those specified in Figure 16-32 results in a #GP(0) exception.

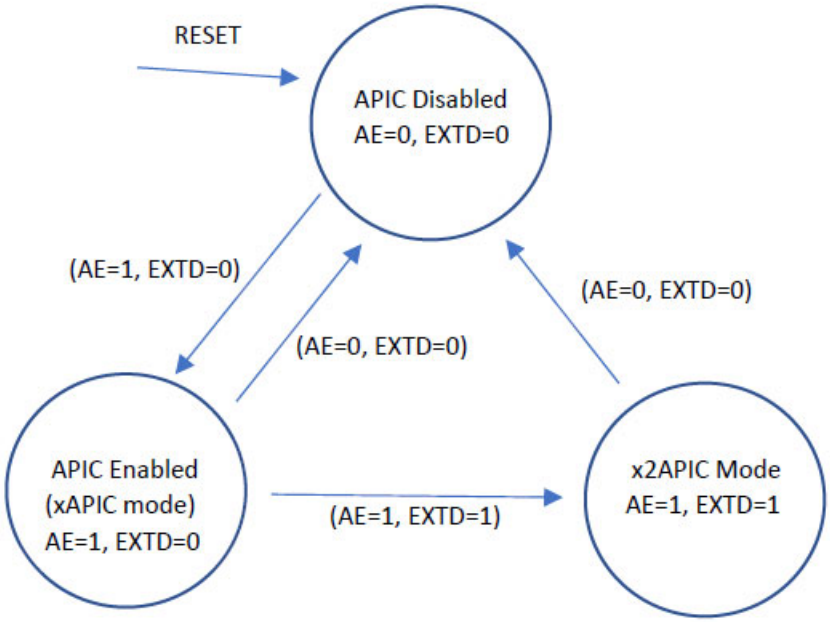

Figure 16-32. Valid APIC State Transitions

16.9.1 Enabling x2APIC Mode

Starting from APIC Disabled mode, enabling x2APIC mode is a two-step process. First, a transition is made to APIC_Enabled mode by setting APIC_Base bit 11 (AE) to 1 with bit 10 (EXTD) left as zero. Next, the transition to x2APIC mode is made by setting both AE and EXTD to 1 simultaneously.

Most APIC registers previously written by software while in APIC_Enabled mode are not affected by the transition to x2APIC mode. The exceptions are:

- The Logical Destination Register (LDR) is not preserved.
- The upper half of the Interrupt Command Register (ICR_High) is not preserved.
- A value previously written by software to the 8-bit APIC_ID register (MMIO offset 30h) is converted by hardware into the appropriate format and reflected into the 32-bit x2APIC_ID register (MSR 802h).

Leaving x2APIC mode. Once in x2APIC mode, the only valid mode transition (other than a reset) is to APIC_Disabled mode by using WRMSR to clear APIC_Base bit 11 (AE) bit 10 (EXTD) to 0 at the same time.

16.10 x2APIC Initialization

A RESET clears the APIC Base Address Register AE bit and EXTD bit, disabling the local APIC. All local APIC registers are initialized to their reset values as described in section 16.3.2 “APIC Registers”.

An INIT does not modify the APIC Base Address Register AE and EXTD bits, thus the local APIC mode is not changed. All other APIC registers are initialized to their values as described in “Reset in x2APIC mode” above.

16.11 Accessing x2APIC Register

The x2APIC system programming interface consists of the Model Specific Registers listed in Table 16-6 below. All APIC registers except the APIC Base Address Register are mapped into the architecturally dedicated MSR range 800h to 8FFh, and accessed using WRMSR and RDMSR instructions.

The RDMSR/WRMSR instructions read and write the MSR specified in the ECX register using the EDX:EAX register pair as the destination and source operand. Bits 31:0 of the APIC register are mapped into EAX[31:0]. For 64-bit x2APIC registers, the high-order bits (bits 63:32) are mapped to EDX[31:0]. A #GP(0) exception is generated if an unimplemented APIC register is specified in ECX. When not in x2APIC mode, attempts to access the APIC register set using the MSR interface results in the WRMSR or RDMSR instruction generating a #GP(0) exception. See APM volume 3 for more information on the WRMSR and RDMSR instructions.

In x2APIC mode, the legacy MMIO access to the APIC register set is disabled. Attempts to use the legacy MMIO access mechanism may result in an unintended memory access or a memory-related exception such as #GP or #PF.

16.11.1 x2APIC Register Address Space

The x2APIC registers are mapped into the MSR address range 800h through 8FFh. This address range is reserved for accessing the APIC register set in x2APIC mode.

The legacy APIC registers are mapped to this MSR address space using on the following formula:

x2APIC MSR address = 800h + ((APIC MMIO offset) >> 4)

The following registers are exceptions to the above formula:

- The two 32-bit Interrupt Command Registers in APIC mode (MMIO offsets 300h and 310h) are merged into a single 64-bit x2APIC register at MSR address 830h.
- The x2APIC Self_IPI register is added at MSR address 83Fh
- The Destination Format Register (DFR) at MMIO offset E0h and the Remote Read Register (RRR) at MMIO offset C0h are not supported in x2APIC mode. Accordingly, MSR addresses 80Eh and 80Ch are not used and are reserved.

The system programming interface of the local APIC in x2APIC mode is made up of the MSRs listed in Table 16-6 below.

Table 16-6. x2APIC Register

MSR Address (x2APIC mode)	MMIO Offset (xAPIC mode)	Register Name	Read/ Write	Notes
802h	20h	x2APIC ID Register [31:0]	RO	Expanded to 32-bits in x2APIC mode
803h	30h	APIC Version Register	RO	
808h	80h	Task Priority Register (TPR)	RW	
809h	90h	Arbitration Priority Register (APR)	RO	
80Ah	A0h	Processor Priority Register (PPR)	RO	
80Bh	B0h	End of Interrupt Register (EOI)	WO	#GP(0) if non-zero value is written
-	C0h	Remote Read Register	-	Eliminated in x2APIC mode
80Dh	D0h	Logical Destination Register (LDR)	RO	Expanded to 32-bits in x2APIC mode
-	E0h	Destination Format Register	-	Eliminated in x2APIC mode
80Fh	F0h	Spurious Interrupt Vector Register	RW	
800-817h	100-170h	In-Service Register (ISR)	RO	
818-81Fh	180-1F0h	Trigger Mode Register (TMR)	RO	
820-827h	200-270h	Interrupt Request Register (IRR)	RO	
828h	280h	Error Status Register (ESR)	RW	#GP(0) if non-zero value is written
830h	300h	Interrupt Command Register (bits 63:0)	RW	
832h	320h	Timer Local Vector Table Entry	RW	
833h	330h	Thermal Local Vector Table Entry	RW	
834h	340h	Perf Counter Local Vector Table Entry	RW	
835h	350h	Local Interrupt 0 Vector Table Entry	RW	
836h	360h	Local Interrupt 1 Vector Table Entry	RW	
837h	370h	Error Vector Table Entry	RW	
838h	380h	Timer Initial Count Register	RW	
839h	390h	Timer Current Count Register	RO	
83Eh	3E0h	Timer Divide Configuration Register	RW	
83Fh	—	Self IPI Register	WO	See Figure 16-6
840h	400h	Extended APIC Feature Register	RO	
841h	410h	Extended APIC Control Register	RW	
842h	420h	Specific End of Interrupt Register (SEOI)	RW	
848-84Fh	480-4F0h	Interrupt Enable Registers (IER)	RW	
850-853h	500-530h	Extended Interrupt [3:0] Local Vector Table Registers	RW	

MSR addresses in the range 800h through 8FFh that are not listed in Table 16-2 are unimplemented and reserved. A #GP(0) exception is generated if a WRMSR or an RDMSR instruction attempts to access an unimplemented MSR in the x2APIC address range.

16.11.2 WRMSR / RDMSR serialization for x2APIC Register

The WRMSR instruction is used to write the APIC register set in x2APIC mode. Normally WRMSR is a serializing instruction, however when accessing x2APIC registers, the serializing aspect of WRMSR is relaxed to allow for more efficient access to those registers. Consequently, a WRMSR write to an x2APIC register may complete before older store operations are complete and have become globally visible. When strong ordering of an x2APIC write access is required with respect to preceding memory operations, software can insert a serializing instruction (such as MFENCE) before the WRMSR instruction.

The RDMSR instruction is not a serializing instruction and remains non-serializing when reading x2APIC MSRs. However, WRMSR and RDMSR instructions targeting the x2APIC MSRs are always executed in program order with respect to each other.

16.11.3 Reserved Bit Checking in x2APIC Mode

When writing x2APIC MSRs, the WRMSR instruction checks for reserved bits. Attempting to write a ‘1’ to a reserved bit causes a #GP(0) exception. For x2APIC MSRs, WRMSR reserved bit checks are summarized as follows:

Legacy APIC registers. Reserved bit checks for existing APIC registers are the same as described for each register in non-x2APIC mode. For details, see the APIC register descriptions in sections 16.3 through section 16.6 above. Except for the Interrupt Command Register, attempting to write a ‘1’ into bits 63:32 of the legacy APIC registers causes a #GP(0) exception.

Interrupt Command Register (ICR). See the description of the 64-bit ICR register in section 16.13.

Error Status Register (ESR). A WRMSR of a non-zero value causes a #GP(0) exception.

SELF IPI register. See the description of the 32-bit SELF IPI register in section 16.15.

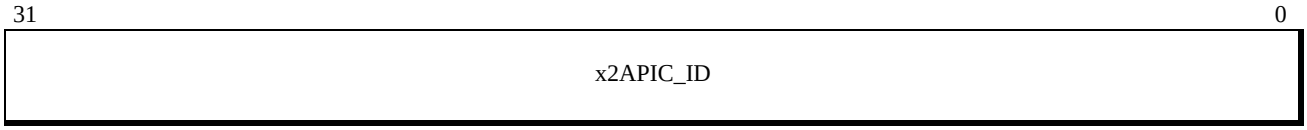
The RDMSR instruction returns a zero for any reserved bit.

16.12 x2APIC_ID

Unique local APIC IDs are assigned to each logical processor in the system. In x2APIC mode, the APIC ID is expanded to 32 bits and is referred to as the ‘x2APIC_ID’. It is assigned by hardware at reset time based on the processor topology of the system. The x2APIC_ID is a concatenation of several fields such as socket ID, core ID and thread ID.

Because the number of sockets, cores and threads may differ for each SOC, the format of x2APIC ID is model-dependent. Some fields may not be present, depending on the processor model and the

processor topology. The presence, size and position of each field is discoverable using the CPUID instruction (see “Cache and Processor Topology” on page 207).



Bits	Mnemonic	Description	R/W
31:0	x2APIC_ID	x2APICID	R

Figure 16-33. x2APIC_ID Register (MSR 802h)

System software can read x2APIC_ID using either of the following mechanisms:

RDMSR. An RDMSR of MSR 0802h returns the x2APIC_ID in EAX[31:0]. The x2APIC_ID is a read-only register. Attempting to write MSR 802h or attempting to read this MSR when not in x2APIC mode causes a #GP(0) exception. See 16.11 “Accessing x2APIC Registers”.

CPUID. The x2APIC ID is reported by the following CPUID functions Fn0000_000B (Extended Topology Enumeration) and CPUID Fn8000_001E (Extended APIC ID) as follows:

- Fn0000_000B_EDX[31:0]_x0 reports the full 32-bit ID, independent of APIC mode (i.e. even with APIC disabled)
- Fn8000_001E_EAX[31:0] conditionally reports APIC ID. There are 3 cases:
  - 32-bit x2APIC_ID, in x2APIC mode.
  - 8-bit APIC ID (upper 24 bits are 0), in xAPIC mode.
  - 0, if the APIC is disabled.

The above CPUID functions also report the presence, width and location of the sub-fields comprising the x2APIC ID. See APM Volume 3 Appendix E, “Obtaining Processor Information Via the CPUID Instruction” for detailed information.

16.13 x2APIC Interrupt Command Register (ICR) Operations

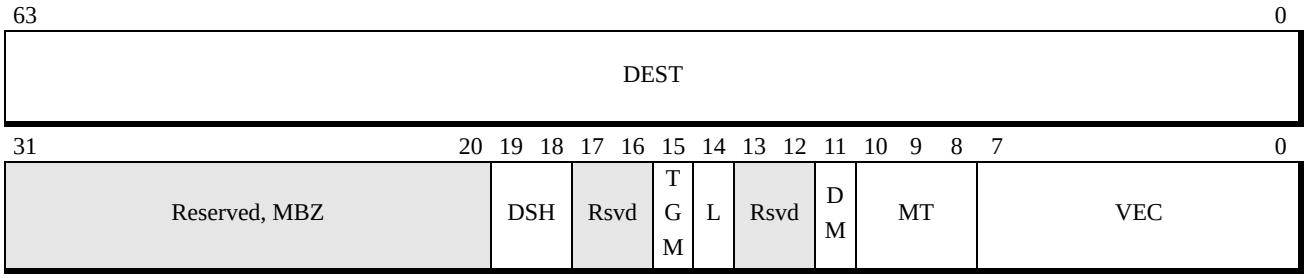
In legacy APIC mode, two 32-bit registers (ICR Low and ICR High) are used by system software to send Inter-Processor Interrupts (IPIs) to other local APICs. The x2APIC architecture combines these two registers into a single 64-bit Interrupt Command Register located at MSR address 830h. Thus in x2APIC mode sending an IPI requires only a single WRMSR to the ICR as opposed to two MMIO accesses in xAPIC mode.

The upper half of the x2APIC ICR (bits 63:32) contains the Destination ID (DEST) field, which is expanded to 32 bits in x2APIC mode. A DEST value of FFFF_FFFFh is used to broadcast IPIs to all local APICs.

The lower half of the x2APIC ICR (bits 31:0) is identical to the APIC Interrupt Command Register Low[31:0] (see Fig 16-18 on page 582), with the following exceptions:

- The Remote Read Status field (bits 17:16) is eliminated and must be zero.
- Message Type field (bits 10:8). Encodings 1, 3 and 7 are eliminated and the encodings are reserved.
- The Delivery Status field (bit 12) is eliminated and must be zero.

The format of the x2APIC ICR register is shown in Figure 16-34.

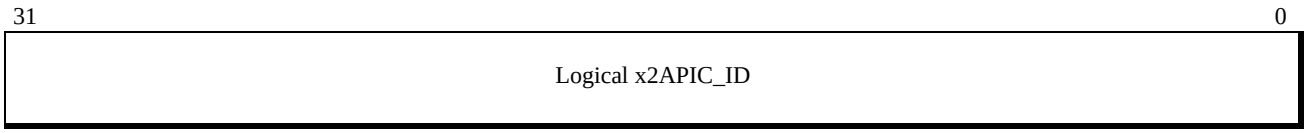


Bits	Mnemonic	Description	R/W
63:32	DEST	Destination	RW
55:20	—	Reserved, MBZ	
19:18	DSH	Destination Shorthand	RW
17:16	—	Reserved, MBZ	
15	TMG	Trigger Mode	RW
14	L	Level	RW
13:12	—	Reserved, MBZ	
11	DM	Destination Mode	RW
10:8	MT	Message Type	RW
7:0	VEC	Vector	RW

Figure 16-34. Interrupt Command Register (MSR 830h)

16.14 Logical Destination Register

When an IPI is sent using logical destination mode, all local APICs in the system use the Logical Destination Register to determine if the interrupt message is directed to them (see 16.6.1 Receiving System and IPI Interrupts). In x2APIC mode, the Logical Destination Register (LDR) is expanded to 32 bits and contains the ‘logical x2APIC_ID’. System hardware initializes LDR with the 32-bit logical x2APIC_ID whenever x2APIC mode is enabled. The LDR is a read-only register located at MSR address 080Dh. The format of the Logical Destination Registers is shown inFigure 16-35.



Bits	Mnemonic	Description	R/W
31:0	x2Logical_ID	Logical x2APICID Identifier	R

Figure 16-35. Logical Destination (MSR 80Dh)

The logical x2APIC_ID consists of two 16-bit sub-fields: cluster_ID and logical_ID.

- LDR[31:16] cluster_ id. Identifies the cluster of which this processor is a member.
- LDR[15:0] logical_id. A bit vector uniquely identifying this processor within the cluster.

In logical destination mode, a given logical processor is addressed by its unique cluster ID and logical_ID combination. The use of a bit vector for logical_ID allows an interrupt message to be routed to multiple processors within the addressed cluster.

The partitioning of logical x2APIC_ID provides for a possible 65,535 (216-1) clusters, with each cluster having up to 16 logical processors. The legacy “flat logical” addressing is not supported in x2APIC mode.

Upon receiving an interrupt message in logical destination format, each x2APIC compares bits 31:16 of the message destination with LDR[31:16] (cluster_id). If there is a match, then bits 15:0 of the destination and LDR[15:0] are tested for matching ones. If bits[31:16] (cluster_id) match and any bit in 15:0 (logical_id) match, this x2APIC is a valid destination.

A DEST value of FFFF_FFFFh in the ICR is used to broadcast IPIs to all local APICs.

The two sub-fields comprising logical x2APIC_ID are derived from the value of local x2APIC_ID. The 16-bit logical_ID sub-field is initialized by setting a single bit, ‘n’, where n= the 4 least significant bits of local x2APIC_ID. The 16-bit cluster_id is derived from the remaining bits of the x2APIC_ID. Specifically, logical_id[15:0] = 1 << x2APIC_ID[3:0] and cluster_id[15:0] = x2APIC_ID[19:4].

16.15 Self_IPI Register

The Self_IPI register (MSR 83Fh) provides a performance-optimized interface for system software to send interrupt messages to the local APIC. This register is write-only and attempts to read it cause a #GP(0) exception. The format of the Self_IPI registers is shown in Figure 16-36.

Bits	Mnemonic	Description	R/W
31:8	—	Reserved, MBZ	
7:0	VEC	Interrupt Vector	WO

Figure 16-36. Self_IPI Register (MSR 83Fh)

The Self_IPI register contains a single field: an interrupt vector. Writing to this register causes a to-self IPI to be generated, equivalent to a to-self IPI generated by writing the Interrupt Command Register (ICR, MSR 830h) with the following settings:

- Destination shorthand = self
- Trigger Mode = edge-triggered
- Message Type = fixed
- Vector = interrupt vector as specified in the Self_IPI register

The x2APIC's response to a self-IPI sent via the Self_IPI register is architecturally identical to one sent via the ICR. In particular, the operation of the Interrupt Response Register (IRR), In-Service Register (ISR) and Trigger Mode Register (TMR) is the same. See "Accepting System and IPI Interrupts" on page 621 for IRR, ISR and TMR details.

The Interrupt Request Register (IRR) contains interrupt requests that have been accepted by the processor core. Completion of the WRMSR to the Self_IPI register ensures that the resulting IPI has been entered into the IRR, and that the associated TMR bit is cleared (as expected for edge-triggered interrupts).

17 Hardware Performance Monitoring and Control

The AMD64 architecture provides several mechanisms by which software can monitor and control processor performance to optimize power use. The following lists the facilities that are described in the sections that follow:

- The P-state control interface allows dynamic control of performance states. See Section 17.1 which follows immediately below.
- Core performance boost (CPB) dynamically increases core clock rate beyond that defined for the P0 power state to achieve higher performance while maintaining power consumption below a preset level. See Section 17.2 on page 641.
- The effective frequency interface provides a measure of the actual core clock rate over a specified period of time. See Section 17.3 on page 642.
- The processor power reporting interface allows system software to measure average processor core power over a given time period. See Section 17.5 on page 644.

17.1 P-State Control

P-states are operational performance states (states in which the processor is executing instructions, that is, running software) characterized by a unique frequency of operation for a CPU core. The P-state control interface supports dynamic P-state changes in up to 16 P-states called P-states 0 through 15 or P0 though P15. P0 is the highest power, highest performance P-state; each ascending P-state number represents a lower-power, lower-performance state.

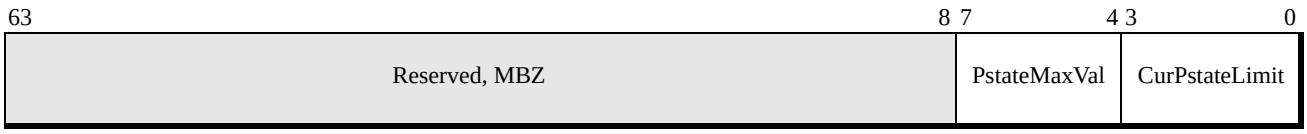
Core P-states are controlled by software. Each CPU core contains one set of P-state control registers. Software controls the P-states of each CPU core independently; however, hardware may include interdependencies that affect the P-state achieved by each core.

Hardware provides the highest P-state value in the PstateMaxVal field of the P-State Current Limit Register. P-states may be limited to a lower performance value under certain conditions. The current P-state limit is dynamic and is specified in the CurPstateLimit field of the P-State Current Limit Register.

Software requests a core P-state change by writing a 4-bit index corresponding to the desired core P-state number to the P-State Control Register of the appropriate core. For example, to request the P3 state for core 0, software writes 3h to the core 0's PstateCmd field in MSR C001_0062h. If the P-state value is greater than the value in PstateMaxVal, the value written is clipped to that value.

As the current P-state limit changes, the P-state for the CPU core is either set to the software-requested P-state value or the new current P-state limit, whichever is the higher P-state value.

The current P-state value can be read using the P-State Status Register. The P-State Current Limit Register and the P-State Status Register are read-only registers. Writes to these registers cause a #GP exception. Support for hardware P-state control is indicated by CPUID Fn8000_0007_EDX[HwPstate] = 1. Figure 17-1 below shows the format of the P-State Current Limit register.

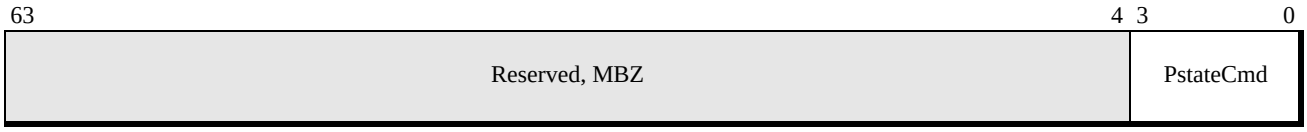


Bits	Mnemonic	Description	R/W
63:8	—	Reserved, MBZ	
7:4	PstateMaxVal	P-state maximum value	R
3:0	CurPstateLimit	Current P-state limit	R

Figure 17-1. P-State Current Limit Register (MSR C001_0061h)

The fields within the P-State Current Limit register are:

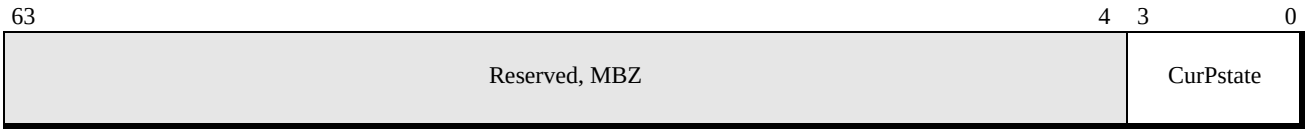
- *Current P-State Limit (CurPstateLimit)*—Bits 3:0. Provides the current P-state limit, which is the lowest P-state value (highest-performance state) that is currently supported by the hardware. This is a dynamic value controlled by hardware. Reset value is implementation specific.
- *P-State Maximum Value (PstateMaxVal)*—Bits 7:4. Specifies the highest P-state value (lowest performance state) supported by the hardware. Attempts to change the current P-state number to a higher value by writes to the P-State Control Register are clipped to the value of this field. Reset value is implementation specific.



Bits	Mnemonic	Description	R/W
63:4	—	Reserved, MBZ	
3:0	PstateCmd	P-state change command	R/W

Figure 17-2. P-State Control Register (MSR C001_0062h)

P-State Change Command (PstateCmd)—Bits 3:0. Writes to this field cause the CPU core to change to the indicated P-state number, which may be clipped by the PstateMaxVal field of the P-State Current Limit Register. Reset value is implementation specific.



Bits	Mnemonic	Description	R/W
63:4	—	Reserved, MBZ	
3:0	CurPstate	Current P-state	R

Figure 17-3. P-State Status Register (MSR C001_0063h)

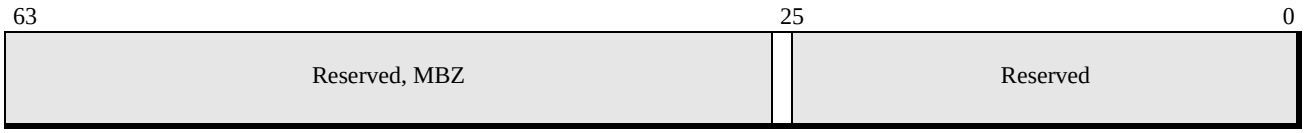
Current P-State (CurPstate)—Bits 3:0. This field provides the current P-state of the CPU core regardless of the source of the P-state change, including writes to the P-State Control Register: 0 = P-state 0, 1 = P-state 1, etc. The value of this field is updated when the frequency transitions to a new value associated with the P-state. Reset value is implementation specific.

17.2 Core Performance Boost

Core performance boost (CPB) dynamically monitors processor activity to create an estimate of power consumption. If the estimated processor consumption is below an internally defined power limit and software has requested P0 on a given core, hardware may transition the core to a frequency and voltage beyond those defined for P0. If the estimated power consumption exceeds the defined power limit, some or all cores are limited to the frequency and voltage defined by P0. CPB ensures that average power consumption over a thermally significant time period remains at or below the defined power limit.

CPB can be disabled using the CPBDis field of the Hardware Configuration Register (HWCR MSR) on the appropriate core. When CPB is disabled, hardware limits the frequency and voltage of the core to those defined by P0.

Support for core performance boost is indicated by CPUID Fn8000_0007_EDX[CPB] = 1. See Section 3.3, “Processor Feature Identification,” on page 71 for more information on using the CPUID instruction.



Bits	Mnemonic	Description	R/W
63:26	—	Reserved	
25	CPBDis	Core Performance Boost Disable	R/W
24:0	—	Reserved	

Figure 17-4. Core Performance Boost (MSR C001_0015h)

Core Performance Boost Disable (CpbDis)—Bit 25. Specifies whether core performance boost is enabled or disabled. 0 = Enabled. 1 = Disabled.

17.3 Determining Processor Effective Frequency

The Max Performance Frequency Clock Count (MPERF) and the Actual Performance Frequency Clock Count (APERF) registers constitute the effective frequency interface. This interface provides a means for software to calculate an average, or effective, frequency of a core over a known window of time. This provides software a measure of actual performance rather than forcing software to assume that the current frequency of the core is the frequency of the last P-state requested.

To calculate an effective clock frequency of a given processor core, on that processor do the following:

1. Read both MPERF and APERF and save their initial values.
   - MPERF_INIT = MPERF and APERF_INIT = APERF
2. Wait an appropriate amount of time.
3. Read both MPERF and APERF again.
4. Effective frequency = {(APERF − APERF_INIT) / (MPERF − MPERF_INIT)} * P0 frequency.

The amount of time that elapses between steps 1 and 3 is determined by software. This allows software to define the time window over which the processor frequency is averaged. Software should disable interrupts or any other events that may occur between the read of MPERF and the read of APERF in step 1 and again when the two MSRs are read in step 3. Step 4 provides the equation for the calculation of the effective frequency value. Software determines the P0 frequency using ACPI defined data structures.

The effective frequency interface only counts clock cycles while the core is in the ACPI defined C0 state.

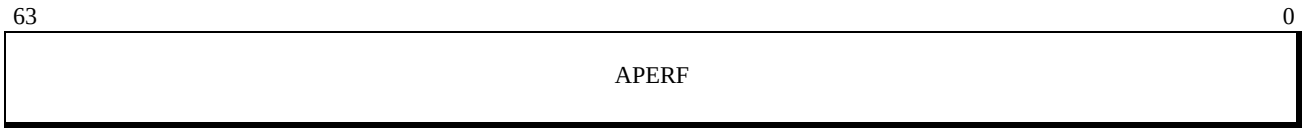
Only the ratio between MPERF and APERF is architecturally defined. Software should not assume any specific definition of the MPERF or APERF registers. If an overflow of either the MPERF or

APERF register occurs between the read of MPERF in step 1 and the read of APERF in step 3, the effective frequency calculated in step 4 is invalid.

Hardware support for the effective frequency interface is indicated by CPUID Fn0000_0006_ECX[EffFreq]. See Section 3.3, “Processor Feature Identification,” on page 71 for more information on using the CPUID instruction.

17.3.1 Actual Performance Frequency Clock Count (APERF)

Specifies the numerator of the effective frequency ratio.



Bits	Mnemonic	Description	Access Type
63:0	APERF	Actual Performance Frequency Clock Count	R/W

Figure 17-5. Actual Performance Frequency Count (MSR0000_00E8h)

17.3.2 Maximum Performance Frequency Clock Count (MPERF)

Specifies the denominator of the effective frequency ratio. The value read is scaled by the TSCRatio value (MSR C000_0104h) for guest reads, but the underlying counters are not affected. Reads in host mode or writes to MPERF are not affected.

Bits	Mnemonic	Description	Access Type
63:0	MPERF	Max Performance Frequency Clock Count	R/W

Figure 17-6. Max Performance Frequency Count (MSR0000_00E7h)

17.3.3 APERF Read-only (AperfReadOnly)

Specifies the numerator of the effective frequency ratio.

Bits	Mnemonic	Description	Access Type
63:0	APERF_RD_ONLY	APREF Read Only	R/O

Figure 17-7. APREF Read Only (MSR C000_00E8h)

17.3.4 MPERF Read-only (MperfReadOnly)

Read-only version of MPERF. The value read is scaled by the TSCRatio value (MSR C000_0104h) for guest reads.

Bits	Mnemonic	Description	Access Type
63:0	MPERF_RD_ONLY	MPERF Read Only	RO

Figure 17-8. MPERF Read Only (MSR C000_00E7h)

17.4 Processor Feedback Interface

The Processor Feedback Interface is deprecated. Some processor products may support this feature. To determine support on a given processor, software can test the feature bit CPUID Fn8000_0007_EDX[ProcFeedbackInterface]. For more information, consult the *BIOS and Kernel Developer's Guide (BKDG)* or *Processor Programming Reference Manual* applicable to your product.

17.5 Processor Core Power Reporting

The processor power reporting interface allows system software to estimate the average power consumed by a processor core over a software-determined time period. Computing the average power involves reading a "core power accumulator" register at the beginning and end of the measurement interval, taking the difference and then dividing by the length of the time interval.

Support for the processor power reporting interface is indicated by CPUID Fn8000_0007_EDX[ProcPowerReporting] = 1.

17.5.1 Processor Facilities

Estimating core average power involves the use of several processor facilities. Processors that support the processor power reporting interface define the following three facilities:

- CpuSwPwrAcc MSR
- MaxCpuSwPwrAcc MSR
- CpuPwrSampleTimeRatio (CPUID Fn8000_0007_ECX)

A fourth facility, available on all processors, is the time-stamp counter (TSC). The TSC is a free-running counter that increments on every processor clock cycle. The current value o f this counter is read using the RDTSC instruction.

The contents of the CpuSwPwrAcc register represents the cumulative *energy* consumed by the core. Each hardware-determined sample period (Tsample) a value that represents the energy consumed since the previous sample is added to the contents of this register. Tsample is on the order of a few microseconds. The exact value is immaterial because the CpuPwrSampleTimeRatio register provides the ratio of Tsample to the TSC period.

CpuSwPwrAcc is cleared to zero at power-on and is never reset. Therefore, it is possible for this counter to overflow and roll over to zero. To account for this, the interface provides the MaxCpuSwPwrAcc register. When read, this register provides a value that represents the maximum energy that the CpuSwPwrAcc register can report.

17.5.2 Software Algorithm

The following algorithm should be used to calculate the average power consumed by a processor core during the measurement interval T_M. To obtain a stable average power value, T_M should be on the order of several milliseconds.

- Determine the value of the ratio of Tsample to the TSC period (CpuPwrSampleTimeRatio) by executing CPUID Fn8000_0007. Call this value *N*.

  N = CPUID Fn8000_0007_ECX[31:0].
- Read the full range of the cumulative energy value from the register MaxCpuSwPwrAcc.

  Jmax = value returned from RDMSR MaxCpuSwPwrAcc.
- At time *x*, read CpuSwPwrAcc and the TSC

  J_x = value returned by RDMSR CpuSwPwrAcc

  T_x = value returned by RDTSC
- At time *y*, read CpuSwPwrAcc and the TSC again

  J_y = value returned by RDMSR CpuSwPwrAcc

  T_y = value returned by RDTSC

Calculate the average power consumption for the processor core over the measurement interval $T_{M} = (Ty – Tx)$.

- If ($J_y < J_x$), rollover has occurred; set $Jdelta = (J_y + Jmax) – J_x$
  else $Jdelta = J_y – J_x$
- PwrCPUave = $N * Jdelta / (T_y - T_x)$

Units of result is milliwatts.

18 Shadow Stacks

The shadow stack mechanism facilitates protection against a common form of computer exploit known as Return Oriented Programming (ROP). ROP exploits utilize intentionally corrupted stack frames to divert normal processor control flow into short fragments of existing executable code, which ultimately end with a RET instruction. These fragments are then chained together using return addresses previously written to the stack by the attacker.

The shadow stack mechanism protects against ROP exploits by ensuring that return addresses read from the stack by RET and IRET instructions originated from a CALL instruction or similar control transfer.

In the following sections, the term ‘program stack’ is used to distinguish the stack pointed to by the SP register and manipulated by instructions (such as PUSH, POP, ENTER, LEAVE) from the shadow stack.

18.1 Shadow Stack Overview

A shadow stack is a separate, protected stack that is conceptually parallel to the program stack and used only by control-transfer and return instructions. When shadow stacks are enabled, most control transfers that save a return address (such as CALL, INTn, exceptions and interrupts) write the return address to the shadow stack in addition to the program stack. Upon the subsequent RET or IRET operation, the processor reads the return address from both stacks and checks that they match. A control-protection exception (#CP) is raised if the return addresses do not match.

The shadow stack is implemented in regions of memory marked with the “shadow stack” attribute in the page tables (see “Page-Protection Checks” on page 158). Pages with the shadow stack attribute are writeable only by control transfer operations that save a return address and by the shadow stack management instructions. Shadow stack pages are not writeable by ordinary data-access instructions and thus protected from tampering.

18.1.1 Detecting and Enabling Shadow Stack Support

Support for the shadow stack feature is indicated by CPUID Fn0000_0007_ECX_x0[CET_SS](bit 7)=1. This bit also indicates the shadow stack MSRs are present.

The shadow stack feature is enabled by setting CR4.CET (bit 23) = 1 (see “CR4 Register” on page 47). The shadow stack feature is operational when in protected mode (CR0.PE=1) with paging enabled (CR0.PG=1). Shadow stacks are disabled in virtual x86 mode (rFLAGS.VM=1).

Once the feature is enabled, shadow stack operation can be separately enabled in user mode and in supervisor mode using control bits in the S_CET and U_CET MSRs (see “Shadow Stack MSRs” on page 659).

18.2 The Shadow Stack Pointer

On processors implementing the shadow stack feature, the Shadow Stack Pointer (SSP) register contains the address of the current top of the shadow stack. The width of the shadow stack is 64 bits in 64-bit mode and 32 bits in legacy and compatibility modes. The address size of SSP is 64 bits in 64-bit mode and 32 bits in legacy and compatibility modes.

The SSP register cannot be encoded as a source or destination register by regular instructions and thus is not directly accessible to software as a general operand, nor as an address operand. The SSP register is directly accessible only by using the shadow stack management instructions (see “Shadow Stack Management Instructions” on page 658).

18.3 Shadow Stack Operation for CALL (near) and RET (near)

When shadow stacks are enabled, the CALL (near) instruction pushes the return address onto the shadow stack, in addition to pushing it onto the program stack. On the subsequent near RET/RETn instruction, the return addresses are read from both stacks and compared. If the return addresses do not match, a control-protection (#CP) exception is generated.

A CALL (near) with a displacement of 0 (CALL +0) does not push the return address onto the shadow stack since the ’CALL +0’ idiom does not actually branch to another code sequence, and is typically not followed by a return instruction.

One form of the return instruction, RETn, pops ‘n’ additional parameters from the program stack before returning to the caller. Since the shadow stack does not store any data items, RETn does not pop additional parameters from the shadow stack.

18.4 Shadow Stack Operation for Far Transfers

The term ‘far transfer’ in the following discussion encompasses the following types of control transfers:

- Explicit CALL (far) to a procedure in another code segment
- Exceptions and interrupts that transfer to a handler in another code segment
- RET (far) and IRET instructions

A far transfer may also change the CPL. The exact operation of the shadow stack depends on the type of far transfer involved, the associated CPL change (if any) and whether the shadow stack capability is enabled for the target CPL. Shadow stack operations for far transfers are described in the following sections and summarized in Table 18-1. (See AMD Architecture Programmers Manual Volume 3 for detailed instruction algorithms for CALL (far), RET (far), IRET and INTn.)

Table 18-1. Shadow Stack Operations for Far Transfers

CALLF/int/excp From CPL	To CPL	Stack switch?	New SSP loaded from: (where n=new CPL)	CS, LIP saved to and restored from:	SSP saved to and restored from:	RETF/IRET checks returns address?
0,1,2,3	Same	No	Uses current SSP	Current Shadow Stack	Current Shadow Stack	Yes
3	0,1,2	Yes	PLn_SSP	<not saved/restored>	PL3_SSP	No
2	0,1	Yes	PLn_SSP	New shadow stack	New shadow stack	Yes
1	0	Yes	PLn_SSP	New shadow stack	New shadow stack	Yes

18.5 Far Transfer to the Same Privilege Level

When shadow stacks are enabled, a far transfer to the same privilege level pushes the CS and LIP (linear address of the return IP) onto the current shadow stack in addition to pushing the return IP onto the program stack. Upon the subsequent RET (far) or IRET operation, the return addresses are popped from both stacks and the linear forms of the two addresses are compared. If the return addresses do not match, a control-protection (#CP) exception is generated.

18.6 Far Transfer to Different Privilege Level

In addition to changing code segments, far transfers can also be used to change to a different privilege level (CPL). When changing the CPL, inter-privilege far transfers switch to a new program stack. In a similar manner, inter-privilege far transfers also switch to a new shadow stack, providing that shadow stacks are enabled for the new privilege level.

18.6.1 Shadow Stack Switching

When an inter-privilege far transfer switches to a new program stack, the new program stack pointer is selected from the either the inner-level stack pointers in the TSS or the Interrupt Stack Table (IST), depending on the type of far transfer. (See “Interrupt To Higher Privilege” on page 264). Similarly, when shadow stacks are enabled, inter-privilege far transfers also switch to a new shadow stack. The new shadow stack pointer is selected from shadow stack pointer MSRs (PLn_SSP) or the Interrupt Shadow Stack Table (ISST) as described in the following sections.

18.6.1.1 Shadow Stack Switching for Inter-Privilege CALL (far)

When a CALL (far) changes privilege level, a shadow stack switch occurs to an inner-level shadow stack. The new SSP is loaded from one of the following MSRs:

- PL2_SSP for transitions to CPL 2.
- PL1_SSP for transitions to CPL 1.
- PL0_SSP for transitions to CPL 0.

When switching shadow stacks, the processor validates the new shadow stack using a special value called a *shadow stack token* as described in Section 18.6.3 “Supervisor Shadow Stack Token” on page 651.

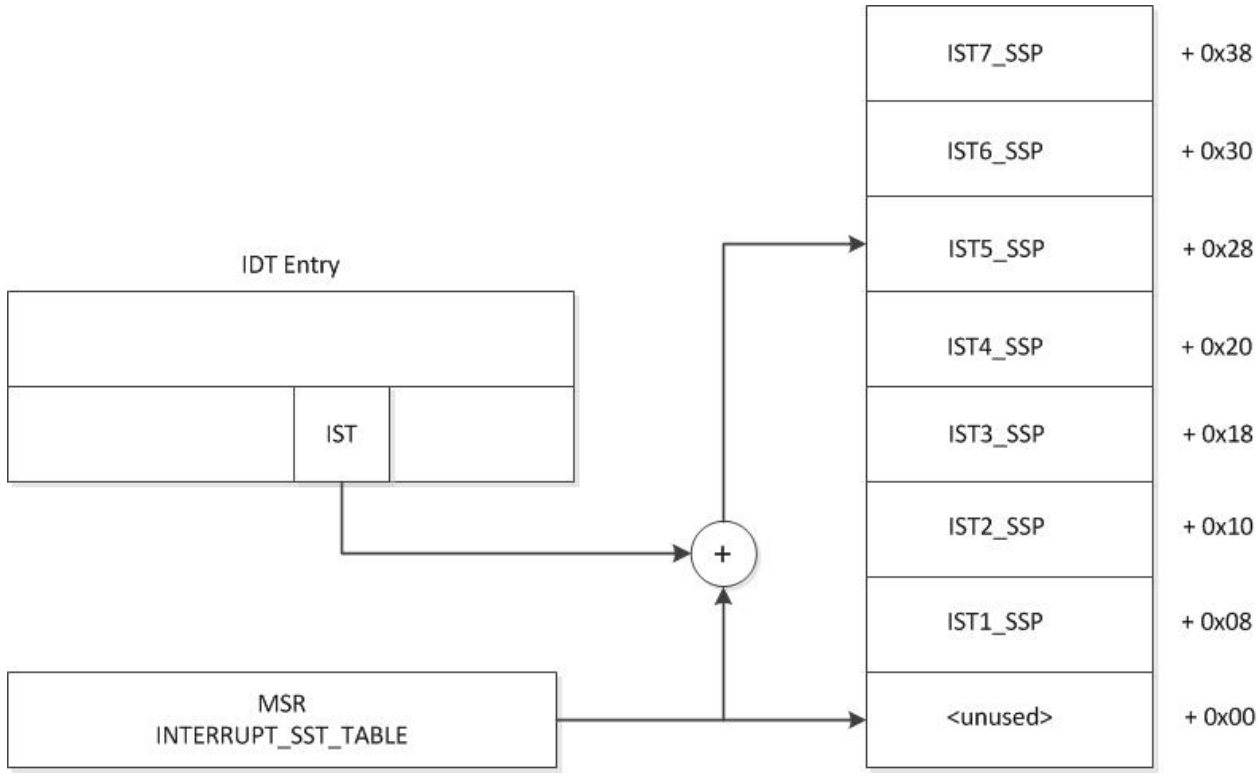
18.6.1.2 Shadow Stack Switching for Interrupts and Exceptions

In long mode (EFER.LMA=1), the processor provides an additional mechanism, the Interrupt Stack Table (IST) to switch program stacks for interrupts and exceptions. The IST mechanism uses the IST field in the Interrupt Descriptor Table (IDT) entry as an index into a table of inner-level program stack pointers (see “Interrupt-Stack Table” on page 276). The shadow stack feature provides a similar mechanism, the Interrupt Shadow Stack Table (ISST), for switching shadow stacks.

The ISST is an 8-entry table containing supervisor shadow stack pointers. The base of the ISST is specified by the INTERRUPT_SSP_TABLE MSR. If the IST field in the IDT entry is non-zero, it is used as an index into the ISST to select a new SSP as shown in Figure 18-1 “Interrupt Shadow Stack Table (ISST)” on page 650.

If the IST field is zero or if the processor is not in long mode, the ISST mechanism is not used and the new inner-level SSP is selected from the PLn_SSP MSRs as previously described in Section 18.6.4 “Shadow Stack Switching for Inter-Privilege CALL (far)” on page 649.

Figure 18-1. Interrupt Shadow Stack Table (ISST)



18.6.2 Handling CS, LIP and SSP on Privilege Transistions

When changing to a new code segment, the shadow stack behavior for saving and restoring CS, LIP and SSP depends on the CPL of the originating far transfer.

Transitions from CPL=3

Inter-privilege far transfers originating at CPL=3 save the current user-level SSP to PL3_SSP rather than to the supervisor shadow stack. Upon the subsequent RETF/IRET back to CPL=3, the user-level SSP is restored from PL3_SSP and the return CS and LIP are not verified.

Transitions from CPL=1 and CPL=2

Far transfers originating at CPL=1 or CPL=2 to an inner (more privileged) level save the current CS, LIP and SSP to the inner level shadow stack after switching shadow stacks as described in section Section 18.6.1, “Shadow Stack Switching,” on page 649. Upon the subsequent RET(far)/IRET, the SSP is restored (Section 18.6.1, “Shadow Stack Switching,” on page 649) from the inner-level shadow stack and the CS and LIP popped from the shadow stack are verified against the values read from the program stack. If the return addresses do not match, a control-protection (#CP) exception is generated.

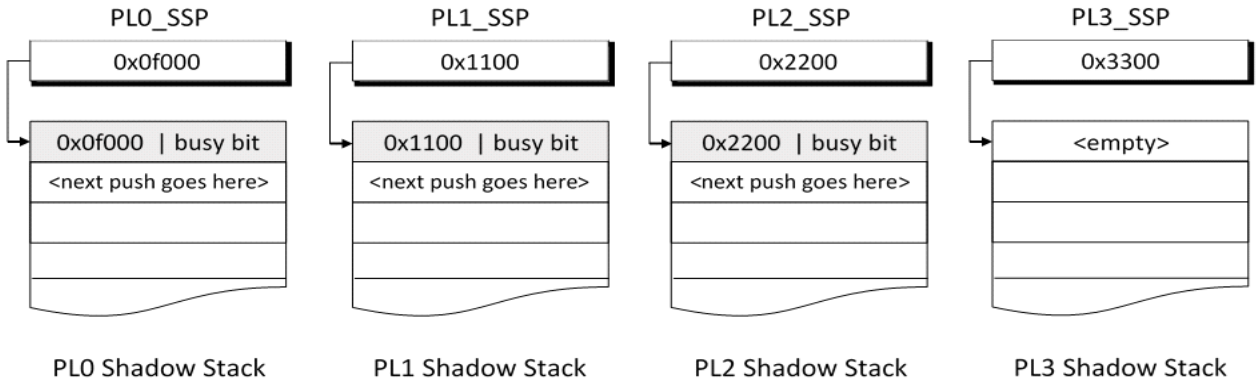
18.6.3 Supervisor Shadow Stack Token

When switching shadow stacks, the processor validates the new shadow stack by checking a *supervisor shadow stack token* located at the base of the stack.

When initially creating a shadow stack for use at privilege levels 0, 1 and 2, system software must place a supervisor shadow stack token at the base of each stack. System software must also store a pointer to each shadow stack in the appropriate shadow stack base register, PLn_SSP (n=0,1,2,3) using the WRMSR instruction.

The relationship of the shadow stacks, supervisor shadow stack tokens, and the PLn_SSP registers are shown in Figure 18.6.3 “Shadow Stacks and Supervisor Shadow Stack Tokens” on page 652. The three supervisor shadow stacks (PL0, PL1 and PL2) have shadow stack tokens stored at the base of the stack. Tokens are not used for PL3 shadow stacks.

Figure 18-2. Shadow Stacks and Supervisor Shadow Stack Tokens



The supervisor shadow stack token is a 64-bit value and is formatted as shown in Figure 18-3:

Figure 18-3. Supervisor Shadow Stack Token

The supervisor shadow stack token fields are defined as follows:

Linear Address. Bits 63:3 of the linear address of this token. The linear address is required to be 8-byte aligned.

Rsvd. Reserved, must be zero.

Busy Bit. If 0, this indicates this supervisor shadow stack is not in use by any logical processor. If 1, it indicates this supervisor shadow stack is currently in use by one of the logical processors. The processor sets the busy bit when switching to a supervisor shadow stack and clears it when switching away from that stack.

18.6.4 Shadow Stack Token Validation for Inter-privilege CALL (far) and Interrupts/Exceptions

Before switching shadow stacks, a CALL (far) or an interrupt/exception that changes to a more privileged level validates the supervisor shadow stack token located at the base of the new stack. If the validation checks pass, the supervisor shadow stack token is marked busy. The following steps are performed to validate the supervisor shadow stack token and set the busy bit:

1. Check that the incoming SSP is 8-byte aligned, otherwise a #GP exception is generated. The incoming SSP is located in PLn_SSP (where ‘n’ is the new privilege level: 0, 1, 2), or the ISST for interrupts/exceptions (see Section 18.6.1, “Shadow Stack Switching,” on page 649).

<Steps 2-6 are performed atomically.>

2. Fetch the 8-byte shadow stack token using the address specified by the incoming SSP (using a locked load with shadow stack access rights).
3. Check that the shadow stack token reserved bits and the busy bit are 0.
4. Check that the address specified in the shadow stack token matches the incoming SSP.
5. If checks 3 and 4 pass, set the supervisor shadow stack token busy bit (using a store, unlock).
6. If checks 3 or 4 fail, the shadow stack token is not modified and a #GP exception is generated.

18.6.5 Shadow Stack Token Validation for Inter-privilege RET and IRET

RET (far) and IRET to lower privilege levels validate the shadow stack token located on the current supervisor shadow stack before switching shadow stacks. If the token is valid, the token’s busy bit is cleared. The processor performs the following steps to validate the token:

1. Check that the return SSP (located on the current shadow stack) is 4-byte aligned, else a #CP exception is generated.

<Steps 2-7 are performed atomically.>

2. Fetch the 8-byte shadow stack token from the current shadow stack at SSP+24 (using a locked load with shadow stack access rights).
3. Check that the busy bit is 1.
4. Check that the reserved bits are 0.
5. Check that the address specified in the shadow stack token matches the SSP.
6. If checks 3 through 5 pass, the shadow stack token busy bit is cleared.
7. If any of checks 3 through 5 fail, the shadow stack token is not modified. A fault is not generated.

18.7 Shadow Stack Operation for SYSCALL and SYSRET

SYSCALL and SYSRET are low-latency system call and return instructions designed for use by system and application software implementing a flat-memory model. These instructions do not use the program stack to store return addresses, and therefore do not use the shadow stack to validate return addresses. However, SYSCALL and SYSRET modify SSP as described below. The Shadow stack operations described for SYSCALL and SYSRET also apply to SYSENTER and SYSEXIT respectively, although the latter are available only in legacy mode.

The SYSCALL instruction is used by application software executing at CPL=3. When shadow stacks are enabled at CPL=3, SYSCALL saves the current SSP to PL3_SSP. SYSCALL changes to CPL=0

before entering the operating system and if shadow stacks are enabled at CPL=0, then SSP is cleared to 0.

Unlike other inter-privilege far transfers, SYSCALL does not automatically perform a switch to a supervisor shadow stack. If shadow stacks are enabled at CPL=0, prior to executing a CALL instruction or similar transfer of control that pushes a return address to the shadow stack, software at the OS entry point must ensure that a supervisor shadow stack is available for use. System software can use SETSSBSY to set up a supervisor shadow stack.

The operating system uses the SYSRET instruction to return to the application running at CPL=3. If shadow stacks are enabled at CPL=3, SYSRET restores SSP from PL3_SSP. Prior to using SYSRET to return to the application, system software can use the CLRSSBSY to tear down the supervisor shadow stack. Because CLRSSYBSY clears the SSP to 0, system software must ensure that any subsequent interrupt or exception that may occur in CPL=0 prior to the SYSRET is configured to use the ISST stack-switching mechanism. Otherwise taking an interrupt or exception with SSP=0 will likely result in a fault due to SSP wrap-around.

18.8 Shadow Stack Operation for Task Switches

The legacy x86 task-switch mechanism transfers program control to a new task when any of the following control transfers occur:

- A CALL or JMP instruction references a task gate or TSS descriptor.
- A software-interrupt instruction (INTn), exception or external interrupt references a task gate.
- An IRET is executed when the EFLAGS.NT bit is set to 1.

Shadow stack operations for legacy x86 task switches are summarized in this section. Because the x86 task management feature is supported by the AMD64 architecture only in legacy mode (EFER.LMA=0), the shadow stack operations described below only apply to legacy mode. (See “Switching Tasks” on page 375 for more information on task switching).

When switching to a new task with shadow stacks enabled, the new task must use a 32-bit TSS. The SSP for the new task is located at TSS offset 104. Since the SSP is 4 bytes in legacy mode, the TSS must be at least 108 bytes in size. The SSP must be aligned to an 8-byte boundary and point to a supervisor shadow stack token.

If the task switch is initiated by a CALL/JMP/INTn instruction, or an interrupt or exception:

- For task switches originating at CPL=3, and if shadow stacks are enabled at that CPL, the current SSP is saved to PL3_SSP. Otherwise, for task switches originating at supervisor-level (CPL=0,1,2) the current SSP is saved onto the new shadow stack along with current CS and LIP. If shadow stacks are enabled at the CPL of the new task, the busy bit is set in the supervisor shadow stack token pointed to by the SSP of the incoming task.

If the task switch is initiated by an IRET instruction:

- For task switches originating at supervisor-level (CPL=0,1,2) and returning to CPL=3, the SSP is restored from PL3_SSP, otherwise the SSP is restored from the current shadow stack. The return CS and LIP are read from the current shadow stack and compared to the CS and linear form of the EIP in the TSS of the incoming task. A control-protection (#CP) exception is generated if the return addresses do not match.

18.9 Restricting Speculative Execution of RET targets

When shadow stacks are enabled, the processor will not speculatively execute instructions from a RET address on the program stack unless the address matches the corresponding address on the shadow stack, or the target of the RET is predicted by a return address branch prediction mechanism.

18.10 Shadow Stack Switching Using RSTORSSP

As previously described in Section 18.6.1, “Shadow Stack Switching,” on page 649, the processor automatically switches shadow stacks as part of the inter-privilege far transfer mechanism. In order to allow programs to switch stacks at other times (when performing operations such as initializing a shadow stack or recovering from a #CP fault) the RSTORSSP and SAVEPREVSSP instructions are provided.

The RSTORSSP instruction is used to switch shadow stacks. The instruction expects to find a shadow stack restore token at the top of the proposed new shadow stack. Upon validating this token, RSTORSSP points the SSP to the top of the new shadow stack and sets the token’s busy bit, making the new shadow stack ready for use.

Upon successful completion, the RSTORSSP instruction modifies the restore token by saving the old SSP into the token’s SSP Restore Value field in order to facilitate a later return to the old shadow stack.

The shadow stack restore token used by RSTORSSP is formatted as follows:

Figure 18-4. Shadow Stack Restore Token

The shadow stack restore token fields are defined as follows:

SSP Restore value. Bits 63:2 of the linear address of this token. Replaced by the previous SSP upon successful completion of the RSTORSSP instruction.

Busy. Initially must be 0. Set to 1 upon successful completion of the RSTORSSP instruction.

Mode. If 0, this indicates the shadow stack restore token is for use in legacy or compatibility mode. If 1, this indicates the restore token is for use in 64-bit mode.

After RSTORSSP switches to the new stack the modified shadow stack token is at the top of the new in-use shadow stack. If a return to the old stack is not required, the modified token (to which the previous SSP has been saved) can be popped from the stack using the INCSSP instruction.

If a return to the old stack is desired, the SAVEPREVSSP instruction can be used to copy the token back to the previous stack for later use by an RSTORSSP instruction. The SAVEPREVSSP expects to find a *previous SSP token* on the top of the current shadow stack. After moving this token to the previous stack, SAVEPREVSSP pops it off the new stack by incrementing SSP.

The previous SSP token used by SAVEPREVSSP is formatted as follows:

Figure 18-5. Previous SSP Token

The previous SSP token fields are defined as follows:

Previous SSP. Bits 63:2 of the previous SSP. Upon successful completion, the SAVEPREVSSP instruction copies the token to this address.

Busy. Must be set to 1 initially. Cleared to 0 upon successful completion of the SAVEPREVSSP instruction.

Mode. If 0, this indicates the previous SSP token is for use in legacy or compatibility mode. If 1, this indicates the token is for use in 64-bit mode.

Figure 18-6 “RSTORSSP and SAVEPREVSSP Operation” on page 657 illustrates the operation of the RSTORSSP instruction when switching to a new shadow stack, followed by a SAVEPREVSSP instruction to save a previous token back to the original stack.

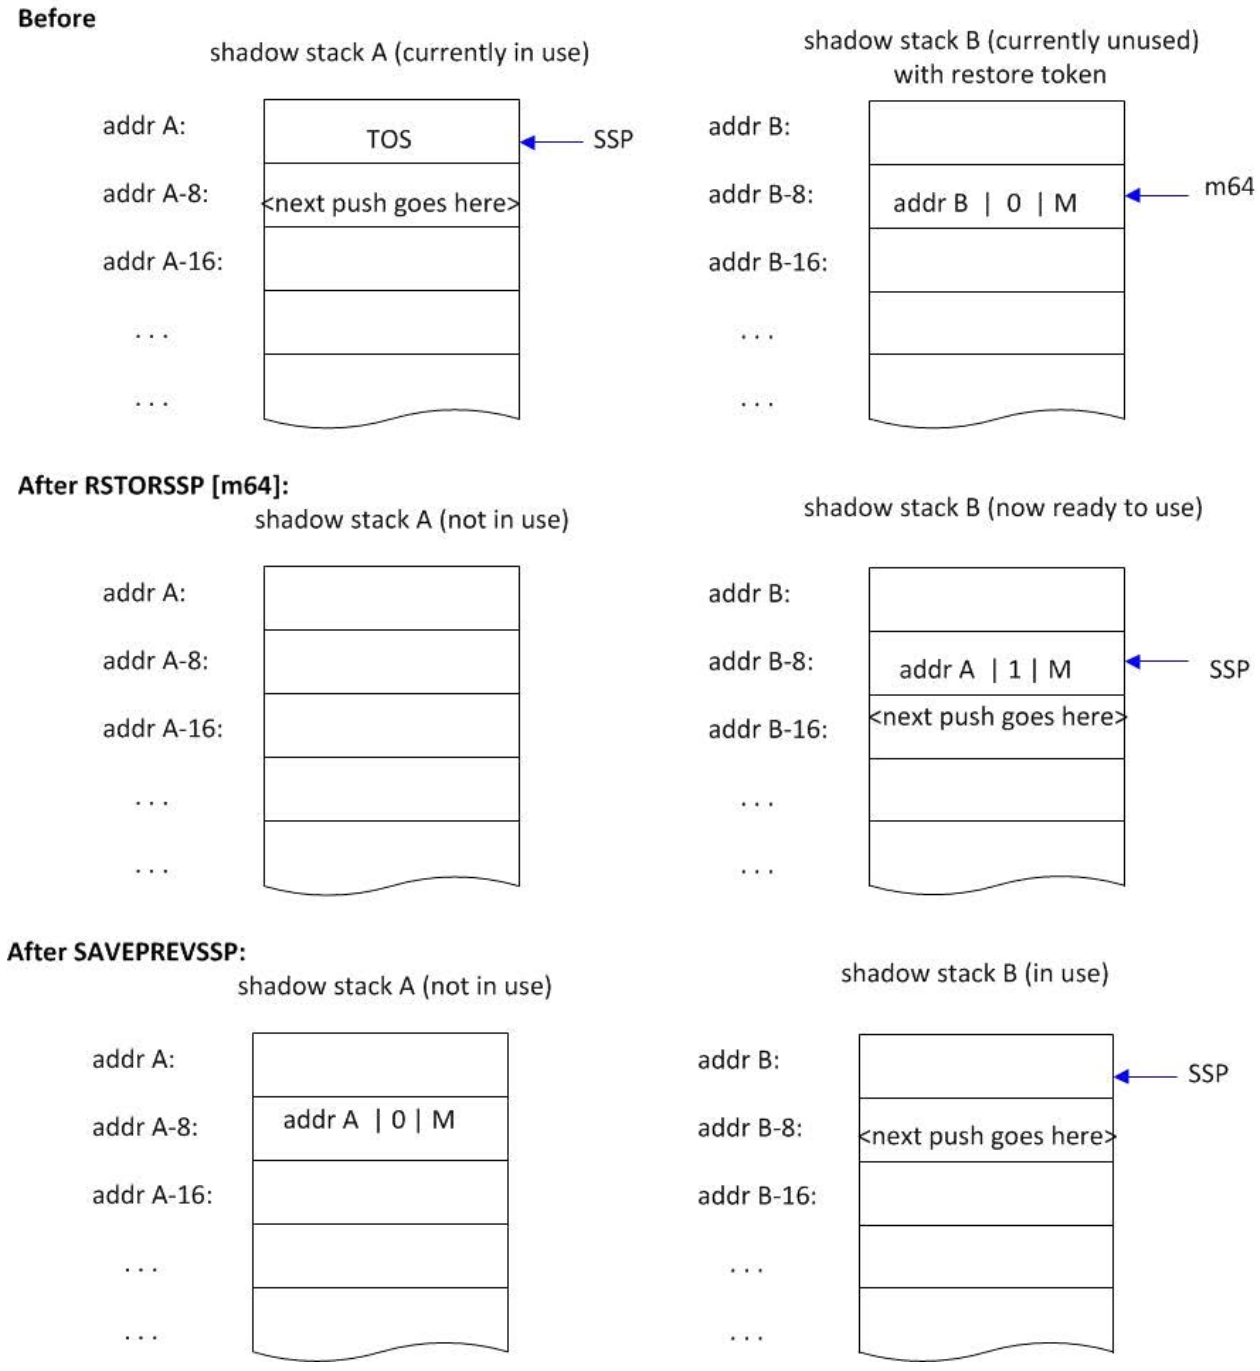


Figure 18-6. RSTORSSP and SAVEPREVSSP Operation

In this example (Figure 18-6 “RSTORSSP and SAVEPREVSSP Operation” on page 657), RSTORSSP is used to switch from shadow stack A to shadow stack B. Subsequently, a SAVEPREVSSP instruction is used to save a shadow stack restore token.

Initially, shadow stack A is in-use, and the proposed shadow stack B contains a shadow stack restore token at address B - 8. An RSTORSSP instruction is then executed with the operand pointing to the restore token.

The RSTORSSP instruction checks the restore token for validity, copies the previous SSP to the token, sets bit 1 of the token and sets the new value of SSP to address B. Shadow stack B is now ready for use.

Next, a SAVEPREVSSP instruction is executed to facilitate a later return to shadow stack A (using a subsequent RSTORSSP instruction, not shown). The SAVEPREVSSP instruction copies the token to address A - 8 and clears token bit 1, then pops the old token from shadow stack B.

For detailed RSTORSSP and SAVEPREVSSP algorithms refer to the instruction descriptions in APM Volume 3.

18.11 Shadow Stack Management Instructions

When shadow stacks are enabled, the following instructions are available to software for use in managing shadow stacks. Except for RDSSP, attempting to execute these instructions when shadow stacks are disabled results in a #UD exception. RDSSP is treated as a NOP when shadow stacks are disabled. For more information refer to the detailed instruction descriptions in APM volume 3.

Table 18-2. Shadow Stack Management Instructions

Mnemonic	Name	Description
CLRSSBSY	Clear Shadow Stack Busy	Validates a shadow stack token and clears its busy bit. This is a privileged instruction.
INCSSP	Increment Shadow Stack Pointer	Increment SSP by ‘n’ stack frames. Used to pop unneeded items from a shadow stack.
RDSSP	Read Shadow Stack Pointer	Read the SSP into a GPR. Treated as a NOP if shadow stacks are disabled.
RSTORSSP	Restore Shadow Stack Pointer	Used to switch shadow stacks. Expects a ‘shadow stack restore token’ at the top of the new shadow stack. Upon validating this token, sets the token’s busy bit and sets SSP to the top of the new shadow stack.
SAVEPREVSSP	Save Previous Shadow Stack Pointer	Copies a ‘previous SSP token’ from the current shadow stack back to the previous stack for later use by an RSTORSSP instruction.

Table 18-2. Shadow Stack Management Instructions (continued)

Mnemonic	Name	Description
SETSSBSY	Set Shadow Stack Busy	Validates the shadow stack token pointed to by the PL0_SSP MSR. If valid, clears the busy bit and sets SSP = PL0_SSP. This is a privileged instruction.
WRSS	Write Shadow Stack	Writes the source operand to a shadow stack. This instruction has associated enable bits in the U_CET and S_CET MSRs
WRUSS	Write User Shadow Stack	Writes the source operand to a user shadow stack. This is a privileged instruction.

18.12 Shadow Stack MSRs

The following MSRs are defined if the shadow stack feature is supported as indicated by CPUID Fn 0000_0007_0 ECX[CET_SS] (bit 7) = 1:

U_CET. MSR 0x6A0. Specifies the user mode shadow stack controls. The individual fields are as follows:

- Bit 0 - SH_STK_EN. When set to 1, enables the shadow stacks in user mode.
- Bit 1 - WR_SHSTK_EN. When set to 1, enables the WRSS instruction is user mode.
- Bits 63:2 – reserved, MBZ

S_CET. MSR 0x6A2. Specifies the supervisor mode shadow stack controls.

- Bit 0 - SH_STK_EN. When set to 1, enables the shadow stacks in supervisor mode.
- Bit 1 - WR_SHSTK_EN. When set to 1, enables the WRSS instruction is supervisor mode.
- Bits 63:2 – reserved, MBZ

PL0_SSP. MSR 0x6A4. Specifies the linear address to be loaded into SSP on the next transition to CPL=0. The linear address must be in canonical format and aligned to 4 bytes when initializing this register.

PL1_SSP. MSR 0x6A5. Specifies the linear address to be loaded into SSP on the next transition to CPL=1. The linear address must be in canonical format and aligned to 4 bytes when initializing this register.

PL2_SSP. MSR 0x6A6. Specifies the linear address to be loaded into SSP on the next transition to CPL=2. The linear address must be in canonical format and aligned to 4 bytes when initializing this register.

PL3_SSP. MSR 0x6A7. The user mode SSP is saved to and restored from this register. The linear address must be in canonical format and aligned to 4 bytes when initializing this register.

ISST_ADDR. MSR 0x6A8. This register specifies the linear address of the Interrupt Shadow Stack Table (ISST). The linear address must be in canonical format.

18.13 XSAVE/XRSTOR

The XSAVE/XRSTOR instructions can be used to manage the shadow stack registers as processor extended state components 11 (CET_U state) and 12 (CET_S state) as described below:

- **CET_U state.** The shadow stack user controls are identified as state component 11 in XFEATURE_ENABLED_MASK and consist of the two 64-bit MSRs U_CET and PL3_SSP. Bytes 7:0 in the XSAVE area are used for U_CET and bytes 15:8 are used for PL3_SSP. The XSAVE area size and offset for the CET_U state are available using CPUID Fn0000_000D_ECX_x0B (ECX=11).
- **CET_S state.** The shadow stack supervisor controls are identified as state component 12 in XFEATURE_ENABLED_MASK and consist of the three 64-bit MSRs PL0_SSP, PL1_SSP and PL2_SSP. Bytes 7:0 in the XSAVE area are used for PL0_SSP, bytes 15:8 are used for PL2_SSP and bytes 23:16 are used for PL3_SSP. The XSAVE area size and offset for the CET_S state are available using CPUID Fn0000_000D_ECX_x0C (ECX=12).

The CET_U and CET_S state components are managed by XSAVE/XRSTOR by setting bits 11 and 12 respectively in XFEATURE_ENABLE_MASK. See Section 11.5.2, “XFEATURE_ENABLED_MASK,” on page 349 for more details. When restoring CET_U and CET_S state, XRSTOR checks for reserved bits and canonicality as described in Section 18.11 “Shadow Stack Management Instructions” on page 658.

System software can enable XSAVES/XRSTORS management of the CET_U and CET_S state components by setting bits 11 and 12 respectively in the XSS MSR.

Appendix A MSR Cross-Reference

This appendix lists the MSRs that are defined in the AMD64 architecture. The AMD64 architecture supports some of the same MSRs as previous versions of the x86 architecture and implementations thereof. Where possible, the AMD64 architecture supports the same MSRs, for the same functions, as these previous architectures and implementations.

The first section lists the MSRs according to their MSR address, and it gives a cross reference for additional information. The remaining sections list the MSRs by their functional group. Those sections also give a brief description of the register and specify the register reset value.

Some MSRs are implementation-specific For information about these MSRs, see the documentation for specific implementations of the AMD64 architecture.

A.1 MSR Cross-Reference by MSR Address

Table A-1 lists the MSRs in the AMD64 architecture in order of MSR address.

Table A-1. MSRs of the AMD64 Architecture

MSR Address	MSR Name	Functional Group	Cross-Reference
0010h	TSC	Performance	“Time-Stamp Counter” on page 407
001Bh	APIC_BASE	System Software	“Local APIC Enable” on page 603
0048h	SPEC_CTRL	Speculation Control	“Speculation Control MSRs” on page 67
0049h	PRED_CMD	Speculation Control	“Speculation Control MSRs” on page 67
00E7h	MPERF	Performance	“Determining Processor Effective Frequency” on page 642
00E8h	APERF	Performance	“Determining Processor Effective Frequency” on page 642
00FEh	MTRRcap	Memory Typing	“Identifying MTRR Features” on page 215
0174h	SYSENTER_CS	System Software	“SYSENTER and SYSEXIT MSRs” on page 173
0175h	SYSENTER_ESP

A.2 System-Software MSRs

Table A-2 lists the MSRs defined for general use by system software in controlling long mode and in allowing fast control transfers between applications and the operating system.

Table A-2. System-Software MSR Cross-Reference

MSR Address	MSR Name	Description	Reset Value
0000_001Bh	APIC_BASE	See appropriate *BIOS and Kernel Developer's Guide (BKDG)* or *Processor Programming Reference Manual* for details.	0000_0000_FEE0_0x00h
C000_0080h	EFER	Contains control bits that enable extended features supported by the processor, including long mode.	0000_0000_0000_0000h
C000_0081h	STAR	In legacy mode, used to specify the target address of a SYSCALL instruction, as well as the CS and SS selectors of the called and returned procedures.	undefined
C000_0082h	LSTAR	In 64-bit mode, used to specify the target RIP of a SYSCALL instruction.	undefined
C000_0083h	CSTAR	In compatibility mode, used to specify the target RIP of a SYSCALL instruction.	undefined
C000_0084h	SF_MASK	SYSCALL Flags Mask	undefined
C000_0100h	FS.Base	Contains the 64-bit base address in the hidden portion of the FS register (the base address from the FS descriptor).	0000_0000_0000_0000h
C000_0101h	GS.Base	Contains the 64-bit base address in the hidden portion of the GS register (the base address from the GS descriptor).	0000_0000_0000_0000h
C000_0102h	KernelGSbase	The SWAPGS instruction exchanges the value in KernelGSbase with the value in GS.base, providing a fast method for system software to load a pointer to system data-structures.	undefined
C000_0103h	TSC_AUX	The RDTSCP instruction copies the value of this MSR into the ECX register.	0000_0000_0000_0000h
C000_0104h	TSC_RATIO	Specifies the TSCRatio value which is used to scale the TSC value read by a Guest.	0000_0001_0000_0000h
0174h	SYSENTER_CS	In legacy mode, used to specify the CS selector of the procedure called by SYSENTER.	undefined
0175h	SYSENTER_ESP	In legacy mode, used to specify the stack pointer for the procedure called by SYSENTER.	undefined
0176h	SYSENTER_EIP	In legacy mode, used to specify the EIP of the procedure called by SYSENTER.	undefined

A.3 Memory-Typing MSRs

Table A-3 lists the MSRs used to control memory-typing and the page-attribute-table mechanism.

Table A-3. Memory-Typing MSR Cross-Reference

MSR Address	MSR Name	Description	Reset Value
00FEh	MTRRcap	A *read-only* register containing information describing the level of MTRR support provided by the processor.	0000_0000_0000_0508h
0200h	MTRRphysBase0	Specifies the memory-range base address in physical-address space of a variable-range memory region. These registers also specify the memory type used for the memory region.	undefined
0202h	MTRRphysBase1		
0204h	MTRRphysBase2		
0206h	MTRRphysBase3		
0208h	MTRRphysBase4		
020Ah	MTRRphysBase5		
020Ch	MTRRphysBase6		
020Eh	MTRRphysBase7		
0201h	MTRRphysMask0	Specifies the size of a variable-range memory region.	Valid (bit 11) = 0 All Other Bits Undefined
0203h	MTRRphysMask1		
0205h	MTRRphysMask2		
0207h	MTRRphysMask3		
0209h	MTRRphysMask4		
020Bh	MTRRphysMask5		
020Dh	MTRRphysMask6		
020Fh	MTRRphysMask7		
0250h	MTRRfix64K_00000	Fixed-range MTRRs used to characterize the first 1 Mbyte of physical memory. Each 64-bit register contains eight type fields for characterizing a total of eight memory ranges. • MTRRfix64K_n characterizes 64 Kbyte ranges. • MTRRfix16K_n characterizes 16 Kbyte ranges. • MTRRfix4K_n characterizes 4 Kbyte ranges.	undefined
0258h	MTRRfix16K_80000		
0259h	MTRRfix16K_A0000		
0268h	MTRRfix4K_C0000		
0269h	MTRRfix4K_C8000		
026Ah	MTRRfix4K_D0000		
026Bh	MTRRfix4K_D8000		
026Ch	MTRRfix4K_E0000		
026Dh	MTRRfix4K_E8000		
026Eh	MTRRfix4K_F0000		
026Fh	MTRRfix4K_F8000		
0277h	PAT	Used to extend the page-table entry format, allowing memory-type characterization on a physical-page basis.	0007_0406_0007_0406h

Table A-3. Memory-Typing MSR Cross-Reference (continued)

MSR Address	MSR Name	Description	Reset Value
02FFh	MTRRdefType	Sets the default memory-type for physical addresses not within ranges established by fixed-range and variable-range MTRRs.	0000_0000_0000_0000h
C001_0010h	SYSCFG	Contains control bits for enabling and configuring system bus features.	0000_0000_0002_0601h
C001_0016h	IORRBase0	Specifies the memory-range base address in physical-address space of a variable-range I/O region.	undefined
C001_0018h	IORRBase1		
C001_0017h	IORRMask0	Specifies the size of a variable-range I/O region.	Valid (bit 11) = 0 All Other Bits Undefined
C001_0019h	IORRMask1		
C001_001Ah	TOP_MEM	Sets the boundary between system memory and memory-mapped I/O for addresses below 4 Gbytes.	0000_0000_0400_0000h
C001_001Dh	TOP_MEM2	Sets the boundary between system memory and memory-mapped I/O for addresses above 4 Gbytes.	undefined

A.4 Machine-Check MSRs

Table A-4 lists the MSRs used in support of the machine-check mechanism.

Table A-4. Machine-Check MSR Cross-Reference

MSR Address	MSR Name	Description	Reset Value
0179h	MCG_CAP	A read-only register that specifies the machine-check mechanism capabilities supported by the processor.	0000_0000_0000_010xh
017Ah	MCG_STATUS	Provides basic information about the processor state immediately after the occurrence of a machine-check error.	undefined
017Bh	MCG_CTL	Controls global reporting of machine-check errors from various sources.	0000_0000_0000_0000h
0400h + 4i for 0 <=i <=31	MCi_CTL	Control for error reporting banks, per implementation.	0000_0000_0000_0000h
0401h + 4i	MCi_STATUS[5:0]	Status registers for each error-reporting register bank, used to report machine-check error information for the specified register bank.	undefined
0402h + 4i	MCi_ADDR[5:0]	Reports the instruction memory-address or data memory-address responsible for the machine-check error for the specified register bank.	undefined
0403h + 4i	MCi_MISC[5:0]	Reports miscellaneous information about the machine-check error for the specified register bank.	c00x_xxxx_xx00_0000
C000_0408h	MC4_MISC1		c00x_xxxx_0000_0000
C000_0409h	MC4_MISC2		
C000_040Ah	MC4_MISC3		
C000_0410h	MCA_INTR_CFG	MCA interrupt configuration.	0000_0000_0000_0000h
C000_2000h + i*10h	MCA_CTL	Control for error reporting banks per implementation.	0000_0000_0000_0000h
C000_2001h + i*10h	MCA_STATUS	Status registers for each error-reporting register bank, used to report machine-check error information for the specified register bank.	undefined
C000_2002h + i*10h	MCA_ADDR	Reports the instruction memory-address or data memory-address responsible for the machine-check error for the specified register bank.	undefined

Table A-4. Machine-Check MSR Cross-Reference (continued)

MSR Address	MSR Name	Description	Reset Value
C000_2003h + i*10h	MCA_MISC0	Reports miscellaneous information about the machine-check error for the specified register bank.	c00x_xxxx_xx00_0000
C000_2004h + i*10h	MCA_CONFIG	Controls configuration information of each MCA bank.	See BKDG/PPR
C000_2005h + i*10h	MCA_IPID	Holds information to identify the MCA bank type	See BKDG/PPR
C000_2006h + i*10h	MCA_SYND	Holds syndrome associated with the error	See BKDG/PPR
C000_2008h + i*10h	MCA_DESTAT	Holds status information for deferred errors.	See BKDG/PPR
C000_2009h + i*10h	MCA_DEADDR	Provides the address associated with the deferred error.	See BKDG/PPR
(C000_200Ah: C000_200Dh) + i*10h	MCA_MISC[4:1]	Reports miscellaneous-error information	See BKDG/PPR
(C000_200Eh: C000_200Fh) + i*10h	MCA_SYND[2:1]	Stores information associated with the error in MCA_STATUS or MCA_DESTAT	See BKDG/PPR
***i* - indicates the register bank number**			

A.5 Software-Debug MSRs

Table A-5 lists the MSRs used in support of the software-debug architecture.

Table A-5. Software-Debug MSR Cross-Reference

MSR Address	MSR Name	Description	Reset Value
01D9h	DebugCtl	Provides debug controls for control-transfer recording and control-transfer single stepping, and external-breakpoint reporting and trace messages.	0000_0000_0000_0000h
01DBh	LastBranchFromIP	During control-transfer recording, this register is loaded with the segment offset of the control-transfer source.	undefined
01DCh	LastBranchToIP	During control-transfer recording, this register is loaded with the segment offset of the control-transfer target.	undefined

Table A-5. Software-Debug MSR Cross-Reference (continued)

MSR Address	MSR Name	Description	Reset Value
01DDh	LastIntFromIP	When an interrupt occurs during control-transfer recording, this register is loaded with LastBranchFromIP before LastBranchFromIP is updated.	undefined
01DEh	LastIntToIP	When an interrupt occurs during control-transfer recording, this register is loaded with LastBranchToIP before LastBranchToIP is updated.	undefined
C000_1027h	DR0_ADDR_MASK	Address mask for DR0 breakpoint [31:0]	0000_0000_0000_0000h
C000_1019h	DR1_ADDR_MASK	Address mask for DR1 breakpoint [31:0]	0000_0000_0000_0000h
C000_101Ah	DR2_ADDR_MASK	Address mask for DR2 breakpoint [31:0]	0000_0000_0000_0000h
C000_101Bh	DR3_ADDR_MASK	Address mask for DR3 breakpoint [31:0]	0000_0000_0000_0000h

A.6 Performance-Monitoring MSRs

Table A-6 lists the MSRs used in support of performance monitoring, including the time-stamp counter.

Table A-6. Performance-Monitoring MSR Cross-Reference

MSR Address	MSR Name	Description	Reset Value
0010h	TSC	Counts processor-clock cycles. It is incremented once for each processor-clock cycle.	0000_0000_0000_0000h
00E7h	MPERF	Denominator of effective frequency ratio.	0000_0000_0000_0000h
00E8h	APERF	Numerator of effective frequency ratio.	0000_0000_0000_0000h
C000_00E7h	MPerfReadOnly	Read only version of MPERF.	0000_0000_0000_0000h
C000_00E8h	APerfReadOnly	Read only version of APERF.	
C000_00E9h	IRPerfCount	Dedicated instructions retired performance counter.	
C001_0000h	PerfEvtSel0	For the corresponding performance counter, this register specifies the events counted, and controls other aspects of counter operation.	0000_0000_0000_0000h
C001_0001h	PerfEvtSel1		
C001_0002h	PerfEvtSel2		
C001_0003h	PerfEvtSel3		
C001_0004h	PerfCtr0	Used to count specific processor events, or the duration of events, as specified by the corresponding PerfEvtSel*n* register.	undefined
C001_0005h	PerfCtr1		
C001_0006h	PerfCtr2		
C001_0007h	PerfCtr3		

Table A-6. Performance-Monitoring MSR Cross-Reference (continued)

MSR Address	MSR Name	Description	Reset Value
C001_0200h	PerfEvtSel0	These MSR addresses are aliases for the base set of performance event-select registers PerfEvtSel[3:0].	0000_0000_0000_0000h
C001_0202h	PerfEvtSel1		
C001_0204h	PerfEvtSel2		
C001_0206h	PerfEvtSel3		
C001_0208h	PerfEvtSel4	Extended core performance event-select registers. Support for these MSRs is indicated by CPUID Fn8000_0001_ECX[PerfCtrExtCore] = 1.	
C001_020Ah	PerfEvtSel5		
C001_0201h	PerfCtr0	These MSR addresses are aliases for the base set of performance-monitoring counter registers PerfCtr[3:0].	undefined
C001_0203h	PerfCtr1		
C001_0205h	PerfCtr2		
C001_0207h	PerfCtr3		
C001_0209h	PerfCtr4	Extended core performance counter registers. Support for these MSRs is indicated by CPUID Fn8000_0001_ECX[PerfCtrExtCore] = 1.	
C001_020Bh	PerfCtr5		
C001_0230h	L2I_PerfEvtSel0	Specifies the L2 cache events to be counted and controls other aspects of counter operation. Support for these MSRs is indicated by CPUID Fn8000_0001_ECX[PerfCtrExtL2I] = 1.	0000_0000_0000_0000h
C001_0232h	L2I_PerfEvtSel1		
C001_0234h	L2I_PerfEvtSel2		
C001_0236h	L2I_PerfEvtSel3		
C001_0231h	L2I_PerfCtr0	Counts specific L2 cache events as specified by the corresponding L2I_PerfEvtSel*n* Register. Support for these MSRs is indicated by CPUID Fn8000_0001_ECX[PerfCtrExtL2I] = 1.	undefined
C001_0233h	L2I_PerfCtr1		
C001_0235h	L2I_PerfCtr2		
C001_0237h	L2I_PerfCtr3		
C001_0240h	NB_PerfEvtSel0	Specifies northbridge events to be counted and controls other aspects of counter operation. Support for these MSRs is indicated by CPUID Fn8000_0001_ECX[PerfCtrExtNB] = 1.	0000_0000_0000_0000h
C001_0242h	NB_PerfEvtSel1		
C001_0244h	NB_PerfEvtSel2		
C001_0246h	NB_PerfEvtSel3		
C001_0241h	NB_PerfCtr0	Counts specific northbridge events as specified by the corresponding NB_PerfEvtSel*n* Register. Support for these MSRs is indicated by CPUID Fn8000_0001_ECX[PerfCtrExtNB] = 1.	undefined
C001_0243h	NB_PerfCtr1		
C001_0245h	NB_PerfCtr2		
C001_0247h	NB_PerfCtr3		

A.7 Secure Virtual Machine MSRs

Table A-7 lists the MSRs used in support of SVM functions.

Table A-7. Secure Virtual Machine MSR Cross-Reference

MSR Address	MSR Name	Description	Reset Value
C000_0104h	TSC Ratio	Ratio for scaling TSC, MPERF, and MPerfReadOnly values read by guest.	
C001_0114h	VM_CR	Controls certain global aspects of SVM.	undefined
C001_0115h	IGNNE	Sets the state of the processor-internal IGNNE signal.	
C001_0116h	SMM_CTL	Provides software control over SMM signals.	
C001_0117h	VM_HSAVE_PA	Holds the physical address of a block of memory where VMRUN saves host state, and from which #VMEXIT reloads host state.	
C001_0118h	SVM_KEY	Creates a password-protected mechanism to clear VM_CR.LOCK.	
C001_011Bh	Doorbell Register	Sends a doorbell signal to the specified physical APIC.	
C001_011Eh	VMPAGE_FLUSH	“Secure Encrypted Virtualization” on page 571	
C001_0130h	GHCB	Guest-HV Communication Block address (see section 15.35.7)	
C001_0131h	SEV_STATUS	SEV active features indication (see section 15.35.10)	
C001_0132h	RMP_BASE	Base address of RMP (see 15.36.4)	0000_0000_0000_0000h
C001_0133h	RMP_END	Ending address of RMP (see 15.36.4)	0000_0000_0000_0000h
C001_0134h	GUEST_TSC_FREQ	Guest TSC Frequency (see 15.36.18)	0000_0000_0000_0000h

A.8 System Management Mode MSRs

Table A-8 lists the MSRs used in support of SMM functions.

Table A-8. System Management Mode MSR Cross-Reference

MSR Address	MSR Name	Description	Reset Value
C001_0056h	SMI_Trigger_IO_Cycle	Specifies an IO cycle that may be generated when a local SMI trigger event occurs. See the appropriate *BIOS and Kernel Developer's Guide (BKDG)* or *Processor Programming Reference Manual* for details.	0000_0000_0000_0000h
C001_0061h	P-State Current Limit		
C001_0062h	P-State Control		
C001_0063h	P-State Status		
C001_0111h	SMBASE	Contains the SMRAM base address.	0000_0000_0003_0000h
C001_0112h	SMM_ADDR	Contains the base address of protected memory for the SMM Handler.	0000_0000_0000_0000h
C001_0113h	SMM_MASK	Contains a mask which determines the size of the protected area for the SMM handler.	0000_0000_0000_0000h
C001_0119h	SMM_KEY_MSR		
C001_011Ah	Local_SMI_Status	Contains status associated with SMI sources local to the CPU core. See the appropriate *BIOS and Kernel Developer's Guide (BKDG)* or *Processor Programming Reference Manual* for details.	0000_0000_0000_0000h

A.9 CPUID Name MSR Cross-Reference

Table A-9 lists the MSRs used to support CPUID namestring.

Table A-9. CPUID Namestring MSR Cross Reference

MSR Address	MSR Name	Description	Reset Value
C001_0030h	Processor_Name_String	See appropriate *BIOS and Kernel Developer's Guide (BKDG)* or *Processor Programming Reference Manual* and *Processor Revision Guide*.	0000_0000_0000_0000h
C001_0031h			
C001_0032h			
C001_0033h			
C001_0034h			
C001_0035h			

A.10 Shadow Stack MSRs

Table A-10 lists the MSRs that support the shadow stack feature. These registers are defined if the shadow stack feature is present as indicated by CPUID Fn0000_0007_x0_ECX[CET_SS] (bit 7) =1.

Table A-10. Shadow Stack MSR Cross Reference

MSR Address	MSR Name	Description	Reset Value
06A0h	U_CET	User-mode shadow stack controls	0000_0000_0000_0000h
06A2h	S_CET	Supervisor-mode shadow stack controls	
06A4h	PL0_SSP	CPL 0 shadow stack pointer	
06A5h	PL1_SSP	CPL 1 shadow stack pointer	
06A6h	PL2_SSP	CPL 2 shadow stack pointer	
06A7h	PL3_SSP	CPL 3 shadow stack pointer	
06A8h	ISST_ADDR	Contains the base address of the Interrupt SSP Table	

A.11 Speculation Control MSRs

Table A-11 lists the MSRs that support speculation control. See “Speculation Control MSRs” on page 67 for further details, including how to determine whether these registers are defined.

Table A-11. Speculation Control MSRs

MSR Address	MSR Name	Description	Reset Value
0048h	SPEC_CTRL	Speculation Control	0000_0000_0000_0000h
0049h	PRED_CMD	Prediction Control	
C000_011Fh	VIRT_SPEC_CTRL	Virtual Speculation Control	

Appendix B Layout of VMCB

The VMCB is divided into two areas—the first one contains various control bits including the intercept vectors and the second one contains saved guest state.

Table B-1 describes the layout of the control area of the VMCB, which starts at offset zero within the VMCB page. The control area is padded to a size of 1024 bytes. All unused bytes must be zero, as they are reserved for future expansion. It is recommended that software zero out any newly allocated VMCB.

Table B-1. VMCB Layout, Control Area

Byte Offset	Bit(s)	Function
000h (vector 0)	15:0	Intercept reads of CR0–15, respectively.
	31:16	Intercept writes of CR0–15, respectively.
004h (vector 1)	15:0	Intercept reads of DR0–15, respectively.
	31:16	Intercept writes of DR0–15, respectively.
008h (vector 2)	31:0	Intercept exception vectors 0–31, respectively.
00Ch (vector 3)	0	Intercept INTR (physical maskable interrupt).
	1	Intercept NMI.
	2	Intercept SMI.
	3	Intercept INIT.
	4	Intercept VINTR (virtual maskable interrupt).
	5	Intercept CR0 writes that change bits other than CR0.TS or CR0.MP.
	6	Intercept reads of IDTR.
	7	Intercept reads of GDTR.
	8	Intercept reads of LDTR.
	9	Intercept reads of TR.
	10	Intercept writes of IDTR.
	11	Intercept writes of GDTR.
	12	Intercept writes of LDTR.
	13	Intercept writes of TR.
	14	Intercept RDTSC instruction.
	15	Intercept RDPMC instruction.

Table B-1. VMCB Layout, Control Area (continued)

Byte Offset	Bit(s)	Function
00Ch (continued)	16	Intercept PUSHF instruction.
	17	Intercept POPF instruction.
	18	Intercept CPUID instruction.
	19	Intercept RSM instruction.
	20	Intercept IRET instruction.
	21	Intercept INT*n* instruction.
	22	Intercept INVD instruction.
	23	Intercept PAUSE instruction.
	24	Intercept HLT instruction.
	25	Intercept INVLPG instruction.
	26	Intercept INVLPGA instruction.
	27	IOIO_PROT—Intercept IN/OUT accesses to selected ports.
	28	MSR_PROT—intercept RDMSR or WRMSR accesses to selected MSRs.
	29	Intercept task switches.
	30	FERR_FREEZE: intercept processor “freezing” during legacy FERR handling.
	31	Intercept shutdown events.

Table B-1. VMCB Layout, Control Area (continued)

Byte Offset	Bit(s)	Function
010h (vector 4)	0	Intercept VMRUN instruction.
	1	Intercept VMMCALL instruction.
	2	Intercept VMLOAD instruction.
	3	Intercept VMSAVE instruction.
	4	Intercept STGI instruction.
	5	Intercept CLGI instruction.
	6	Intercept SKINIT instruction.
	7	Intercept RDTSCP instruction.
	8	Intercept ICEBP instruction.
	9	Intercept WBINVD and WBNOINVD instructions.
	10	Intercept MONITOR/MONITORX instruction.
	11	Intercept MWAIT/MWAITX instruction unconditionally.
	12	Intercept MWAIT/MWAITX instruction if monitor hardware is armed.
	13	Intercept XSETBV instruction.
	14	Intercept RDPRU instruction.
	15	Intercept writes of EFER (occurs after guest instruction finishes).
	31:16	Intercept writes of CR0-15 (occurs after guest instruction finishes).
014h (vector 5)	0	Intercept all INVLPGB instructions.
	1	Intercept only illegally specified INVLPGB instructions.
	2	Intercept INVPCID instruction.
	3	Intercept MCOMMIT instruction.
	4	Intercept TLBSYNC instruction. Presence of this bit is indicated by CPUID Fn8000_000A, EDX[24] = 1.
	31:5	RESERVED, SBZ
018h–03Bh	RESERVED, SBZ	
03Ch	15:0	PAUSE Filter Threshold.
03Eh	15:0	PAUSE Filter Count.
040h	63:0	IOPM_BASE_PA—Physical base address of IOPM (bits 11:0 are ignored.)
048h	63:0	MSRPM_BASE_PA—Physical base address of MSRPM (bits 11:0 are ignored.)
050h	63:0	TSC_OFFSET—To be added in RDTSC and RDTSCP.

Table B-1. VMCB Layout, Control Area (continued)

Byte Offset	Bit(s)	Function
058h	31:0	Guest ASID
	39:32	TLB_CONTROL 00h—Do nothing. 01h—Flush entire TLB (all entries, all ASIDs) on VMRUN. Should only be used by legacy hypervisors. 03h—Flush this guest's TLB entries. 07h—Flush this guest's non-global TLB entries. ***NOTE:*** *All other encodings are reserved.*
	63:40	RESERVED, SBZ
060h	7:0	V_TPR—The virtual TPR for the guest. Bits 3:0 are used for a 4-bit virtual TPR value; bits 7:4 are SBZ. *NOTE: This value is written back to the VMCB at #VMEXIT.*
	8	V_IRQ—If nonzero, virtual INTR is pending. ***NOTE:*** *This value is written back to the VMCB at #VMEXIT. This field is ignored on VMRUN when AVIC is enabled.*
	9	VGIF value (0 – Virtual interrupts are masked, 1 – Virtual Interrupts are unmasked)
	15:10	RESERVED, SBZ
	19:16	V_INTR_PRIO—Priority for virtual interrupt ***NOTE:*** *This field is ignored on VMRUN when AVIC is enabled.*
	20	V_IGN_TPR—If nonzero, the current virtual interrupt ignores the (virtual) TPR. ***NOTE:*** *This field is ignored on VMRUN when AVIC is enabled.*
	23:21	RESERVED, SBZ
	24	V_INTR_MASKING—Virtualize masking of INTR interrupts ("Virtualizing APIC.TPR" on page 518).
	25	AMD Virtual GIF enabled for this guest (0 - Disabled, 1 - Enabled)
	30:26	Reserved, SBZ
	31	AVIC Enable
	39:32	V_INTR_VECTOR—Vector to use for this interrupt. *NOTE: This field is ignored on VMRUN when AVIC is enabled.*
	63:40	RESERVED, SBZ
068h	0	INTERRUPT_SHADOW - Guest is in an interrupt shadow
	1	GUEST_INTERRUPT_MASK - Value of the RFLAGS.IF bit for the guest. ***Note:*** *This value is written back to the VMCB on #VMEXIT. It is not used during VMRUN*
	63:2	RESERVED, SBZ
070h	63:0	EXITCODE
078h	63:0	EXITINFO1

Table B-1. VMCB Layout, Control Area (continued)

Byte Offset	Bit(s)	Function
080h	63:0	EXITINFO2
088h	63:0	EXITINTINFO
090h	0	NP_ENABLE—Enable nested paging.
	1	Enable Secure Encrypted Virtualization
	2	Enable Encrypted State for Secure Encrypted Virtualization
	3	Guest Mode Execute Trap
	4	SSSCheckEn - Enable supervisor shadow stack restrictions in nested page tables. Support for this feature is indicated by CPUID Fn8000_000A_EDX[19] (SSSCheck).
	5	Virtual Transparent Encryption
	6	RESERVED, SBZ
	7	Enable INVLPGB/TLBSYNC. 0 - INVLPGB and TLBSYNC will result in #UD. 1 - INVLPGB and TLBSYNC can be executed in guest. Presence of this bit is indicated by CPUID bit 8000_000A, EDX[24] = 1. When in SEV-ES guest or this bit is not present, INVLPGB/TLBSYNC is always enabled in guest if supported by processor.
	63:8	RESERVED, SBZ
098h	63:52	RESERVED, SBZ
	51:0	AVIC APIC_BAR
0A0h	63:0	Guest physical address of GHCB
0A8h	63:0	EVENTINJ—Event injection (“Event Injection” on page 516 for details.)
0B0h	63:0	N_CR3—Nested page table CR3 to use for nested paging
0B8h	0	LBR_VIRTUALIZATION_ENABLE 0—Do nothing. 1—Enable LBR virtualization hardware acceleration.
	1	Virtualized VMSAVE/VMLOAD (0 –Disabled, 1- Enabled)
	63:2	RESERVED, SBZ
0C0h	31:0	VMCB Clean Bits. See “Layout of VMCB Clean Field” on page 512.
	63:32	RESERVED, SBZ
0C8h	63:0	nRIP—Next sequential instruction pointer
0D0h	7:0	Number of bytes fetched
	127:8	Guest instruction bytes
0E0h	63:52	RESERVED, SBZ
	51:0	AVIC APIC_BACKING_PAGE Pointer

Table B-1. VMCB Layout, Control Area (continued)

Byte Offset	Bit(s)	Function
0E8h–0EFh	Reserved, SBZ	
0F0h	63:52	RESERVED, SBZ
	51:12	AVIC LOGICAL_TABLE Pointer
	11:0	Reserved, SBZ
0F8h	63:52	RESERVED, SBZ
	51:12	AVIC PHYSICAL_TABLE Pointer[51:12]
	11:8	RESERVED, SBZ
	7:0	AVIC_PHYSICAL_MAX_INDEX
100h – 107h	RESERVED, SBZ	
108h	63:52	RESERVED, SBZ
	51:12	VMSA Pointer[51:12]
	11:0	RESERVED, SBZ
All other fields up to 3DFh	RESERVED, SBZ	
3E0h – 3FFh	Reserved for Host usage	

When SEV-ES is not enabled, the state-save area within the VMCB starts at offset 400h into the VMCB page; Table B-2 describes the fields within the state-save area; note that the table lists offsets *relative to the state-save area* (not the VMCB as a whole).

Table B-2. VMCB Layout, State Save Area

Offset	Size	Contents		Notes
000h	word	ES	selector	
002h	word		attrib

270h	qword	DBGCTL	Guest DebugCtl MSR—only used if hardware acceleration of LBR virtualization is supported and enabled by setting the LBR_VIRTUALIZATION_ENABLE bit of the VMCB control area.
278h	qword	BR_FROM	Guest LastBranchFromIP MSR—only used if hardware acceleration of LBR virtualization is supported and enabled.
280h	qword	BR_TO	Guest LastBranchToIP MSR—only used if hardware acceleration of LBR virtualization is supported and enabled.
288h	qword	LASTEXCPFROM	Guest LastIntFromIP MSR—Only used if hardware acceleration of LBR virtualization is supported and enabled.
298h–2DFh	72 bytes	RESERVED	
2E0h	qword	SPEC_CTRL	
2E8h to end of VMCB		RESERVED	

When SEV-ES is enabled (Section 15.35 “Encrypted State (SEV-ES)” on page 578), the VMSA structure starts at offset 0h in the page indicated by the VMSA Pointer. The format of the VM save state for SEV-ES guests is described in the table below.

All state is categorized into 3 swap types based on how it is handled by hardware during a world switch:

Table B-3. Swap Types

Swap Type	Behavior in VMRUN	Behavior in AE VMEXIT
A	Host state saved to host save area Guest state loaded from VMSA	Guest state saved to VMSA Host state loaded from host save area
B	Guest state loaded from VMSA (Host state **not** saved to host save area)	Guest state saved to VMSA Host state loaded from host save area
C	Guest state loaded from VMSA (Host state **not** saved to host save area)	Guest state saved to VMSA Host state initialized to default (reset) values

The format of the host save area is identical to the guest save area described in the table below, except that it begins at offset 400h in the host save page (e.g., the host TR value is stored at offset 490h relative to the start of the host save page).

Table B-4. VMSA Layout, State Save Area for SEV-ES

Offset	Size	Content	Swap Type	Notes
000h	16 bytes	ES	A

Appendix C SVM Intercept Exit Codes

When the VMRUN instruction exits (back to the host), an exit/reason code is stored in the EXITCODE field in the VMCB. The exit codes are defined in Table C-1. Intercept exit codes 0h–8Dh equal the bit position of the corresponding flag in the VMCB's intercept vector.

Table C-1. SVM Intercept Codes

Code	Name	Cause
0h–Fh	VMEXIT_CR[0–15]_READ	read of CR 0 through 15, respectively
10h–1Fh	VMEXIT_CR[0–15]_WRITE	write of CR 0 through 15, respectively
20h–2Fh	VMEXIT_DR[0–15]_READ	read of DR 0 through 15, respectively
30h–3Fh	VMEXIT_DR[0–15]_WRITE	write of DR 0 through 15, respectively
40h–5Fh	VMEXIT_EXCP[0–31]	exception vector 0–31, respectively
60h	VMEXIT_INTR	physical INTR (maskable interrupt)
61h	VMEXIT_NMI	physical NMI
62h	VMEXIT_SMI	physical SMI (the EXITINFO1 field provides more information)
63h	VMEXIT_INIT	physical INIT
64h	VMEXIT_VINTR	virtual INTR
65h	VMEXIT_CR0_SEL_WRITE	write of CR0 that changed any bits other than CR0.TS or CR0.MP
66h	VMEXIT_IDTR_READ	read of IDTR
67h	VMEXIT_GDTR_READ	read of GDTR
68h	VMEXIT_LDTR_READ	read of LDTR
69h	VMEXIT_TR_READ	read of TR
6Ah	VMEXIT_IDTR_WRITE	write of IDTR
6Bh	VMEXIT_GDTR_WRITE	write of GDTR
6Ch	VMEXIT_LDTR_WRITE	write of LDTR
6Dh	VMEXIT_TR_WRITE	write of TR
6Eh	VMEXIT_RDTSC	RDTSC instruction
6Fh	VMEXIT_RDPMC	RDPMC instruction
70h	VMEXIT_PUSHF	PUSHF instruction
71h	VMEXIT_POPF	POPF instruction
72h	VMEXIT_CPUID	CPUID instruction
73h	VMEXIT_RSM	RSM instruction
74h	VMEXIT_IRET	IRET instruction
75h	VMEXIT_SWINT	software interrupt (INT*n* instructions)
76h	VMEXIT_INVD	INVD instruction
77h	VMEXIT_PAUSE	PAUSE instruction
78h	VMEXIT_HLT	HLT instruction

Table C-1. SVM Intercept Codes (continued)

Code	Name	Cause
79h	VMEXIT_INVLPG	INVLPG instructions
7Ah	VMEXIT_INVLPGA	INVLPGA instruction
7Bh	VMEXIT_IOIO	IN or OUT accessing protected port (the EXITINFO1 field provides more information)
7Ch	VMEXIT_MSR	RDMSR or WRMSR access to protected MSR
7Dh	VMEXIT_TASK_SWITCH	task switch
7Eh	VMEXIT_FERR_FREEZE	FP legacy handling enabled, and processor is frozen in an x87/mmx instruction waiting for an interrupt
7Fh	VMEXIT_SHUTDOWN	Shutdown
80h	VMEXIT_VMRUN	VMRUN instruction
81h	VMEXIT_VMMCALL	VMMCALL instruction
82h	VMEXIT_VMLOAD	VMLOAD instruction
83h	VMEXIT_VMSAVE	VMSAVE instruction
84h	VMEXIT_STGI	STGI instruction
85h	VMEXIT_CLGI	CLGI instruction
86h	VMEXIT_SKINIT	SKINIT instruction
87h	VMEXIT_RDTSCP	RDTSCP instruction
88h	VMEXIT_ICEBP	ICEBP instruction
89h	VMEXIT_WBINVD	WBINVD or WBNOINVD instruction
8Ah	VMEXIT_MONITOR	MONITOR or MONITORX instruction
8Bh	VMEXIT_MWAIT	MWAIT or MWAITX instruction
8Ch	VMEXIT_MWAIT_CONDITIONAL	MWAIT or MWAITX instruction, if monitor hardware is armed.
8Eh	VMEXIT_RDPRU	RDPRU instruction
8Dh	VMEXIT_XSETBV	XSETBV instruction
8Fh	VMEXIT_EFER_WRITE_TRAP	Write of EFER MSR (occurs after guest instruction finishes)
90h-9Fh	VMEXIT_CR[0-15]_WRITE_TRAP	Write of CR0-15, respectively (occurs after guest instruction finishes)
A0h	VMEXIT_INVLPGB	INVLPGB instruction
A1h	VMEXIT_INVLPGB_ILLEGAL	Illegal INVLPGB instruction
A2h	VMEXIT_INVPCID	INVPCID instruction
A3h	VMEXIT_MCOMMIT	MCOMMIT instruction
A4h	VMEXIT_TLBSYNC	TLBSYNC instruction
400h	VMEXIT_NPF	Nested paging: host-level page fault occurred (EXITINFO1 contains fault error code; EXITINFO2 contains the guest physical address causing the fault.)
401h	AVIC_INCOMPLETE_IPI	AVIC—Virtual IPI delivery not completed. See "AVIC IPI Delivery Not Completed" for EXITINFO1–2 definitions.

Table C-1. SVM Intercept Codes (continued)

Code	Name	Cause
402h	AVIC_NOACCEL	AVIC—Attemped access by guest to vAPIC register not handled by AVIC hardware. See "AVIC Access to un-accelerated vAPIC register" for EXITINFO1–2 definitions.
403h	VMEXIT_VMGEXIT	VMGEXIT instruction
F000_000h	Unused	Reserved for Host
–1	VMEXIT_INVALID	Invalid guest state in VMCB
–2	VMEXIT_BUSY	BUSY bit was set in the encrypted VMSA (see "Interrupt Injection Restrictions")

Appendix D SMM Containerization

To minimally participate in SMM activity, the VMM can implement simple containerization. This appendix provides example pseudocode to perform this simple containerization. VMMs that do not trust SMM code should implement secure containerization, which requires further extension of the code provided here.

D.1 SMM Containerization Pseudocode

This code emulates transitions to and from SMM:

- The process of entering SMM mode as a result of a system management interrupt (SMI)
- The RSM instruction, which returns the processor from SMM.

A hypervisor that containerizes SMM must set the SMM intercept bit in all guest VMCBs. When the hypervisor encounters a #VMEXIT(SMI), it should then emulate SMM entry and execute the SMM handler by means of VMRUN with the RSM intercept bit set. When the RSM instruction is intercepted, the hypervisor should emulate the RSM instruction and then resume normal execution.

In this code, the hypervisor sets up the `smm_vmcb` from scratch and assigns it the supplied address space identifier (ASID).

This example code sets up a container VMCB for the SMM handler and copies appropriate state information into the SMM save area. After calling `emulate_smm()`, the hypervisor should repeatedly VMRUN the SMM handler VMCB until the hypervisor encounters a #VMEXIT(RSM). Finally, the hypervisor should call `emulate_rsm()`.

```
//emulate_smm( ):
// Inputs:
//   smm_vmcb:   the _virtual address_ of a VMCB that will be configured
//               as an SMM container
//   asid:       the asid to use for the SMM handler; the hypervisor should
//               ensure that no TLB entries for this ASID are present in the TLB
//   smm_regs:   an array of 64-bit values that will be filled with the
//               GPRs (except RSP and RAX) for the SMM handler
//   guest_vmcb:  the _virtual address_ of the VMCB of the guest
//                that was running when the intercepted SMI occurred
//   guest_regs: an array of 64-bit values that contains the GPRs (except RSP
//               and RAX) for the guest that was running when the intercepted
//               SMI occurred

void
emulate_smm(VMCB *smm_vmcb, uint32 asid, uint64 smm_regs[16],
            VMCB *guest_vmcb, uint64 guest_regs[16])
{
   setup_smm_container(*smm_vmcb, asid, smm_regs, *guest_vmcb, guest_regs)
```

```
   //Enter SMM mode:
   wrmsr(SMM_CTL_MSR, ENTER+DISMISS+SMI_CYCLE)
   setup_smm_save_state(*guest_vmcb, guest_regs)

   do { VMRUN(smm_vmcb) } until we see #VMEXIT(RSM).
       Shadow EFER reads and writes to protect the SVME bit.

   //Emulate RSM:
   copy_smm_save_to_guest_vmcb(guest_vmcb, guest_regs)
   //Leave SMM mode:
   wrmsr(SMM_CTL_MSR, EXIT+RSM_CYCLE)
}

   } else if (smmsave.hltrestart is set) {
      // (In the event that the guest is allowed to execute HLT and
      // the SMM code wants to use the auto-halt restart function,
      // we need to re-execute the HLT instruction in the guest context.
      // Even if the HLT has prefixes (all of which would be ignored),
      // we know that RIP-1 is the F4 opcode itself.)

      Subtract 1 from the guest RIP under a mask that masks out bits
             above the current default address size:

      mask = (1 << current_address_size) - 1
      g_vmcb.RIP = mask & (g_vmcb.RIP-1)
   } else {
      set g_vmcb.RIP = smmsave.RIP
   }
// Note that it is undefined to have both iorestart and hltrestart set at
// the same time.

// Perform the RSM consistency checks listed in volume 3 of the
// AMD64 Architecture Programmer's manual, except the check that
// disallows CR0.PG = 1 when CR0.PE = 0.  Note that the expected
// value for the SMM revision field is 0x0003_0064.  If any of the
// checks fail, the native RSM instruction would have caused a
// processor shutdown (which commonly results in a reboot
// triggered by the chipset). The hypervisor may wish to destroy
// the guest or cause its own shutdown.
}
```

D.1.1 Converting Simple Containerization into Secure Containerization

To convert this simple containerization example into secure containerization, the hypervisor must limit the SMM handler's access to I/O ports, MSRs, and memory. Based on security policy decisions, the hypervisor should set appropriate bits in the I/O Protection Map and the MSR Protection map and emulate any accesses the SMM handler makes to those protected resources. The hypervisor should run the SMM handler in paged real mode, with a page table that appropriately limits memory accessible to SMM code. Additionally, the hypervisor may wish to conceal some or all of the contents of a guest's general purpose and floating-point registers from the SMM handler.

Appendix E OS-Visible Workarounds

Operating system software may provide a workaround for a hardware erratum. These operating system-visible workarounds are provisional and should be removed or disabled when the erratum is corrected in a subsequent hardware release.

The OS-Visible Workaround (OSVW) architecture provides a means by which operating system software may determining the status of a known erratum for the hardware on which the software is running. Support for the OSVW mechanism is indicated by CPUID Fn8000_0001_ECX[OSVW] = 1.

See Section 3.3, "Processor Feature Identification," on page 71 for information on using the CPUID instruction.

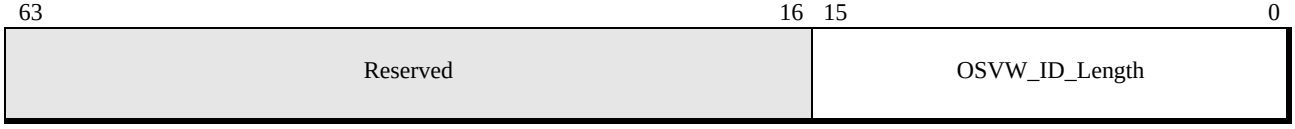
Each hardware erratum is assigned a unique OSVW ID number. OSVW ID numbers start at 0 and are assigned sequentially up to the most recently identified erratum which is assigned the number *m*–1. The OSVW mechanism encodes the status of each erratum for a given hardware system in a bit vector of length *m* accessed through OSVM MSRs 1–N. The state of bit *n* of the vector indicates the status of the erratum with the OSVW ID number *n*. The OSVW ID number for the erratum and the bit position within the erratum status bit vector, once assigned, are global across all AMD processors; the OSVW ID and bit position will not be re-used.

The OSVW MSRs are defined as follows:

- OSVW MSR0 contains the *OSVW_ID_Length* field, used to indicate the total number of valid OSVW ID bits (*m*). The format of this MSR is shown in Figure E-1 below.
- OSVW MSR 1 and following contain the erratum status bit vector of length *m*. Each bit *n* of this vector encodes the status of erratum *n* (OSVW ID = *n*). The format of these MSRs is shown in Figure E-2 on page 704.

The bank of OSVW MSRs is located at address C001_0140h, starting with OSVW MSR0.

The OSVW MSRs should be treated as read-only registers for the OS. The OS should never write into these registers. Hardware allows platform firmware writes to these registers.



Bits	Mnemonic	Description	R/W[1]
63:16	Reserved		
15:0	OSVW_ID_Length	Total length of the status vector OSVW_E in bits.	R/W

Note 1: MSR should be treated as read-only by operating system software.

Figure E-1. OSVW MSR0: OSVW_ID_Length

OSVW_ID_Length—Bits [15:0]. The number of valid bits in the OSVW erratum status vector OSVW_E. If a specific erratum has an OSVW ID that is greater than or equal to the *OSVW_ID_Length*, the erratum is unknown to the latest release. Otherwise, the erratum status bit in the appropriate OSVW MSR can be checked to see if a workaround is required.

The erratum status bit vector (OSVW_E) is accessed through OSVW MSR 1 and following. For MSR *N*, the 64-bit MSR holds erratum status bits (*N*–1)*64+63:(*N*–1)*64. To access the erratum status for OSVW ID number *n* (E[*n*] in the diagram), read MSR *N*, where *N* = *n*/64 + 1, and test bit *i*, where *i* = *n* modulo 64.

Figure E-2 below gives the format of the OSVW MSRs 1–N.

Bit	Mnemonic	Description	R/W[1]
i	OSVW_E[*n*]	OS-visible workaround status bit *n*	R/W

Note 1: MSR should be treated as read-only by operating system software.

Figure E-2. OSVW MSRs 1–N: OSVW Erratum Status Registers

OS-Visible Workaround Erratum Status (OSVW_E[n])—Bits 63:0. Each bit indicates whether platform hardware is affected by OS-visible erratum *n* and whether the OS needs to apply a workaround.

For the status bit:

1 = Hardware contains the erratum; an OS software workaround is required.

0 = Hardware has corrected the erratum; an OS software workaround is unnecessary. If one is installed, it must be disabled.

The location of an OSVW ID status bit within a bank of OSVW MSRs is determined as follows:

- MSR address = OSVW_MSR0 + 1 + floor (OSVW_ID /64)
- Bit offset in MSR = OSVW_ID modulo 64

If a specific erratum has an OSVW_ID that is greater than or equal to the OSVW_ID_LENGTH, hardware does not know about the erratum and the processor model must be used to determine whether the workaround must be applied.

OSVW MSR bits beyond the end of the OSVW_E bit vector are reserved.

E.1 Erratum Process Overview

Following is an overview of the AMD erratum process:

1. When an OS-visible erratum is discovered, AMD assigns a unique OSVW ID to the erratum and publishes to OS vendors the starting range of affected processor models and suggested workarounds.
2. AMD works with platform firmware vendors and OEMs in parallel to develop a firmware update to add the new erratum status bit to the OSVW_E erratum status bit vector for affected silicon revisions to report the new OSVW ID as requiring a workaround. The OSVW_ID_Length field in OSVW MSR0 is incremented by one.
3. OS vendors schedule the workaround into their release schedules and eventually release it.
4. The OS detection logic for the workaround first checks whether the processor OSVW MSRs 1–N record the erratum by comparing the OSVW ID of the erratum with the OSVW_ID_Length field in OSVW MSR0.
5. If the erratum OSVW ID is greater than or equal to the OSVW_ID_Length, the current firmware does not know about this erratum. In this case, the OS software compares the processor model ID with the starting model ID that AMD supplied with the erratum to determine if the workaround should be applied.
6. If the erratum OSVW ID is less than the OSVW_ID_Length, the firmare is aware of the erratum. In this case, the OS uses the state of the associated OSVW_E status bit to conditionally apply the workaround. If the associated status bit is set, the workaround is applied.
7. Once AMD fixes the erratum in a future release, updated firmware ensures that the OSVW_E status bit associated with the erratum is cleared. When OS workaround detection logic runs on the new hardware, it will see that the bit corresponding to the OSVW ID is cleared and not apply the OS workaround for that erratum.

Revision History

Date	Revision	Description
November 2021	3.33	Added CET exception case to RET FAR pseudo code. Added missing INCSSP exception information. Clarified INVLPGB description. Added details to RDPMC description. Corrected exception information for PSMASH, RMPADJUST, RMPUPDATE. Added clarification to TLBSYNC. Added CPUID information for various new features. Corrected opcode map note for PREFETCH encodings.
March 2021	3.32	Chapter 1: Updated Instruction Encoding Syntax and An Instruction as Stored in Memory figures. Added content to Summary of Legacy Prefixes section. Chapter 3: Added content Instruction Support Indicated by CPUID Feature Bits table. Added content to LFENCE Updated note 1 in the Legacy Instruction Prefixes table. Chapter 4: Added content to the System Instruction Support Indicated by CPUID Feature Bits table. Added VMGEXIT instruction. Added content to WRMSR instruction. Appendix D: Added content to the Feature Flags for Instruction / Instruction Subset Support table. Appendix E: Updated instructions and added instructions to sections E.3 and E.4: See bold line items.

Date	Revision	Description
October 2020	3.31	Chapter 2: Added to pseudocode Definition section. Table 2-1: Added content. Chapter 3: Added pseudocode updates. Chapter 4: Added pseudocode updates. Added 8 new instructions. Added INVLPGB, TLBSYNC to System Instruction Support Indicated by CPUID Feature Bits table. Updated INVLPGB and TLBSYNC description. Appendix A: Instructions encoding clarifications. Appendix D: Added new instructions to Feature Flags for Instruction / Instruction Subset Support table. Appendix E: Added content to CPUID Fn0000_0007_ECX_x0 Structured Extended Feature Identifiers (ECX=0) table and to Function Dh—Processor Extended State Enumeration section. Added content to CPUID Fn8000_0008_EBX Extended Feature Identifiers, CPUID Fn8000_000A_EDX SVM Feature Identification, and CPUID Fn8000_001F_EAX tables.
April 2020	3.30	Chapter 4: Updated INVLPG, MOV CRn, and RSM sections. Chapter 4: Added INVLPGB, INVPCID, RDPKRU, TLBSYNC, and WRPKRU instructions. Appendix D: Table D-1. Updated table. Appendix E: Updated E.3.6, E.4.7, and E.4.9 sections.
April 2020	3.29	Table 2-1: Added content. Chapter 4: Added PSMASH, PVALIDATE, RMPADJUST, and RMPUPDATE instructions. Appendix A: Table A-6, A-7, and A-8: Updated table. Appendix D: Table D-1: Added content. Removed D.3 section. Appendix E: Material for new features plus clarifications. Appendix F: Table F-1: Added content.
September 2019	3.28	Added MCOMMIT instruction. Corrected CPUID function 8000_001Dh description.
July 2019	3.27	Added CLWB, RDPID, RDPRU, and WBNOINVD instructions. Corrected functional details of BZHI instruction. Corrected SAHF and LAHF #UD fault details. Corrected RSM reserved-bit behavioral details.

Date	Revision	Description
May 2018	3.26	Modified description of CLFLUSH. Added clarification that MOVD is referred to in some forms as MOVQ. Corrected the operands for VMOVNTDQA . Updated L2/L3 Cache and Associativity tables with new encodings over old reserved encodings Updated CPUID with Nested Virtualization and Virtual GIF indication bits.
December 2017	3.25	Updated Appendix E.
November 2017	3.24	Modified Mem16int in Section 2.5.1 Mnemonic Syntax Corrected Opcode for ADCX and ADOX. Clarified the explanation for Load Far Pointer Modified the Description for CLAC and STAC Added clarification to MWAITX. Added clarifying footnote to Table A-6. Added CPUID flags for new SVM features. Added Bit descriptions for CPUID Fn8000_0008_EBX Reserved Modified SAL1 and SAL count in Appendix F, Table F-1.
March 2017	3.23	Added CR0.PE, CR0.PE=1, EFER.LME=0 to Conventions and Definitions in the Preface. Modified Note 4 in Table 1-10. Chapter 3: Added ADCX, ADOX, CLFLUSHOPT, CLZERO, RDSEED, UD0 and UD1. Modified CALL (Far). Moved UD2 and MONITORX, MWAITX, from Chapter 4. Chapter 4: Modified RDTSC and RDTSCP. Added CLAC and STAC. Appendix A: Modified Table A-7, Group 11. Appendix D: Modified Table D-1 and Added new Feature Flags.
June 2015	3.22	Added MONITORX and MWAITX to Chapter 4.

Date	Revision	Description
October 2013	3.21	Added BMI2 instructions to Chapter 3. Added BZHI to Table F-1 on page 635. Changed CPUID Fn8000_0001_ECX[25] to reserved. Changed CPUID Fn8000_0007_EAX and _EDX[11] to reserved. Added CPUID Fn0000_0006_EDX[ARAT] (bit 2).
May 2013	3.20	Updated Appendix D "Instruction Subsets and CPUID Feature Flags" on page 587 to make instruction list comprehensive. Added a new Appendix E "Obtaining Processor Information Via the CPUID Instruction" on page 593 which describes all defined processor feature bits. Supersedes and replaces the *CPUID Specification* (PID # 25481). Previous Appendix E "Instruction Effects on RFLAGS" renumbered as Appendix F.
September 2012	3.19	Corrected the value specified for the most significant nibble of the encoding for the VPSHAx instructions in Table A-28 on page 544.
March 2012	3.18	Added MOVBE instruction reference page to Chapter 3 "General-Purpose Instruction Reference" on page 71. Added instruction reference pages for the RDFSBASE/RDGSBASE and WRFSBASE/WRGSBASE instructions to Chapter 3. Added opcodes for the instructions to the opcode maps in Appendix A.

Date	Revision	Description
December 2011	3.17	Corrected second byte of VEX C5 escape sequence in Figure 1-2 on page 5. Made multiple corrections to the description of register-indirect addressing in Section 1.4 on page 17. Corrected *mod* field value in third row of Figure 1-16 on page 25. Updated pseudocode definition (see Section 2.5.3 on page 57). Corrected exception tables for LZCNT and TZCNT instructions. Added discussion of UD opcodes to introduction of Appendix A. Provided ommitted definition of “B” used in the specification of operand types in opcode maps of Appendix A. Provided numerous corrections to instruction entries in opcode maps of Appendix A. Added ymm register mnemonic to Table A-32 on page 546 and Table A-34 on page 548. Changed notational convention for indicating addressing modes in Table A-33 on page 546, Table A-35 on page 549, Table A-36 on page 551, and Table A-37 on page 552; edited footnotes.
September 2011	3.16	Reworked “Instruction Byte Order” section of Chapter 1. See “Instruction Encoding Overview” on page 1. Added clarification: Execution of VMRUN is disallowed while in System Management Mode. Made wording for BMI and TBM feature flag indication consistent with other instructions. Moved BMI and TBM instructions to this volume from Volume 4. Added instruction reference page for CRC32 Instruction. Removed one cause of #GP fault from exception table for LAR and LSL instructions. Added three-byte, VEX, and XOP opcode maps to Appendix A. Revised description of RDPMC instruction. Corrected errors in description of CLFLUSH instruction. Corrected footnote of Table A-35 on page 549.
November 2009	3.15	Clarified MFENCE serializing behavior. Added multibyte variant to “NOP” on page 237. Corrected descriptive text to “CMPXCHG8B CMPXCHG16B” on page 151.
September 2007	3.14	Added minor clarifications and corrected typographical and formatting errors.

Date	Revision	Description
July 2007	3.13	Added the following instructions: LZCNT, POPCNT, MONITOR, and MWAIT. Reformatted information on instruction support indicated by CPUID feature bits into a table. Added minor clarifications and corrected typographical and formatting errors.
September 2006	3.12	Added minor clarifications and corrected typographical and formatting errors.
December 2005	3.11	Added SVM instructions; added PAUSE instructions; made factual changes.
January 2005	3.10	Clarified CPUID information in exception tables on instruction pages. Added information under “CPUID” on page 153. Made numerous small corrections.
September 2003	3.09	Corrected table of valid descriptor types for LAR and LSL instructions and made several minor formatting, stylistic and factual corrections. Clarified several technical definitions.
April 2003	3.08	Corrected description of the operation of flags for RCL, RCR, ROL, and ROR instructions. Clarified description of the MOVSXD and IMUL instructions. Corrected operand specification for the STOS instruction. Corrected opcode of SET*cc*, J*cc*, instructions. Added thermal control and thermal monitoring bits to CPUID instruction. Corrected exception tables for POPF, SFENCE, SUB, XLAT, IRET, LSL, MOV(CR*n*), SGDT/SIDT, SMSW, and STI instructions. Corrected many small typos and incorporated branding terminology.

Preface

About This Book

This book is part of a multivolume work entitled the *AMD64 Architecture Programmer's Manual*. This table lists each volume and its order number.

Title	Order No.
Volume 1: Application Programming	24592
Volume 2: System Programming	24593
Volume 3: General-Purpose and System Instructions	24594
Volume 4: 128-Bit and 256-Bit Media Instructions	26568
Volume 5: 64-Bit Media and x87 Floating-Point Instructions	26569

Audience

This volume (Volume 3) is intended for all programmers writing application or system software for a processor that implements the AMD64 architecture. Descriptions of general-purpose instructions assume an understanding of the application-level programming topics described in Volume 1. Descriptions of system instructions assume an understanding of the system-level programming topics described in Volume 2.

Organization

Volumes 3, 4, and 5 describe the AMD64 architecture's instruction set in detail. Together, they cover each instruction's mnemonic syntax, opcodes, functions, affected flags, and possible exceptions.

The AMD64 instruction set is divided into five subsets:

- General-purpose instructions
- System instructions
- Streaming SIMD Extensions–SSE (includes 128-bit and 256-bit media instructions)
- 64-bit media instructions (MMX™)
- x87 floating-point instructions

Several instructions belong to—and are described identically in—multiple instruction subsets.

This volume describes the general-purpose and system instructions. The index at the end cross-references topics within this volume. For other topics relating to the AMD64 architecture, and for

information on instructions in other subsets, see the tables of contents and indexes of the other volumes.

Conventions and Definitions

The following section **Notational Conventions** describes notational conventions used in this volume and in the remaining volumes of this *AMD64 Architecture Programmer's Manual*. This is followed by a **Definitions** section which lists a number of terms used in the manual along with their technical definitions. Finally, the **Registers** section lists the registers which are a part of the application programming model.

Notational Conventions

#GP(0)

An instruction exception—in this example, a general-protection exception with error code of 0.

1011b

A binary value—in this example, a 4-bit value.

F0EA_0B02h

A hexadecimal value. Underscore characters may be inserted to improve readability.

128

Numbers without an alpha suffix are decimal unless the context indicates otherwise.

7:4

A bit range, from bit 7 to 4, inclusive. The high-order bit is shown first. Commas may be inserted to indicate gaps.

CPUID Fn*XXXX_XXXX_RRR*[*FieldName*]

Support for optional features or the value of an implementation-specific parameter of a processor can be discovered by executing the CPUID instruction on that processor. To obtain this value, software must execute the CPUID instruction with the function code *XXXX_XXXX*h in EAX and then examine the field *FieldName* returned in register *RRR*. If the "*_RRR*" notation is followed by "*_xYYY*", register ECX must be set to the value *YYY*h before executing CPUID. When *FieldName* is not given, the entire contents of register *RRR* contains the desired value. When determining optional feature support, if the bit identified by *FieldName* is set to a one, the feature is supported on that processor.

CR0–CR4

A register range, from register CR0 through CR4, inclusive, with the low-order register first.

CR0[PE], CR0.PE

Notation for referring to a field within a register—in this case, the PE field of the CR0 register.

CR0[PE] = 1, CR0.PE = 1

Notation indicating that the PE bit of the CR0 register has a value of 1.

DS:rSI

The contents of a memory location whose segment address is in the DS register and whose offset relative to that segment is in the rSI register.

EFER[LME] = 0, EFER.LME = 0

Notation indicating that the LME bit of the EFER register has a value of 0.

RFLAGS[13:12]

A field within a register identified by its bit range. In this example, corresponding to the IOPL field.

Definitions

Many of the following definitions assume an in-depth knowledge of the legacy x86 architecture. See "Related Documents" on page xxxvi for descriptions of the legacy x86 architecture.

128-bit media instructions

Instructions that operate on the various 128-bit vector data types. Supported within both the legacy SSE and extended SSE instruction sets.

256-bit media instructions

Instructions that operate on the various 256-bit vector data types. Supported within the extended SSE instruction set.

64-bit media instructions

Instructions that operate on the 64-bit vector data types. These are primarily a combination of MMX™ and 3DNow!™ instruction sets, with some additional instructions from the SSE1 and SSE2 instruction sets.

16-bit mode

Legacy mode or compatibility mode in which a 16-bit address size is active. See *legacy mode* and *compatibility mode*.

32-bit mode

Legacy mode or compatibility mode in which a 32-bit address size is active. See *legacy mode* and *compatibility mode*.

64-bit mode

A submode of *long mode*. In 64-bit mode, the default address size is 64 bits and new features, such as register extensions, are supported for system and application software.

absolute

Said of a displacement that references the base of a code segment rather than an instruction pointer. Contrast with *relative*.

biased exponent

The sum of a floating-point value's exponent and a constant bias for a particular floating-point data type. The bias makes the range of the biased exponent always positive, which allows reciprocation without overflow.

byte

Eight bits.

clear

To write a bit value of 0. Compare *set*.

compatibility mode

A submode of *long mode*. In compatibility mode, the default address size is 32 bits, and legacy 16-bit and 32-bit applications run without modification.

commit

To irreversibly write, in program order, an instruction's result to software-visible storage, such as a register (including flags), the data cache, an internal write buffer, or memory.

CPL

Current privilege level.

direct

Referencing a memory location whose address is included in the instruction's syntax as an immediate operand. The address may be an absolute or relative address. Compare *indirect*.

dirty data

Data held in the processor's caches or internal buffers that is more recent than the copy held in main memory.

displacement

A signed value that is added to the base of a segment (absolute addressing) or an instruction pointer (relative addressing). Same as *offset*.

doubleword

Two words, or four bytes, or 32 bits.

double quadword

Eight words, or 16 bytes, or 128 bits. Also called *octword*.

effective address size

The address size for the current instruction after accounting for the default address size and any address-size override prefix.

effective operand size

The operand size for the current instruction after accounting for the default operand size and any operand-size override prefix.

element

See *vector*.

exception

An abnormal condition that occurs as the result of executing an instruction. The processor's response to an exception depends on the type of the exception. For all exceptions except 128-bit media SIMD floating-point exceptions and x87 floating-point exceptions, control is transferred to the handler (or service routine) for that exception, as defined by the exception's vector. For floating-point exceptions defined by the IEEE 754 standard, there are both masked and unmasked responses. When unmasked, the exception handler is called, and when masked, a default response is provided instead of calling the handler.

flush

An often ambiguous term meaning (1) writeback, if modified, and invalidate, as in "flush the cache line," or (2) invalidate, as in "flush the pipeline," or (3) change a value, as in "flush to zero."

GDT

Global descriptor table.

IDT

Interrupt descriptor table.

IGN

Ignored. Value written is ignored by hardware. Value returned on a read is indeterminate. See *reserved*.

indirect

Referencing a memory location whose address is in a register or other memory location. The address may be an absolute or relative address. Compare *direct*.

IRB

The virtual-8086 mode interrupt-redirection bitmap.

IST

The long-mode interrupt-stack table.

IVT

The real-address mode interrupt-vector table.

LDT

Local descriptor table.

legacy x86

The legacy x86 architecture. See “Related Documents” on page xxxvi for descriptions of the legacy x86 architecture.

legacy mode

An operating mode of the AMD64 architecture in which existing 16-bit and 32-bit applications and operating systems run without modification. A processor implementation of the AMD64 architecture can run in either *long mode* or *legacy mode*. Legacy mode has three submodes, *real mode*, *protected mode*, and *virtual-8086 mode*.

LIP

Linear Instruction Pointer. LIP = (CS.base + rIP).

long mode

An operating mode unique to the AMD64 architecture. A processor implementation of the AMD64 architecture can run in either *long mode* or *legacy mode*. Long mode has two submodes, *64-bit mode* and *compatibility mode*.

lsb

Least-significant bit.

LSB

Least-significant byte.

main memory

Physical memory, such as RAM and ROM (but not cache memory) that is installed in a particular computer system.

mask

(1) A control bit that prevents the occurrence of a floating-point exception from invoking an exception-handling routine. (2) A field of bits used for a control purpose.

MBZ

Must be zero. If software attempts to set an MBZ bit to 1, a general-protection exception (#GP) occurs.

memory

Unless otherwise specified, *main memory*.

ModRM
: A byte following an instruction opcode that specifies address calculation based on mode (Mod), register (R), and memory (M) variables.

moffset
: A 16, 32, or 64-bit offset that specifies a memory operand directly, without using a ModRM or SIB byte.

msb
: Most-significant bit.

MSB
: Most-significant byte.

multimedia instructions
: A combination of *128-bit media instructions* and *64-bit media instructions*.

octword
: Same as *double quadword.*

offset
: Same as *displacement*.

overflow
: The condition in which a floating-point number is larger in magnitude than the largest, finite, positive or negative number that can be represented in the data-type format being used.

packed
: See *vector*.

PAE
: Physical-address extensions.

physical memory
: Actual memory, consisting of *main memory* and cache.

probe
: A check for an address in a processor's caches or internal buffers. *External probes* originate outside the processor, and *internal probes* originate within the processor.

procedure stack
: A portion of a stack segment in memory that is used to link procedures. Also known as a program

stack.

program stack
: See procedure stack.

protected mode
: A submode of *legacy mode*.

quadword
: Four words, or eight bytes, or 64 bits.

RAZ
: Read as zero. Value returned on a read is always zero (0) regardless of what was previously written. See *reserved*.

real-address mode
: See *real mode*.

real mode
: A short name for *real-address mode*, a submode of *legacy mode*.

relative
: Referencing with a displacement (also called offset) from an instruction pointer rather than the base of a code segment. Contrast with *absolute*.

reserved
: Fields marked as reserved may be used at some future time.

  To preserve compatibility with future processors, reserved fields require special handling when read or written by software. Software must not depend on the state of a reserved field (unless qualified as RAZ), nor upon the ability of such fields to return a previously written state.

  If a field is marked reserved without qualification, software must not change the state of that field; it must reload that field with the same value returned from a prior read.

  Reserved fields may be qualified as IGN, MBZ, RAZ, or SBZ (see definitions).

REX
: An instruction prefix that specifies a 64-bit operand size and provides access to additional registers.

RIP-relative addressing
: Addressing relative to the 64-bit RIP instruction pointer.

SBZ
: Should be zero. An attempt by software to set an SBZ bit to 1 results in undefined behavior.

shadow stack

A shadow stack is a separate, protected stack that is conceptually parallel to the procedure stack and used only by the shadow stack feature.

set

To write a bit value of 1. Compare *clear*.

SIB

A byte following an instruction opcode that specifies address calculation based on scale (S), index (I), and base (B).

SIMD

Single instruction, multiple data. See *vector*.

SSE

Streaming SIMD extensions instruction set. See *128-bit media instructions* and *64-bit media instructions*.

SSE2

Extensions to the SSE instruction set. See *128-bit media instructions* and *64-bit media instructions*.

SSE3

Further extensions to the SSE instruction set. See *128-bit media instructions.*

sticky bit

A bit that is set or cleared by hardware and that remains in that state until explicitly changed by software.

TOP

The x87 top-of-stack pointer.

TPR

Task-priority register (CR8).

TSS

Task-state segment.

underflow

The condition in which a floating-point number is smaller in magnitude than the smallest nonzero, positive or negative number that can be represented in the data-type format being used.

vector

(1) A set of integer or floating-point values, called *elements*, that are packed into a single operand. Most of the 128-bit and 64-bit media instructions use vectors as operands. Vectors are also called *packed* or *SIMD* (single-instruction multiple-data) operands.

(2) An index into an interrupt descriptor table (IDT), used to access exception handlers. Compare *exception*.

virtual-8086 mode

A submode of *legacy mode*.

word

Two bytes, or 16 bits.

x86

See *legacy x86*.

Registers

In the following list of registers, the names are used to refer either to a given register or to the contents of that register:

AH–DH

The high 8-bit AH, BH, CH, and DH registers. Compare *AL–DL*.

AL–DL

The low 8-bit AL, BL, CL, and DL registers. Compare *AH–DH*.

AL–r15B

The low 8-bit AL, BL, CL, DL, SIL, DIL, BPL, SPL, and R8B–R15B registers, available in 64-bit mode.

BP

Base pointer register.

CR*n*

Control register number *n*.

CS

Code segment register.

eAX–eSP

The 16-bit AX, BX, CX, DX, DI, SI, BP, and SP registers or the 32-bit EAX, EBX, ECX, EDX, EDI, ESI, EBP, and ESP registers. Compare *rAX–rSP*.

EFER

Extended features enable register.

eFLAGS

16-bit or 32-bit flags register. Compare *rFLAGS*.

EFLAGS

32-bit (extended) flags register.

eIP

16-bit or 32-bit instruction-pointer register. Compare *rIP*.

EIP

32-bit (extended) instruction-pointer register.

FLAGS

16-bit flags register.

GDTR

Global descriptor table register.

GPRs

General-purpose registers. For the 16-bit data size, these are AX, BX, CX, DX, DI, SI, BP, and SP. For the 32-bit data size, these are EAX, EBX, ECX, EDX, EDI, ESI, EBP, and ESP. For the 64-bit data size, these include RAX, RBX, RCX, RDX, RDI, RSI, RBP, RSP, and R8–R15.

IDTR

Interrupt descriptor table register.

IP

16-bit instruction-pointer register.

LDTR

Local descriptor table register.

MSR

Model-specific register.

r8–r15

The 8-bit R8B–R15B registers, or the 16-bit R8W–R15W registers, or the 32-bit R8D–R15D registers, or the 64-bit R8–R15 registers.

rAX–rSP

The 16-bit AX, BX, CX, DX, DI, SI, BP, and SP registers, or the 32-bit EAX, EBX, ECX, EDX, EDI, ESI, EBP, and ESP registers, or the 64-bit RAX, RBX, RCX, RDX, RDI, RSI, RBP, and RSP registers. Replace the placeholder *r* with nothing for 16-bit size, “E” for 32-bit size, or “R” for 64-bit size.

RAX

64-bit version of the EAX register.

RBP
64-bit version of the EBP register.

RBX
64-bit version of the EBX register.

RCX
64-bit version of the ECX register.

RDI
64-bit version of the EDI register.

RDX
64-bit version of the EDX register.

rFLAGS
16-bit, 32-bit, or 64-bit flags register. Compare *RFLAGS*.

RFLAGS
64-bit flags register. Compare *rFLAGS*.

rIP
16-bit, 32-bit, or 64-bit instruction-pointer register. Compare *RIP*.

RIP
64-bit instruction-pointer register.

RSI
64-bit version of the ESI register.

RSP
64-bit version of the ESP register.

SP
Stack pointer register.

SS
Stack segment register.

SSP
Shadow-stack pointer register.

TPR
Task priority register, a new register introduced in the AMD64 architecture to speed interrupt management.

TR

Task register.

Endian Order

The x86 and AMD64 architectures address memory using little-endian byte-ordering. Multibyte values are stored with their least-significant byte at the lowest byte address, and they are illustrated with their least significant byte at the right side. Strings are illustrated in reverse order, because the addresses of their bytes increase from right to left.

1 Instruction Encoding

AMD64 technology instructions are encoded as byte strings of variable length. The order and meaning of each byte of an instruction's encoding is specified by the architecture. Fields within the encoding specify the instruction's basic operation, the location of the one or more source operands, and the destination of the result of the operation. Data to be used in the execution of the instruction or the computation of addresses for memory-based operands may also be included. This section describes the general format and parameters used by all instructions.

For information on the specific encoding(s) for each instruction, see:

- Chapter 3, "General-Purpose Instruction Reference."
- Chapter 4, "System Instruction Reference."
- "SSE Instruction Reference" in Volume 4.
- "64-Bit Media Instruction Reference" in Volume 5.
- "x87 Floating-Point Instruction Reference" in Volume 5.

For information on determining the instruction form and operands specified by a given binary encoding, see Appendix A.

1.1 Instruction Encoding Overview

An instruction is encoded as a string between one and 15 bytes in length. The entire sequence of bytes that represents an instruction, including the basic operation, the location of source and destination operands, any operation modifiers, and any immediate and/or displacement values, is called the instruction encoding.The following sections discuss instruction encoding syntax and representation in memory.

1.1.1 Encoding Syntax

Figure 1-1 provides a schematic representation of the encoding syntax of an instruction.

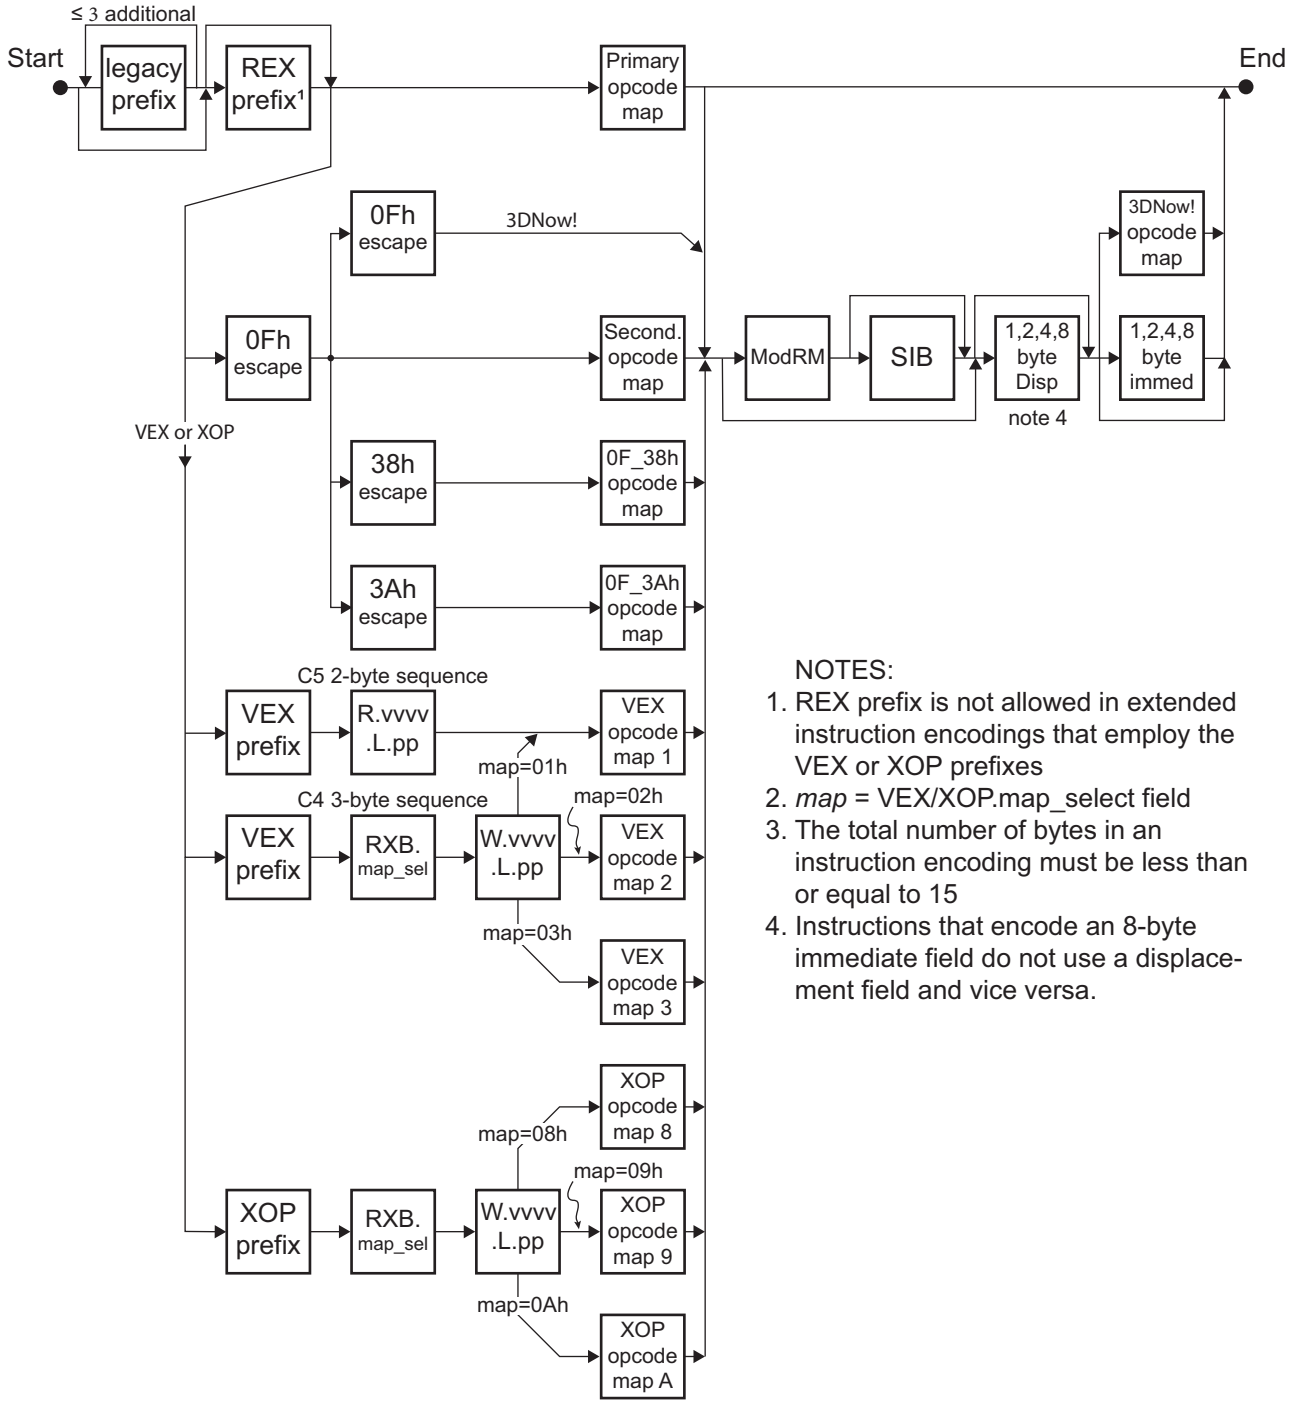

Figure 1-1. Instruction Encoding Syntax

Each square in this diagram represents an instruction byte of a particular type and function. To understand the diagram, follow the connecting paths in the direction indicated by the arrows from "Start" to "End." The squares passed through as the graph is traversed indicate the order and number of

bytes used to encode the instruction. Note that the path shown above the legacy prefix byte loops back indicating that up to four additional prefix bytes may be used in the encoding of a single instruction. Branches indicate points in the syntax where alternate semantics are employed based on the instruction being encoded. The “VEX or XOP” gate across the path leading down to the VEX prefix and XOP prefix blocks means that only extended instructions employing the VEX or XOP prefixes use this particular branch of the syntax diagram. This diagram will be further explained in the sections that follow.

1.1.1.1 Legacy Prefixes

As shown in the figure, an instruction optionally begins with up to five *legacy prefixes*. These prefixes are described in “Summary of Legacy Prefixes” on page 6. The legacy prefixes modify an instruction’s default address size, operand size, or segment, or they invoke a special function such as modification of the opcode, atomic bus-locking, or repetition.

In the encoding of most SSE instructions, a legacy operand-size or repeat prefix is repurposed to modify the opcode. For the extended encodings utilizing the XOP or VEX prefixes, these prefixes are not allowed.

1.1.1.2 REX Prefix

Following the optional legacy prefix or prefixes, the REX prefix can be used in 64-bit mode to access the AMD64 register number and size extensions. Refer to the diagram in “Application-Programming Register Set” in Volume 1 for an illustration of these facilities. If a REX prefix is used, it must immediately precede the opcode byte or the first byte of a legacy *escape sequence*. The REX prefix is not allowed in extended instruction encodings using the VEX or XOP encoding escape prefixes. Violating this restriction results in an #UD exception.

1.1.1.3 Opcode

The *opcode* is a single byte that specifies the basic operation of an instruction. Every instruction requires an opcode. The correspondence between the binary value of an opcode and the operation it represents is presented in a table called an *opcode map*. Because it is indexed by an 8-bit value, an opcode map has 256 entries. Since there are more than 256 instructions defined by the architecture, multiple different opcode maps must be defined and the selection of these alternate opcode maps must be encoded in the instruction. Escape sequences provide this access to alternate opcode maps.

If there are no opcode escapes, the primary (“one-byte”) opcode map is used. In the figure this is the path pointing from the REX Prefix block to the Primary opcode map block.

Section , “Primary Opcode Map” of Appendix A provides details concerning this opcode map.

1.1.1.4 Escape Sequences

Escape sequences allow access to alternate opcode maps that are distinct from the primary opcode map. Escape sequences may be one, two, or three bytes in length and begin with a unique byte value designated for this purpose in the primary opcode map. Escape sequences are of two distinct types:

legacy escape sequences and extended escape sequences. The legacy escape sequences will be covered here. For more details on the extended escape sequences, see “VEX and XOP Prefixes” on page 16.

Legacy Escape Sequences

The legacy syntax allows one 1-byte escape sequence (0Fh), and three 2-byte escape sequences (0Fh, 0Fh; 0Fh, 38h; and 0Fh, 3Ah). The 1-byte legacy escape sequence 0Fh selects the secondary (“two-byte”) opcode map. In legacy terminology, the sequence [0Fh, *opcode*] is called a two-byte opcode. See Section , “Secondary Opcode Map” of Appendix A for details concerning this opcode map.

The 2-byte escape sequence 0F, 0Fh selects the 3DNow! opcode map which is indexed using an immediate byte rather than an opcode byte. In this case, the byte following the escape sequence is the ModRM byte instead of the opcode byte. In Figure 1-1 this is indicated by the path labeled “3DNow!” leaving the second 0Fh escape block. Details concerning the 3DNow! opcode map are presented in Section A.1.2, “3DNow!™ Opcodes” of Appendix A.

The 2-byte escape sequences [0Fh, 38h] and [0Fh, 3Ah] respectively select the 0F_38h opcode map and the 0F_3Ah opcode map. These are used primarily to encode SSE instructions and are described in Section , “0F_38h and 0F_3Ah Opcode Maps” of Appendix A.

1.1.1.5 ModRM and SIB Bytes

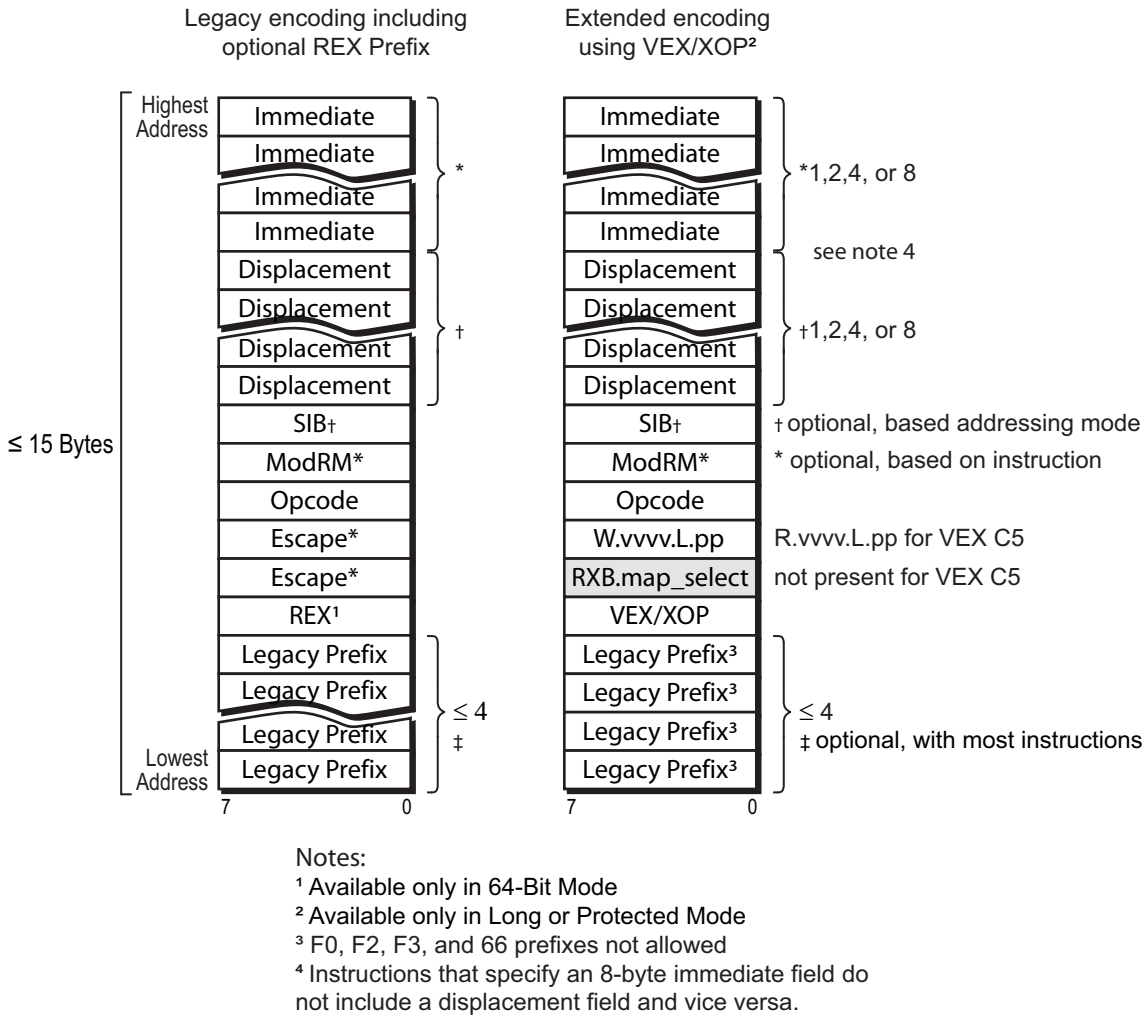
The opcode can be followed by a *mode-register-memory* (ModRM) byte, which further describes the operation and/or operands. The ModRM byte may also be followed by a *scale-index-base* (SIB) byte, which is used to specify indexed register-indirect forms of memory addressing. The ModRM and SIB bytes are described in “ModRM Byte Format” on page 17. Their legacy functions can be augmented by the REX prefix (see “REX Prefix” on page 14) or the VEX and XOP escape sequences (See “VEX and XOP Prefixes” on page 16).

1.1.1.6 Displacement and Immediate Fields

The instruction encoding may end with a 1-, 2-, or 4-byte *displacement* field and/or a 1-, 2-, or 4-byte *immediate* field depending on the instruction and/or the addressing mode. Specific instructions also allow either an 8-byte immediate field or an 8-byte displacement field.

1.1.2 Representation in Memory

Instructions are stored in memory in little-endian order. The first byte of an instruction is stored at the lowest memory address, as shown in Figure 1-2 below. Since instructions are strings of bytes, they may start at any memory address. The total instruction length must be less than or equal to 15. If this limit is exceeded, a general-protection exception results.



Notes:
¹ Available only in 64-Bit Mode
² Available only in Long or Protected Mode
³ F0, F2, F3, and 66 prefixes not allowed
⁴ Instructions that specify an 8-byte immediate field do not include a displacement field and vice versa.

Figure 1-2. An Instruction as Stored in Memory

1.2 Instruction Prefixes

Instruction prefixes are of two types: *instruction modifier* prefixes and *encoding escape* prefixes. Instruction modifier prefixes can change the operation of the instruction (including causing its execution to repeat), change its operand types, specify an alternate operand size, augment register specification, or even change the interpretation of the opcode byte.

The instruction modifier prefixes comprise the legacy prefixes and the REX prefix. The legacy prefixes are discussed in the next section. The REX prefix is discussed in “REX Prefix” on page 14.

Encoding escape prefixes, on the other hand, signal that the two or three bytes that follow obey a different encoding syntax. As a group, the encoding escape prefix and its subsequent bytes constitute a multi-byte escape sequence. These multi-byte escape sequences perform functions similar to that of

the instruction modifier prefixes, but they also provide a means to directly specify alternate opcode maps.

The currently defined encoding escape prefixes are the VEX and XOP prefixes. They are discussed further in the section entitled “VEX and XOP Prefixes” on page 16.

1.2.1 Summary of Legacy Prefixes

Table 1-1 on page 7 shows the legacy prefixes. The legacy prefixes are organized into five groups, as shown in the left-most column of Table 1-1. An instruction encoding may include a maximum of one prefix from each of the five groups. The legacy prefixes can appear in any order within the position shown in Figure 1-1 for legacy prefixes. The result of using multiple prefixes from a single group is undefined.

Some of the restrictions on legacy prefixes are:

- *Operand-Size Override*—This prefix only affects the operand size for general-purpose instructions or for other instructions whose source or destination is a general-pupose register. When used in the encoding of SIMD and some other instructions, this prefix is repurposed to modify the opcode.
- *Address-Size Override*—This prefix only affects the address size of memory operands.
- *Segment Override*—In 64-bit mode, the CS, DS, ES, and SS segment override prefixes are ignored.
- *LOCK Prefix*—This prefix is allowed only with certain instructions that modify memory.
- *Repeat Prefixes*—These prefixes affect only certain string instructions. When used in the encoding of SIMD and some other instructions, these prefixes are repurposed to modify the opcode.

Note that Lock and Repeat prefixes are in effect mutually exclusive when used as instruction modifiers, in that there are no instructions for which both are meaningful.

Table 1-1. Legacy Instruction Prefixes

Prefix Group[1]	Mnemonic	Prefix Byte (Hex)	Description
Operand-Size Override	none	66[2]	Changes the default operand size of a memory or register operand, as shown in Table 1-2 on page 8.
Address-Size Override	none	67[3]	Changes the default address size of a memory operand, as shown in Table 1-3 on page 9.
Segment Override	CS	2E[4]	Forces use of the current CS segment for memory operands.
	DS	3E[4]	Forces use of the current DS segment for memory operands.
	ES	26[4]	Forces use of the current ES segment for memory operands.
	FS	64	Forces use of the current FS segment for memory operands.
	GS	65	Forces use of the current GS segment for memory operands.
	SS	36[4]	Forces use of the current SS segment for memory operands.
Lock	LOCK	F0[5]	Causes certain kinds of memory read-modify-write instructions to occur atomically.
Repeat	REP	F3[6]	Repeats a string operation (INS, MOVS, OUTS, LODS, and STOS) until the rCX register equals 0.
	REPE or REPZ		Repeats a compare-string or scan-string operation (CMPSx and SCASx) until the rCX register equals 0 or the zero flag (ZF) is cleared to 0.
	REPNE or REPNZ	F2[6]	Repeats a compare-string or scan-string operation (CMPSx and SCASx) until the rCX register equals 0 or the zero flag (ZF) is set to 1.

Notes:

1. *A single instruction should include no more than one prefix from each of the Override prefix groups plus either a Lock or Repeat prefix, when used as instruction modifiers.*
2. *When used in the encoding of SIMD and some other instructions, this prefix is repurposed to extend the opcode. The prefix is ignored by 64-bit media floating-point (3DNow!™) instructions. See "Instructions that Cannot Use the Operand-Size Prefix" on page 8.*
3. *This prefix also changes the size of the RCX register when used as an implied count register.*
4. *In 64-bit mode, the CS, DS, ES, and SS segment overrides are ignored.*
5. *The LOCK prefix should not be used for instructions other than those listed in "Lock Prefix" on page 11.*
6. *This prefix should be used only with compare-string and scan-string instructions. When used in the encoding of SIMD and some other instructions, the prefix is repurposed to extend the opcode.*

1.2.2 Operand-Size Override Prefix

The default operand size for an instruction is determined by a combination of its opcode, the D (default) bit in the current code-segment descriptor, and the current operating mode, as shown in Table 1-2. The operand-size override prefix (66h) selects the non-default operand size. The prefix can

be used with any general-purpose instruction that accesses non-fixed-size operands in memory or general-purpose registers (GPRs), and it can also be used with the x87 FLDENV, FNSTENV, FNSAVE, and FRSTOR instructions.

In 64-bit mode, the prefix allows mixing of 16-bit, 32-bit, and 64-bit data on an instruction-by-instruction basis. In compatibility and legacy modes, the prefix allows mixing of 16-bit and 32-bit operands on an instruction-by-instruction basis.

Table 1-2. Operand-Size Overrides

Operating Mode		Default Operand Size (Bits)	Effective Operand Size (Bits)	Instruction Prefix[1]	
				66h	REX.W[3]
Long Mode	64-Bit Mode	32[2]	64	don't care	yes
			32	no	no
			16	yes	no
	Compatibility Mode	32	32	no	Not Appli-cable
			16	yes	
		16	32	yes	
			16	no	
Legacy Mode (Protected, Virtual-8086, or Real Mode)		32	32	no	
			16	yes	
		16	32	yes	
			16	no	

Notes:
1. *A "no' indicates that the default operand size is used.*
2. *This is the typical default, although some instructions default to other operand sizes. See Appendix B, "General-Purpose Instructions in 64-Bit Mode," for details.*
3. *See "REX Prefix" on page 14.*

In 64-bit mode, most instructions default to a 32-bit operand size. For these instructions, a REX prefix (page 14) can specify a 64-bit operand size, and a 66h prefix specifies a 16-bit operand size. The REX prefix takes precedence over the 66h prefix. However, if an instruction defaults to a 64-bit operand size, it does not need a REX prefix and it can only be overridden to a 16-bit operand size. It cannot be overridden to a 32-bit operand size, because there is no 32-bit operand-size override prefix in 64-bit mode. Two groups of instructions have a default 64-bit operand size in 64-bit mode:

- Near branches. For details, see "Near Branches in 64-Bit Mode" in Volume 1.
- All instructions, except far branches, that implicitly reference the RSP. For details, see "Stack Operation" in Volume 1.

Instructions that Cannot Use the Operand-Size Prefix. The operand-size prefix should be used only with general-purpose instructions and the x87 FLDENV, FNSTENV, FNSAVE, and FRSTOR

instructions, in which the prefix selects between 16-bit and 32-bit operand size. The prefix is ignored by all other x87 instructions and by 64-bit media floating-point (3DNow!™) instructions.

For other instructions (mostly SIMD instructions) the 66h, F2h, and F3h prefixes are used as opcode extensions to extend the instruction encoding space in the 0Fh, 0F_38h, and 0F_3Ah opcode maps.

Operand-Size and REX Prefixes. The W bit field of the REX prefix takes precedence over the 66h prefix. See “REX.W: Operand width (Bit 3)” on page 23 for details.

1.2.3 Address-Size Override Prefix

The default address size for instructions that access non-stack memory is determined by the current operating mode, as shown in Table 1-3. The address-size override prefix (67h) selects the non-default address size. Depending on the operating mode, this prefix allows mixing of 16-bit and 32-bit, or of 32-bit and 64-bit addresses, on an instruction-by-instruction basis. The prefix changes the address size for memory operands. It also changes the size of the RCX register for instructions that use RCX implicitly.

For instructions that implicitly access the stack segment (SS), the address size for stack accesses is determined by the D (default) bit in the stack-segment descriptor. In 64-bit mode, the D bit is ignored, and all stack references have a 64-bit address size. However, if an instruction accesses both stack and non-stack memory, the address size of the non-stack access is determined as shown in Table 1-3.

Table 1-3. Address-Size Overrides

Operating Mode		Default Address Size (Bits)	Effective Address Size (Bits)	Address-Size Prefix (67h)[1] Required?
Long Mode	64-Bit Mode	64	64	no
			32	yes
	Compatibility Mode	32	32	no
			16	yes
		16	32	yes
			16	no
Legacy Mode (Protected, Virtual-8086, or Real Mode)		32	32	no
			16	yes
		16	32	yes
			16	no

Notes:
1. *A “no” indicates that the default address size is used.*

As Table 1-3 shows, the default address size is 64 bits in 64-bit mode. The size can be overridden to 32 bits, but 16-bit addresses are not supported in 64-bit mode. In compatibility and legacy modes, the default address size is 16 bits or 32 bits, depending on the operating mode (see “Processor

Initialization and Long Mode Activation" in Volume 2 for details). In these modes, the address-size prefix selects the non-default size, but the 64-bit address size is not available.

Certain instructions reference pointer registers or count registers implicitly, rather than explicitly. In such instructions, the address-size prefix affects the size of such addressing and count registers, just as it does when such registers are explicitly referenced. Table 1-4 lists all such instructions and the registers referenced using the three possible address sizes.

Table 1-4. Pointer and Count Registers and the Address-Size Prefix

Instruction	Pointer or Count Register		
	16-Bit Address Size	32-Bit Address Size	64-Bit Address Size
CMPS, **CMPSB**, **CMPSW**, **CMPSD, CMPSQ**—Compare Strings	SI, DI, CX	ESI, EDI, ECX	RSI, RDI, RCX
INS, INSB, INSW, INSD—Input String	DI, CX	EDI, ECX	RDI, RCX
JCXZ, **JECXZ, JRCXZ**—Jump on CX/ECX/RCX Zero	CX	ECX	RCX
LODS, **LODSB**, **LODSW**, **LODSD, LODSQ**—Load String	SI, CX	ESI, ECX	RSI, RCX
LOOP, LOOPE, LOOPNZ, **LOOPNE, LOOPZ**—Loop	CX	ECX	RCX
MOVS, **MOVSB**, **MOVSW**, **MOVSD, MOVSQ**—Move String	SI, DI, CX	ESI, EDI, ECX	RSI, RDI, RCX
OUTS, OUTSB, OUTSW, OUTSD—Output String	SI, CX	ESI, ECX	RSI, RCX
REP, REPE, REPNE, REPNZ, REPZ—Repeat Prefixes	CX	ECX	RCX
SCAS, **SCASB**, **SCASW**, **SCASD, SCASQ**—Scan String	DI, CX	EDI, ECX	RDI, RCX
STOS, **STOSB**, **STOSW**, **STOSD, STOSQ**—Store String	DI, CX	EDI, ECX	RDI, RCX
XLAT, **XLATB**—Table Look-up Translation	BX	EBX	RBX

1.2.4 Segment-Override Prefixes

Segment overrides can be used only with instructions that reference non-stack memory. Most instructions that reference memory are encoded with a ModRM byte (page 17). The default segment

for such memory-referencing instructions is implied by the base register indicated in its ModRM byte, as follows:

- *Instructions that Reference a Non-Stack Segment*—If an instruction encoding references any base register other than rBP or rSP, or if an instruction contains an immediate offset, the default segment is the data segment (DS). These instructions can use the segment-override prefix to select one of the non-default segments, as shown in Table 1-5.
- *String Instructions*—String instructions reference two memory operands. By default, they reference both the DS and ES segments (DS:rSI and ES:rDI). These instructions can override their DS-segment reference, as shown in Table 1-5, but they cannot override their ES-segment reference.
- *Instructions that Reference the Stack Segment*—If an instruction's encoding references the rBP or rSP base register, the default segment is the stack segment (SS). All instructions that reference the stack (push, pop, call, interrupt, return from interrupt) use SS by default. These instructions cannot use the segment-override prefix.

Table 1-5. Segment-Override Prefixes

Mnemonic	Prefix Byte (Hex)	Description
CS[1]	2E	Forces use of current CS segment for memory operands.
DS[1]	3E	Forces use of current DS segment for memory operands.
ES[1]	26	Forces use of current ES segment for memory operands.
FS	64	Forces use of current FS segment for memory operands.
GS	65	Forces use of current GS segment for memory operands.
SS[1]	36	Forces use of current SS segment for memory operands.

Notes:
1. In 64-bit mode, the CS, DS, ES, and SS segment overrides are ignored.

Segment Overrides in 64-Bit Mode. In 64-bit mode, the CS, DS, ES, and SS segment-override prefixes have no effect. These four prefixes are not treated as segment-override prefixes for the purposes of multiple-prefix rules. Instead, they are treated as null prefixes.

The FS and GS segment-override prefixes are treated as true segment-override prefixes in 64-bit mode. Use of the FS or GS prefix causes their respective segment bases to be added to the effective address calculation. See "FS and GS Registers in 64-Bit Mode" in Volume 2 for details.

1.2.5 Lock Prefix

The LOCK prefix causes certain kinds of memory read-modify-write instructions to occur atomically. The mechanism for doing so is implementation-dependent (for example, the mechanism may involve bus signaling or packet messaging between the processor and a memory controller). The prefix is intended to give the processor exclusive use of shared memory in a multiprocessor system.

The LOCK prefix can only be used with forms of the following instructions that write a memory operand: ADC, ADD, AND, BTC, BTR, BTS, CMPXCHG, CMPXCHG8B, CMPXCHG16B, DEC, INC, NEG, NOT, OR, SBB, SUB, XADD, XCHG, and XOR. An invalid-opcode exception occurs if the LOCK prefix is used with any other instruction.

1.2.6 Repeat Prefixes

The repeat prefixes cause repetition of certain instructions that load, store, move, input, or output strings. The prefixes should only be used with such string instructions. Two pairs of repeat prefixes, REPE/REPZ and REPNE/REPNZ, perform the same repeat functions for certain compare-string and scan-string instructions. The repeat function uses rCX as a count register. The size of rCX is based on address size, as shown in Table 1-4 on page 10.

REP. The REP prefix repeats its associated string instruction the number of times specified in the counter register (rCX). It terminates the repetition when the value in rCX reaches 0. The prefix can be used with the INS, LODS, MOVS, OUTS, and STOS instructions. Table 1-6 shows the valid REP prefix opcodes.

Table 1-6. REP Prefix Opcodes

Mnemonic	Opcode
REP INS *reg/mem8*, DX REP INSB	F3 6C
REP INS *reg/mem16/32*, DX REP INSW REP INSD	F3 6D
REP LODS *mem8* REP LODSB	F3 AC
REP LODS *mem16/32/64* REP LODSW REP LODSD REP LODSQ	F3 AD
REP MOVS *mem8*, *mem8* REP MOVSB	F3 A4
REP MOVS *mem16/32/64*, *mem16/32/64* REP MOVSW REP MOVSD REP MOVSQ	F3 A5
REP OUTS DX, *reg/mem8* REP OUTSB	F3 6E

Table 1-6. REP Prefix Opcodes (continued)

Mnemonic	Opcode
REP OUTS DX, *reg/mem16/32* REP OUTSW REP OUTSD	F3 6F
REP STOS *mem8* REP STOSB	F3 AA
REP STOS *mem16/32/64* REP STOSW REP STOSD REP STOSQ	F3 AB

REPE and REPZ. REPE and REPZ are synonyms and have identical opcodes. These prefixes repeat their associated string instruction the number of times specified in the counter register (rCX). The repetition terminates when the value in rCX reaches 0 or when the zero flag (ZF) is cleared to 0. The REPE and REPZ prefixes can be used with the CMPS, CMPSB, CMPSD, CMPSW, SCAS, SCASB, SCASD, and SCASW instructions. Table 1-7 shows the valid REPE and REPZ prefix opcodes.

Table 1-7. REPE and REPZ Prefix Opcodes

Mnemonic	Opcode
REPx CMPS *mem8*, *mem8* REPx CMPSB	F3 A6
REPx CMPS *mem16/32/64*, *mem16/32/64* REPx CMPSW REPx CMPSD REPx CMPSQ	F3 A7
REPx SCAS *mem8* REPx SCASB	F3 AE
REPx SCAS *mem16/32/64* REPx SCASW REPx SCASD REPx SCASQ	F3 AF

REPNE and REPNZ. REPNE and REPNZ are synonyms and have identical opcodes. These prefixes repeat their associated string instruction the number of times specified in the counter register (rCX). The repetition terminates when the value in rCX reaches 0 or when the zero flag (ZF) is set to 1. The REPNE and REPNZ prefixes can be used with the CMPS, CMPSB, CMPSD, CMPSW, SCAS, SCASB, SCASD, and SCASW instructions. Table 1-8 on page 14 shows the valid REPNE and REPNZ prefix opcodes.

Table 1-8. REPNE and REPNZ Prefix Opcodes

Mnemonic	Opcode
REPNx CMPS *mem8*, *mem8* REPNx CMPSB	F2 A6
REPNx CMPS *mem16/32/64*, *mem16/32/64* REPNx CMPSW REPNx CMPSD REPNx CMPSQ	F2 A7
REPNx SCAS *mem8* REPNx SCASB	F2 AE
REPNx SCAS *mem16/32/64* REPNx SCASW REPNx SCASD REPNx SCASQ	F2 AF

Instructions that Cannot Use Repeat Prefixes. In general, the repeat prefixes should only be used in the string instructions listed in tables 1-6, 1-7, and 1-8 above. For other instructions (mostly SIMD instructions) the 66h, F2h, and F3h prefixes are used as instruction modifiers to extend the instruction encoding space in the 0Fh, 0F_38h, and 0F_3Ah opcode maps.

Optimization of Repeats. Depending on the hardware implementation, the repeat prefixes can have a setup overhead. If the repeated count is variable, the overhead can sometimes be avoided by substituting a simple loop to move or store the data. Repeated string instructions can be expanded into equivalent sequences of inline loads and stores or a sequence of stores can be used to emulate a REP STOS.

For repeated string moves, performance can be maximized by moving the largest possible operand size. For example, use REP MOVSD rather than REP MOVSW and REP MOVSW rather than REP MOVSB. Use REP STOSD rather than REP STOSW and REP STOSW rather than REP MOVSB.

Depending on the hardware implementation, string moves with the direction flag (DF) cleared to 0 (up) may be faster than string moves with DF set to 1 (down). DF = 1 is only needed for certain cases of overlapping REP MOVS, such as when the source and the destination overlap.

1.2.7 REX Prefix

The REX prefix, available in 64-bit mode, enables use of the AMD64 register and operand size extensions. Unlike the legacy instruction modification prefixes, REX is not a single unique value, but occupies a range (40h to 4Fh). Figure 1-1 on page 2 shows how the REX prefix fits within the encoding syntax of instructions.

The REX prefix enables the following features in 64-bit mode:

- Use of the extended GPR (Figure 2-3 on page 39) and YMM/XMM registers (Figure 2-8 on page 44).

- Use of the 64-bit operand size when accessing GPRs.
- Use of the extended control and debug registers, as described in Section 2.4 “Registers” in Volume 2.
- Use of the uniform byte registers (AL–R15).

REX contains five fields. The upper nibble is unique to the REX prefix and identifies it is as such. The lower nibble is divided into four 1-bit fields (W, R, X, and B). See below for a discussion of these fields.Figure 1-3 below shows the format of the REX prefix. Since each bit of the lower nibble can be a 1 or a 0, REX spans one full row of the primary opcode map occupying entries 40h through 4Fh.

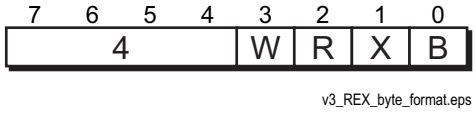


Figure 1-3. REX Prefix Format

A REX prefix is normally required with an instruction that accesses a 64-bit GPR or one of the extended GPR or YMM/XMM registers. A few instructions have an operand size that defaults to (or is fixed at) 64 bits in 64-bit mode, and thus do not need a REX prefix. These instructions are listed in Table 1-9 below.

Table 1-9. Instructions Not Requiring REX Prefix in 64-Bit Mode

CALL (Near)	POP reg/mem
ENTER	POP reg
J*cc*	POP FS
JrCXZ	POP GS
JMP (Near)	POPF, POPFD, POPFQ
LEAVE	PUSH imm8
LGDT	PUSH imm32
LIDT	PUSH reg/mem
LLDT	PUSH reg
LOOP	PUSH FS
LOOP*cc*	PUSH GS
LTR	PUSHF, PUSHFD, PUSHFQ
MOV CR*n*	RET (Near)
MOV DR*n*	

An instruction may have only one REX prefix which must immediately precede the opcode or first escape byte in the instruction encoding. The use of a REX prefix in an instruction that does not access an extended register is ignored. The instruction-size limit of 15 bytes applies to instructions that contain a REX prefix.

Implications for INC and DEC Instructions

The REX prefix values are taken from the 16 single-byte INC and DEC instructions, one for each of the eight legacy GPRs. Therefore, these single-byte opcodes for INC and DEC are not available in 64-bit mode, although they are available in legacy and compatibility modes. The functionality of these INC and DEC instructions is still available in 64-bit mode, however, using the ModRM forms of those instructions (opcodes FF /0 and FF /1).

1.2.8 VEX and XOP Prefixes

The extended instruction encoding syntax, available in protected and long modes, provides one 2-byte and three 3-byte escape sequences introduced by either the VEX or XOP prefixes. These multi-byte sequences not only select opcode maps, they also provide instruction modifiers similar to, but in lieu of, the REX prefix.

The 2-byte escape sequence initiated by the VEX C5h prefix implies a map_select encoding of 1. The three-byte escape sequences, initiated by the VEX C4h prefix or the XOP (8Fh) prefix, select the target opcode map explicitly via the VEX/XOP.map_select field. The five-bit VEX.map_select field allows the selection of one of 31 different opcode maps (opcode map 00h is reserved). The XOP.map_select field is restricted to the range 08h – 1Fh and thus can only select one of 24 different opcode maps.

The VEX and XOP escape sequences contain fields that extend register addressing to a total of 16, increase the operand specification capability to four operands, and modify the instruction operation.

The extended SSE instruction subsets AVX, AES, CLMU, FMA, FMA4, and XOP and a few non-SSE instructions utilize the extended encoding syntax. See “Encoding Using the VEX and XOP Prefixes” on page 29 for details on the encoding of the two- and three-byte extended escape sequences.

1.3 Opcode

The *opcode* is a single byte that specifies the basic operation of an instruction. In some cases, it also specifies the operands for the instruction. Every instruction requires an opcode. The correspondence between the binary value of the opcode and the operation it represents is defined by a table called an *opcode map*. As discussed in the previous sections, the legacy prefixes 66h, F2h, and F3h and other fields within the instruction encoding may be used to modify the operation encoded by the opcode.

The affect of the presence of a 66h, F2h, or F3h prefix on the operation performed by the opcode is represented in the opcode map by additional rows in the table indexed by the applicable prefix. The 3-bit reg and r/m fields of the ModRM byte (“ModRM Byte Format” on page 17 and “SIB Byte Format” on page 18) are used as well in the encoding of certain instructions. This is represented in the opcode maps via instruction group tables that detail the modifications represented via the extra encoding bits. See Section A.1, “Opcode Maps” of Appendix A for examples.

Even though each instruction has a unique opcode map and opcode, assemblers often support multiple alternate mnemonics for the same instruction to improve the readability of assembly language code.

The 64-bit floating-point 3DNow! instructions utilize the two-byte escape sequence 0Fh, 0Fh to select the 3DNow! opcode map. For these instructions the opcode is encoded in the immediate field at the end of the instruction encoding.

For details on how the opcode byte encodes the basic operation for specifc instructions, see Section A.1, “Opcode Maps” of Appendix A

1.4 ModRM and SIB Bytes

The ModRM byte is optional depending on the instruction. When present, it follows the opcode and is used to specify:

- two register-based operands, or
- one register-based operand and a second memory-based operand and an addressing mode.

In the encoding of some instructions, fields within the ModRM byte are repurposed to provide additional opcode bits used to define the instruction’s function.

The ModRM byte is partitioned into three fields—*mod*, *reg*, and *r/m*. Normally the reg field specifies a register-based operand and the mod and r/m fields used together specify a second operand that is either register-based or memory-based. The addressing mode is also specified when the operand is memory-based.

In 64-bit mode, the REX.R and REX.B bits augment the reg and r/m fields respectively allowing the specification of twice the number of registers.

1.4.1 ModRM Byte Format

Figure 1-4 below shows the format of a ModRM byte.

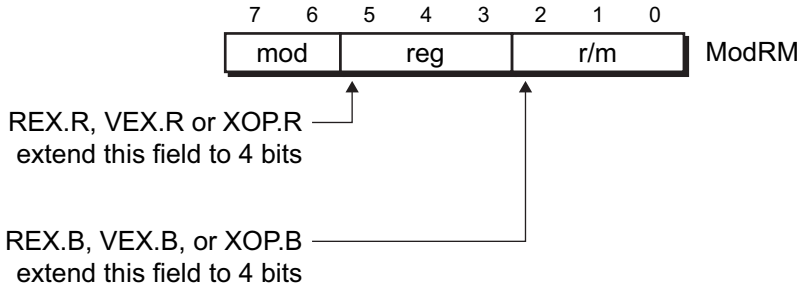

Figure 1-4. ModRM-Byte Format

Depending on the addressing mode, the SIB byte may appear after the ModRM byte. SIB is used in the specification of various forms of indexed register-indirect addressing. See the following section for details.

ModRM.mod (Bits[7:6]). The mod field is used with the r/m field to specify the addressing mode for an operand. ModRM.mod = 11b specifies the register-direct addressing mode. In the register-direct mode, the operand is held in the specified register. ModRM.mod values less than 11b specify register-indirect addressing modes. In register-indirect addressing modes, values held in registers along with an optional displacement specified in the instruction encoding are used to calculate the address of a memory-based operand. Other encodings of the 5 bits {mod, r/m} are discussed below.

ModRM.reg (Bits[5:3]). The reg field is used to specify a register-based operand, although for some instructions, this field is used to extend the operation encoding. The encodings for this field are shown in Table 1-10 below.

ModRM.r/m (Bits[2:0]). As stated above, the r/m field is used in combination with the mod field to encode 32 different operand specifications (See Table 1-14 on page 21). The encodings for this field are shown in Table 1-10 below.

Table 1-10. ModRM.reg and .r/m Field Encodings

Encoded value (binary)	ModRM.reg[1]	ModRM.r/m (mod = 11b)[1]	ModRM.r/m (mod ≠ 11b)[2]
000	rAX, MMX0, XMM0, YMM0	rAX, MMX0, XMM0, YMM0	[rAX]
001	rCX, MMX1, XMM1, YMM1	rCX, MMX1, XMM1, YMM1	[rCX]
010	rDX, MMX2, XMM2, YMM2	rDX, MMX2, XMM2, YMM2	[rDX]
011	rBX, MMX3, XMM3, YMM3	rBX, MMX3, XMM3, YMM3	[rBX]
100	AH, rSP, MMX4, XMM4, YMM4	AH, rSP, MMX4, XMM4, YMM4	SIB[3]
101	CH, rBP, MMX5, XMM5, YMM5	CH, rBP, MMX5, XMM5, YMM5	[rBP][4]
110	DH, rSI, MMX6, XMM6, YMM6	DH, rSI, MMX6, XMM6, YMM6	[rSI]
111	BH, rDI, MMX7, XMM7, YMM7	BH, rDI, MMX7, XMM7, YMM7	[rDI]

Notes:

1. *Specific register used is instruction-dependent.*
2. *mod = 01 and mod = 10 include an offset specified by the instruction displacement field. The notation [*] signifies that the specified register holds the address of the operand.*
3. *Indexed register-indirect addressing. SIB byte follows ModRM byte. See following section for SIB encoding.*
4. *For mod = 00b , r/m = 101b signifies absolute (displacement-only) addressing in 32-bit mode or RIP-relative addressing in 64-bit mode, where the rBP register is not used. For mod = [01b, 10b], r/m = 101b specifies the base + offset addressing mode with [rBP] as the base.*

Similar to the reg field, r/m is used in some instructions to extend the operation encoding.

1.4.2 SIB Byte Format

The SIB byte has three fields—*scale*, *index*, and *base*—that define the scale factor, index-register number, and base-register number for the 32-bit and 64-bit indexed register-indirect addressing modes.

The basic formula for computing the effective address of a memory-based operand using the indexed register-indirect address modes is:

```
effective_address = scale * index + base + offset
```

Specific variants of this addressing mode set one or more elements of the sum to zero.

Figure 1-5 below shows the format of the SIB byte.

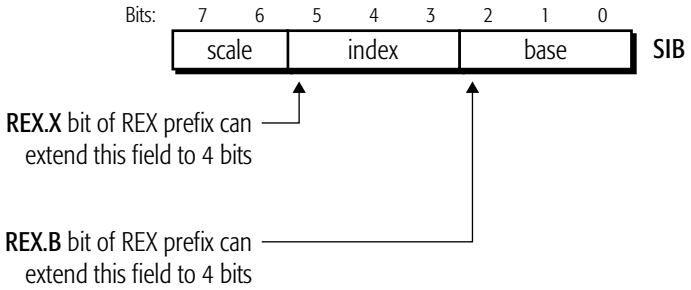

Figure 1-5. SIB Byte Format

SIB.scale (Bits[7:6]). The scale field is used to specify the scale factor used in computing the scale*index portion of the effective address. In normal usage scale represents the size of data elements in an array expressed in number of bytes. SIB.scale is encoded as shown in Table 1-11 below.

Table 1-11. SIB.scale Field Encodings

Encoded value (binary)	scale factor
00	1
01	2
10	4
11	8

SIB.index (Bits[5:3]). The index field is used to specify the register containing the index portion of the indexed register-indirect effective address. SIB.index is encoded as shown in Table 1-12 below.

SIB.base (Bits[2:0]). The base field is used to specify the register containing the base address portion of the indexed register-indirect effective address. SIB.base is encoded as shown in Table 1-12 below.

Table 1-12. SIB.index and .base Field Encodings

Encoded value (binary)	SIB.index	SIB.base
000	[rAX]	[rAX]
001	[rCX]	[rCX]
010	[rDX]	[rDX]
011	[rBX]	[rBX]
100	(none)[1]	[rSP]
101	[rBP]	[rBP], (none)[2]
110	[rSI]	DH, [rSI]
111	[rDI]	BH, [rDI]

Notes:

*1. Register specification is null. The scale*index portion of the indexed register-indirect effective address is set to 0.*

2. If ModRM.mod = 00b, the register specification is null. The base portion of the indexed register-indirect effective address is set to 0. Otherwise, base encodes the rBP register as the source of the base address used in the effective address calculation.

Table 1-13. SIB.base encodings for ModRM.r/m = 100b

	SIB base Field							
mod	000	001	010	011	100	101	110	111
00	[rAX]	[rCX]	[rDX]	[rBX]	[rSP]	disp32	[rSI]	[rDI]
01						[rBP]+disp8		
10						[rBP]+disp32		
11	(not applicable)							

More discussion of operand addressing follows in the next two sections.

1.4.3 Operand Addressing in Legacy 32-bit and Compatibility Modes

The mod and r/m fields of the ModRM byte provide a total of five bits used to encode 32 operand specification and memory addressing modes. Table 1-14 below shows these encodings.

Table 1-14. Operand Addressing Using ModRM and SIB Bytes

ModRM.mod	ModRM.r/m	Register / Effective Address
00	000	[rAX]
	001	[rCX]
	010	[rDX]
	011	[rBX]
	100	SIB[1]
	101	*disp32*
	110	[rSI]
	111	[rDI]
01	000	[rAX]+*disp8*
	001	[rCX]+*disp8*
	010	[rDX]+*disp8*
	011	[rBX]+*disp8*
	100	SIB+*disp8*[2]
	101	[rBP]+*disp8*
	110	[rSI]+*disp8*
	111	[rDI]+*disp8*
10	000	[rAX]+*disp32*
	001	[rCX]+*disp32*
	010	[rDX]+*disp32*
	011	[rBX]+*disp32*
	100	SIB+*disp32*[3]
	101	[rBP]+*disp32*
	110	[rSI]+*disp32*
	111	[rDI]+*disp32*

Notes:

*0. In the following notes, scaled_index = SIB.index * (1 << SIB.scale).*

1. SIB byte follows ModRM byte. Effective address is calculated using scaled_index+base. When SIB.base = 101b, addressing mode depends on ModRM.mod. See Table 1-13 above.

2. SIB byte follows ModRM byte. Effective address is calculated using scaled_index+base+8-bit_offset. One-byte Displacement field provides the offset.

3. SIB byte follows ModRM byte. Effective address is calculated using scaled_index+base+32-bit_offset. Four-byte Displacement field provides the offset.

Table 1-14. Operand Addressing Using ModRM and SIB Bytes (continued)

ModRM.mod	ModRM.r/m	Register / Effective Address
11	000	AL/rAX/MMX0/XMM0/YMM0
	001	CL/rCX/MMX1/XMM1/YMM1
	010	DL/rDX/MMX2/XMM2/YMM2
	011	BL/rBX/MMX3/XMM3/YMM3
	100	AH/SPL/rSP/MMX4/XMM4/YMM4
	101	CH/BPL/rBP/MMX5/XMM5/YMM5
	110	DH/SIL/rSI/MMX6/XMM6/YMM6
	111	BH/DIL/rDI/MMX7/XMM7/YMM7

Notes:

*0. In the following notes, scaled_index = SIB.index * (1 << SIB.scale).*

1. SIB byte follows ModRM byte. Effective address is calculated using scaled_index+base. When SIB.base = 101b, addressing mode depends on ModRM.mod. See Table 1-13 above.

2. SIB byte follows ModRM byte. Effective address is calculated using scaled_index+base+8-bit_offset. One-byte Displacement field provides the offset.

3. SIB byte follows ModRM byte. Effective address is calculated using scaled_index+base+32-bit_offset. Four-byte Displacement field provides the offset.

Note that the addressing mode mod = 11b is a register-direct mode, that is, the operand is contained in the specified register, while the modes mod = [00b:10b] specify different addressing modes for a memory-based operand.

For mod = 11b, the register containing the operand is specified by the r/m field. For the other modes (mod = [00b:10b]), the mod and r/m fields are combined to specify the addressing mode for the memory-based operand. Most are register-indirect addressing modes meaning that the address of the memory-based operand is contained in the register specified by r/m. For these register-indirect modes, mod = 01b and mod = 10b include an offset encoded in the displacement field of the instruction.

The encodings {mod ≠ 11b, r/m = 100b} specify the *indexed register-indirect* addressing mode in which the target address is computed using a combination of values stored in registers and a scale factor encoded directly in the SIB byte. For these addressing modes the effective address is given by the formula:

```
effective_address = scale * index + base + offset
```

Scale is encoded in SIB.scale field. Index is contained in the register specified by SIB.index field and base is contained in the register specified by SIB.base field. Offset is encoded in the displacement field of the instruction using either one or four bytes.

If {mod, r/m} = 00100b, the offset portion of the formula is set to 0. For {mod, r/m} = 01100b and {mod, r/m} =10100b, offset is encoded in the one- or 4-byte displacement field of the instruction.

Finally, the encoding {mod, r/m} = 00101b specifies an absolute addressing mode. In this mode, the address is provided directly in the instruction encoding using a 4-byte displacement field. In 64-bit mode this addressing mode is changed to RIP-relative (see “RIP-Relative Addressing” on page 24).

1.4.4 Operand Addressing in 64-bit Mode

AMD64 architecture doubles the number of GPRs and increases their width to 64-bits. It also doubles the number of YMM/XMM registers. In order to support the specification of register operands contained in the eight additional GPRs or YMM/XMM registers and to make the additional GPRs available to hold addresses to be used in the addressing modes, the REX prefix provides the R, X, and B bit fields to extend the reg, r/m, index, and base fields of the ModRM and SIB bytes in the various operand addressing modes to four bits. A fourth REX bit field (W) allows instruction encodings to specify a 64-bit operand size.

Table 1-15 below and the sections that follow describe each of these bit fields.

Table 1-15. REX Prefix-Byte Fields

Mnemonic	Bit Position(s)	Definition
—	7:4	0100 (4h)
REX.W	3	0 = Default operand size 1 = 64-bit operand size
REX.R	2	1-bit (msb) extension of the ModRM *reg* field[1], permitting access to 16 registers.
REX.X	1	1-bit (msb) extension of the SIB *index* field[1], permitting access to 16 registers.
REX.B	0	1-bit (msb) extension of the ModRM *r/m* field[1], SIB *base* field[1], or opcode *reg* field, permitting access to 16 registers.

Notes:
1. *For a description of the ModRM and SIB bytes, see "ModRM and SIB Bytes" on page 17.*

REX.W: Operand width (Bit 3). Setting the REX.W bit to 1 specifies a 64-bit operand size. Like the existing 66h operand-size override prefix, the REX 64-bit operand-size override has no effect on byte operations. For non-byte operations, the REX operand-size override takes precedence over the 66h prefix. If a 66h prefix is used together with a REX prefix that has the W bit set to 1, the 66h prefix is ignored. However, if a 66h prefix is used together with a REX prefix that has the W bit cleared to 0, the 66h prefix is not ignored and the operand size becomes 16 bits.

REX.R: Register field extension (Bit 2). The REX.R bit adds a 1-bit extension (in the most significant bit position) to the ModRM.reg field when that field encodes a GPR, YMM/XMM, control, or debug register. REX.R does not modify ModRM.reg when that field specifies other registers or is used to extend the opcode. REX.R is ignored in such cases.

REX.X: Index field extension (Bit 1). The REX.X bit adds a 1-bit (msb) extension to the SIB.index field. See "ModRM and SIB Bytes" on page 17.

REX.B: Base field extension (Bit 0). The REX.B bit adds a 1-bit (msb) extension to either the ModRM.r/m field to specify a GPR or XMM register, or to the SIB.base field to specify a GPR. (See Table 2-2 on page 56 for more about the B bit.)

1.5 Displacement Bytes

A *displacement* (also called an *offset)* is a signed value that is added to the base of a code segment (absolute addressing) or to an instruction pointer (relative addressing), depending on the addressing mode. The size of a displacement is 1, 2, or 4 bytes. If an addressing mode requires a displacement, the bytes (1, 2, or 4) for the displacement follow the opcode, ModRM, or SIB byte (whichever comes last) in the instruction encoding.

In 64-bit mode, the same ModRM and SIB encodings are used to specify displacement sizes as those used in legacy and compatibility modes. However, the displacement is sign-extended to 64 bits during effective-address calculations. Also, in 64-bit mode, support is provided for some 64-bit displacement and immediate forms of the MOV instruction. See “Immediate Operand Size” in Volume 1 for more information on this.

1.6 Immediate Bytes

An *immediate* is a value—typically an operand value—encoded directly into the instruction. Depending on the opcode and the operating mode, the size of an immediate operand can be 1, 2, 4, or 8 bytes. 64-bit immediates are allowed in 64-bit mode on MOV instructions that load GPRs, otherwise they are limited to 4 bytes. See “Immediate Operand Size” in Volume 1 for more information.

If an instruction takes an immediate operand, the bytes (1, 2, 4, or 8) for the immediate follow the opcode, ModRM, SIB, or displacement bytes (whichever come last) in the instruction encoding. Some 128-bit media instructions use the immediate byte as a condition code.

1.7 RIP-Relative Addressing

In 64-bit mode, addressing relative to the contents of the 64-bit instruction pointer (program counter)—called RIP-relative addressing or PC-relative addressing—is implemented for certain instructions. In such cases, the effective address is formed by adding the displacement to the 64-bit RIP of the next instruction.

In the legacy x86 architecture, addressing relative to the instruction pointer is available only in control-transfer instructions. In the 64-bit mode, any instruction that uses ModRM addressing can use RIP-relative addressing. This feature is particularly useful for addressing data in position-independent code and for code that addresses global data.

Without RIP-relative addressing, ModRM instructions address memory relative to zero. With RIP-relative addressing, ModRM instructions can address memory relative to the 64-bit RIP using a signed 32-bit displacement. This provides an offset range of ±2 Gbytes from the RIP.

Programs usually have many references to data, especially global data, that are not register-based. To load such a program, the loader typically selects a location for the program in memory and then adjusts program references to global data based on the load location. RIP-relative addressing of data makes this adjustment unnecessary.

1.7.1 Encoding

Table 1-16 shows the ModRM and SIB encodings for RIP-relative addressing. Redundant forms of 32-bit displacement-only addressing exist in the current ModRM and SIB encodings. There is one ModRM encoding with several SIB encodings. RIP-relative addressing is encoded using one of the redundant forms. In 64-bit mode, the ModRM *disp32* (32-bit displacement) encoding ({mod,r/m} = 00101b) is redefined to be *RIP + disp32* rather than displacement-only.

Table 1-16. Encoding for RIP-Relative Addressing

ModRM	SIB	Legacy and Compatibility Modes	64-bit Mode	Additional 64-bit Implications
• mod = 00 • r/m = 101	not present	disp32	RIP + disp32	Zero-based (normal) displacement addressing must use SIB form (see next row).
• mod = 00 • r/m = 100[1]	• base = 101[2] • index = 100[3] • scale = xx	disp32	Same as Legacy	None

Notes:
1. Encodes the indexed register-indirect addressing mode with 32-bit offset.
2. Base register specification is null (base portion of effective address calculation is set to 0)
*3. index register specification is null (scale*index portion of effective address calculation is set to 0)*

1.7.2 REX Prefix and RIP-Relative Addressing

ModRM encoding for RIP-relative addressing does not depend on a REX prefix. In particular, the *r/m* encoding of 101, used to select RIP-relative addressing, is not affected by the REX prefix. For example, selecting R13 (REX.B = 1, r/m = 101) with mod = 00 still results in RIP-relative addressing.

The four-bit r/m field of ModRM is not fully decoded. Therefore, in order to address R13 with no displacement, software must encode it as R13 + 0 using a one-byte displacement of zero.

1.7.3 Address-Size Prefix and RIP-Relative Addressing

RIP-relative addressing is enabled by 64-bit mode, not by a 64-bit address-size. Conversely, use of the address-size prefix (“Address-Size Override Prefix” on page 9) does not disable RIP-relative addressing. The effect of the address-size prefix is to truncate and zero-extend the computed effective address to 32 bits, like any other addressing mode.

1.8 Encoding Considerations Using REX

Figure 1-6 on page 28 shows four examples of how the R, X, and B bits of the REX prefix are concatenated with fields from the ModRM byte, SIB byte, and opcode to specify register and memory addressing.

1.8.1 Byte-Register Addressing

In the legacy architecture, the byte registers (AH, AL, BH, BL, CH, CL, DH, and DL, shown in Figure 2-2 on page 38) are encoded in the ModRM reg or r/m field or in the opcode *reg* field as registers 0 through 7. The REX prefix provides an additional byte-register addressing capability that makes the least-significant byte of any GPR available for byte operations (Figure 2-3 on page 39). This provides a uniform set of byte, word, doubleword, and quadword registers better suited for register allocation by compilers.

1.8.2 Special Encodings for Registers

Readers who need to know the details of instruction encodings should be aware that certain combinations of the ModRM and SIB fields have special meaning for register encodings. For some of these combinations, the instruction fields expanded by the REX prefix are not decoded (treated as don’t cares), thereby creating aliases of these encodings in the extended registers. Table 1-17 on page 27 describes how each of these cases behaves.

Table 1-17. Special REX Encodings for Registers

ModRM and SIB Encodings[2]	Meaning in Legacy and Compatibility Modes	Implications in Legacy and Compatibility Modes	Additional REX Implications
ModRM Byte: • mod ≠ 11 • r/m[1] = 100 (ESP)	SIB byte is present.	SIB byte is required for ESP-based addressing.	REX prefix adds a fourth bit (b), which is decoded and modifies the base register in the SIB byte. Therefore, the SIB byte is also required for R12-based addressing.
ModRM Byte: • mod = 00 • r/m[1] = x101 (EBP)	Base register is not used.	Using EBP without a displacement must be done by setting mod = 01 with a displacement of 0 (with or without an index register).	REX prefix adds a fourth bit (x), which is not decoded (don't care). Therefore, using RBP or R13 without a displacement must be done via mod = 01 with a displacement of 0.
SIB Byte: • index[1] = x100 (ESP)	Index register is not used.	ESP cannot be used as an index register.	REX prefix adds a fourth bit (x), which is decoded. Therefore, there are no additional implications. The expanded index field is used to distinguish RSP from R12, allowing R12 to be used as an index.
SIB Byte: • base = b101 (EBP) • ModRM.mod = 00	Base register is not used if ModRM.mod = 00.	Base register depends on mod encoding. Using EBP with a scaled index and without a displacement must be done by setting mod = 01 with a displacement of 0.	REX prefix adds a fourth bit (b), which is not decoded (don't care). Therefore, using RBP or R13 without a displacement must be done via mod = 01 with a displacement of 0 (with or without an index register).

Notes:

1. *The REX-prefix bit is shown in the fourth (most-significant) bit position of the encodings for the ModRM r/m, SIB index, and SIB base fields. The lower-case "x" for ModRM r/m (rather than the upper-case "B" shown in Figure 1-6 on page 28) indicates that the REX-prefix bit is not decoded (don't care).*
2. *For a description of the ModRM and SIB bytes, see "ModRM and SIB Bytes" on page 17.*

Examples of Operand Addressing Extension Using REX

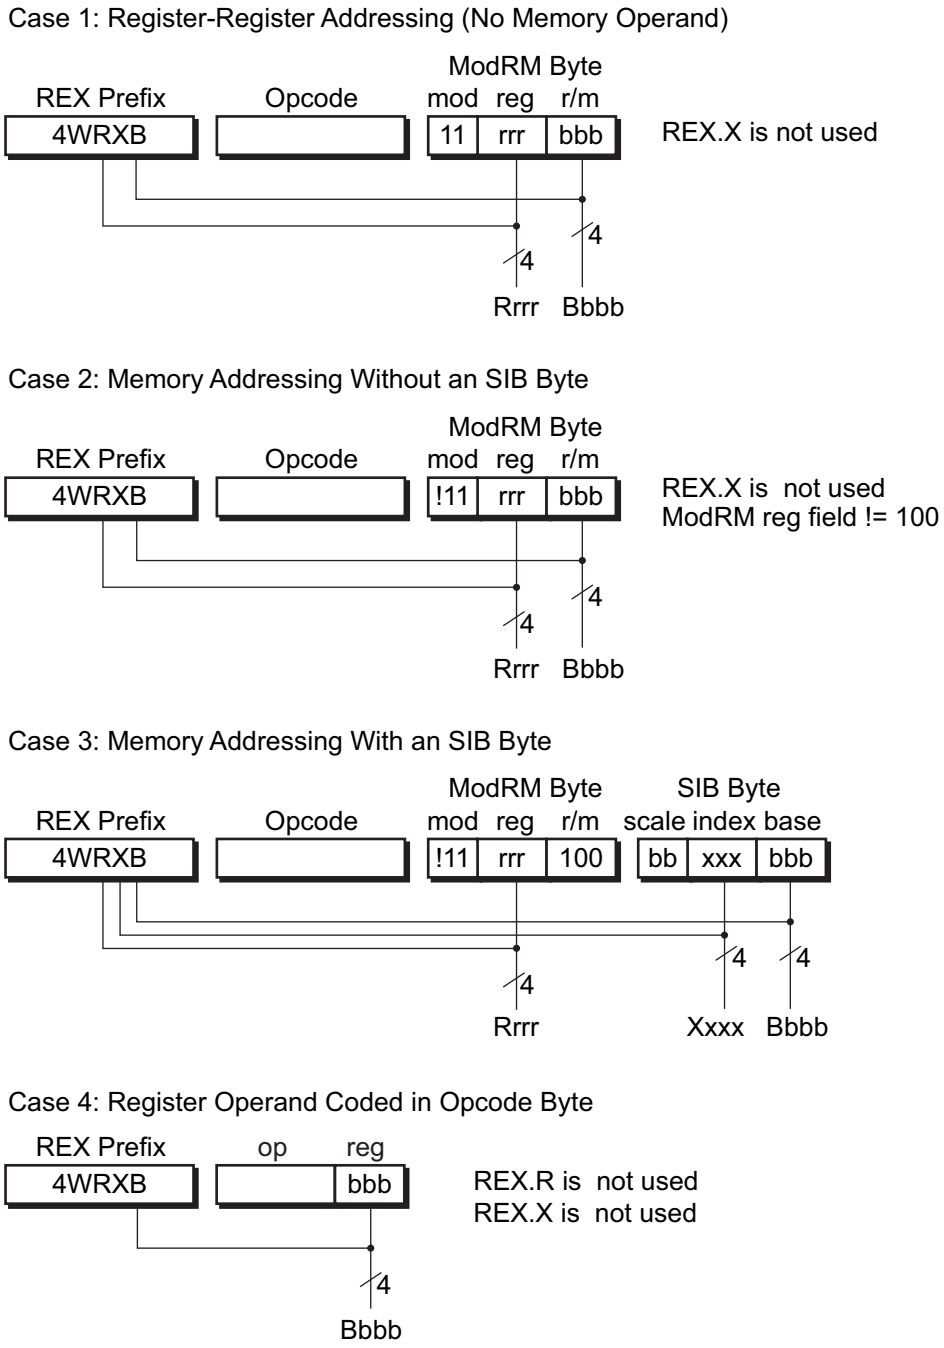

Figure 1-6. Encoding Examples Using REX R, X, and B Bits

1.9 Encoding Using the VEX and XOP Prefixes

An extended escape sequence is introduced by an encoding escape prefix which establishes the context and the format of the bytes that follow. The currently defined prefixes fall in two classes: the XOP and the VEX prefixes (of which there are two). The XOP prefix and the VEX C4h prefix introduce a three byte sequence with identical syntax, while the VEX C5h prefix introduces a two-byte escape sequence with a different syntax.

These escape sequences supply fields used to extend operand specification as well as provide for the selection of alternate opcode maps. Encodings support up to two additional operands and the addressing of the extended (beyond 7) registers. The specification of two of the operands is accomplished using the legacy ModRM and optional SIB bytes with the reg, r/m, index, and base fields extended by one bit in a manner analogous to the REX prefix.

The encoding of the extended SSE instructions utilize extended escape sequences. XOP instructions use three-byte escape sequences introduced by the XOP prefix. The AVX, FMA, FMA4, and CLMUL instruction subsets use three-byte or two-byte escape sequences introduced by the VEX prefixes.

1.9.1 Three-Byte Escape Sequences

All the extended instructions can be encoded using a three-byte escape sequence, but certain VEX-encoded instructions that comply with the constraints described below in Section 1.9.2, “Two-Byte Escape Sequence” can also utilize a two-byte escape sequence. Figure 1-7 below shows the format of the three-byte escape sequence which is common to the XOP and VEX-based encodings.

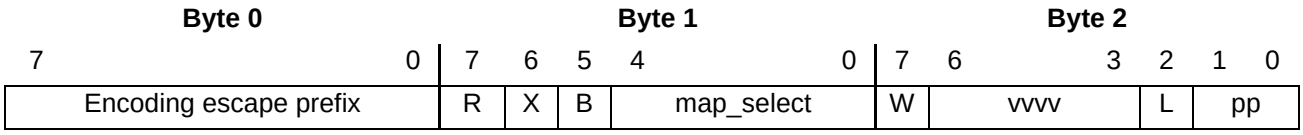

Figure 1-7. VEX/XOP Three-byte Escape Sequence Format

Byte	Bit	Mnemonic	Description
0	[7:0]	VEX, XOP	Value specific to the extended instruction set
1	[7]	R	Inverted one-bit extension of ModRM *reg* field
	[6]	X	Inverted one-bit extension of SIB *index* field
	[5]	B	Inverted one-bit extension, *r/m* field or SIB *base* field
	[4:0]	map_select	Opcode map select

Byte	Bit	Mnemonic	Description
2	[7]	W	Default operand size override for a general purpose register to 64-bit size in 64-bit mode; operand configuration specifier for certain YMM/XMM-based operations.
	[6:3]	vvvv	Source or destination register selector, in ones' complement format
	[2]	L	Vector length specifier
	[1:0]	pp	Implied 66, F2, or F3 opcode extension

Table 1-18. Three-byte Escape Sequence Field Definitions

Byte 0 (VEX/XOP Prefix)

Byte 0 is the encoding escape prefix byte which introduces the encoding escape sequence and establishes the context for the bytes that follow. The VEX and XOP prefixes have the following encodings:

- VEX prefix is encoded as C4h
- XOP prefix is encoded as 8Fh

Byte 1

VEX/XOP.R (Bit 7). The bit-inverted equivalent of the REX.R bit. A one-bit extension of the ModRM.reg field in 64-bit mode, permitting access to 16 YMM/XMM and GPR registers. In 32-bit protected and compatibility modes, the value must be 1.

VEX/XOP.X (Bit 6). The bit-inverted equivalent of the REX.X bit. A one-bit extension of the SIB.index field in 64-bit mode, permitting access to 16 YMM/XMM and GPR registers. In 32-bit protected and compatibility modes, this value must be 1.

VEX/XOP.B (Bit 5). The bit-inverted equivalent of the REX.B bit, available only in the 3-byte prefix format. A one-bit extension of either the ModRM.r/m field, to specify a GPR or XMM register, or of the SIB base field, to specify a GPR. This permits access to all 16 GPR and YMM/XMM registers. In 32-bit protected and compatibility modes, this bit is ignored.

VEX/XOP.map_select (Bits [4:0]). The five-bit map_select field is used to select an alternate opcode map. The map select encoding spaces for VEX and XOP are disjoint. Table 1-19 below lists the encodings for VEX.map_select and Table 1-20 lists the encodings for XOP.map_select.

Table 1-19. VEX.map_select Encoding

Binary Value	Opcode Map	Analogous Legacy Opcode Map
00000	Reserved	–
00001	VEX opcode map 1	Secondary ("two-byte") opcode map

Table 1-19. VEX.map_select Encoding

Binary Value	Opcode Map	Analogous Legacy Opcode Map
00010	VEX opcode map 2	0F_38h (“three-byte”) opcode map
00011	VEX opcode map 3	0F_3Ah (“three-byte”) opcode map
00100 – 11111	Reserved	–

Table 1-20. XOP.map_select Encoding

Binary Value	Opcode Map
00000 – 00111	Reserved
01000	XOP opcode map 8
01001	XOP opcode map 9
01010	XOP opcode map 10 (Ah)
01011 – 11111	Reserved

AVX instructions are encoded using the VEX opcode maps 1–3. The AVX instruction set includes instructions that provide operations similar to most legacy SSE instructions. For those AVX instructions that have an analogous legacy SSE instruction, the VEX opcode maps use the same binary opcode value and modifiers as the legacy version. The correspondence between the VEX opcode maps and the legacy opcode maps are shown in Table 1-19 above.

VEX opcode maps 1–3 are also used to encode the FMA4 and FMA instructions. In addition, not all legacy SSE instructions have AVX equivalents. Therefore, the VEX opcode maps are not the same as the legacy opcode maps.

The XOP opcode maps are unique to the XOP instructions. The XOP.map_select value is restricted to the range [08h:1Fh]. If the value of the XOP.map_select field is less than 8, the first two bytes of the three-byte XOP escape sequence are interpreted as a form of the POP instruction.

Both legacy and extended opcode maps are covered in detail in Appendix A.

Byte 2

VEX/XOP.W (Bit 7). Function is instruction-specific. The bit is often used to configure source operand order.

VEX/XOP.vvvv (Bits [6:3]). Used to specify an additional operand for three and four operand instructions. Encodes an XMM or YMM register in inverted ones’ complement form, as shown in Table 1-21.

Table 1-21. VEX/XOP.vvvv Encoding

Binary Value	Register	Binary Value	Register
0000	XMM15/YMM15	1000	XMM07/YMM07
0001	XMM14/YMM14	1001	XMM06/YMM06
0010	XMM13/YMM13	1010	XMM05/YMM05
0011	XMM12/YMM12	1011	XMM04/YMM04
0100	XMM11/YMM11	1100	XMM03/YMM03
0101	XMM10/YMM10	1101	XMM02/YMM02
0110	XMM09/YMM09	1110	XMM01/YMM01
0111	XMM08/YMM08	1111	XMM00/YMM00

Values 0000h to 0111h are not valid in 32-bit modes. vvvv is typically used to encode the first source operand, but for the VPSLLDQ, VPSRLDQ, VPSRLW, VPSRLD, VPSRLQ, VPSRAW, VPSRAD, VPSLLW, VPSLLD, and VPSLLQ shift instructions, the field specifies the destination register.

VEX/XOP.L (Bit 2). L = 0 specifies 128-bit vector length (XMM registers/128-bit memory locations). L=1 specifies 256-bit vector length (YMM registers/256-bit memory locations). For SSE or XOP instructions with scalar operands, the L bit is ignored. Some vector SSE instructions support only the 128 bit vector size. For these instructions, L is cleared to 0.

VEX/XOP.pp (Bits [1:0]). Specifies an implied 66h, F2h, or F3h opcode extension which is used in a way analogous to the legacy instruction encodings to extend the opcode encoding space. The correspondence between the encoding of the VEX/XOP.pp field and its function as an opcode modifier is shown in Table 1-22. The legacy prefixes 66h, F2h, and F3h are not allowed in the encoding of extended instructions.

Table 1-22. VEX/XOP.pp Encoding

Binary Value	Implied Prefix
00	None
01	66h
10	F3h
11	F2h

1.9.2 Two-Byte Escape Sequence

All VEX-encoded instructions can be encoded using the three-byte escape sequence, but certain instructions can also be encoded utilizing a more compact, two-byte VEX escape sequence. The format of the two-byte escape sequence is shown in Figure 1-8 below.

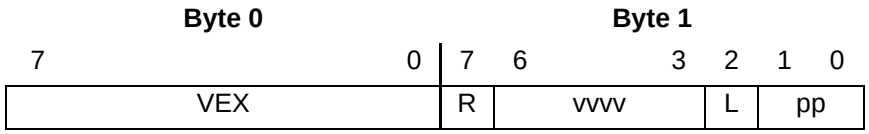

Figure 1-8. VEX Two-byte Escape Sequence Format

Prefix Byte	Bit	Mnemonic	Description
0	[7:0]	VEX	VEX 2-byte encoding escape prefix
1	[7]	R	Inverted one-bit extension of ModRM.reg field
	[6:3]	vvvv	Source or destination register selector, in ones' complement format.
	[2]	L	Vector length specifier
	[1:0]	pp	Implied 66, F2, or F3 opcode extension.

Table 1-23. VEX Two-byte Escape Sequence Field Definitions

Byte 0 (VEX Prefix)

The VEX prefix for the two-byte escape sequence is encoded as C5h.

Byte 1

Note that the bit 7 of this byte is used to encode VEX.R instead of VEX.W as in the three-byte escape sequence form. The R, vvvv, L, and pp fields are defined as in the three-byte escape sequence.

When the two-byte escape sequence is used, specific fields from the three-byte format take on fixed values as shown in Table 1-24 below.

Table 1-24. Fixed Field Values for VEX 2-Byte Format

VEX Field	Value
X	1
B	1
W	0
map_select	00001b

Although they may be encoded using the VEX three-byte escape sequence, all instructions that conform with the constraints listed in Table 1-24 may be encoded using the two-byte escape sequence. Note that the implied value of map_select is 00001b, which means that only instructions included in the VEX opcode map 1 may be encoded using this format.

VEX-encoded instructions that use the other defined values of map_select (00010b and 00011b) cannot be encoded using this a two-byte escape sequence format. Note that the VEX.pp field value is

explicitly encoded in this form and can be used to specify any of the implied legacy prefixes as defined in Table 1-22.

2 Instruction Overview

2.1 Instruction Groups

For easier reference, the instruction descriptions are divided into five groups based on usage. The following sections describe the function, mnemonic syntax, opcodes, affected flags, and possible exceptions generated by all instructions in the AMD64 architecture:

- *Chapter 3, "General-Purpose Instruction Reference"*—The general-purpose instructions are used in basic software execution. Most of these load, store, or operate on data in the general-purpose registers (GPRs), in memory, or in both. Other instructions are used to alter sequential program flow by branching to other locations within the program or to entirely different programs.
- *Chapter 4, "System Instruction Reference"*—The system instructions establish the processor operating mode, access processor resources, handle program and system errors, and manage memory.
- *"SSE Instruction Reference" in Volume 4*—The Streaming SIMD Extensions (SSE) instructions load, store, or operate on data located in the YMM/XMM registers. These instructions define both vector and scalar operations on floating-point and integer data types. They include the SSE and SSE2 instructions that operate on the YMM/XMM registers. Some of these instructions convert source operands in YMM/XMM registers to destination operands in GPR, MMX, or x87 registers or otherwise affect YMM/XMM state.
- *"64-Bit Media Instruction Reference" in Volume 5*—The 64-bit media instructions load, store, or operate on data located in the 64-bit MMX registers. These instructions define both vector and scalar operations on integer and floating-point data types. They include the legacy MMX™ instructions, the 3DNow!™ instructions, and the AMD extensions to the MMX and 3DNow! instruction sets. Some of these instructions convert source operands in MMX registers to destination operands in GPR, YMM/XMM, or x87 registers or otherwise affect MMX state.
- *"x87 Floating-Point Instruction Reference" in Volume 5*—The x87 instructions are used in legacy floating-point applications. Most of these instructions load, store, or operate on data located in the x87 ST(0)–ST(7) stack registers (the FPR0–FPR7 physical registers). The remaining instructions within this category are used to manage the x87 floating-point environment.

The description of each instruction covers its behavior in all operating modes, including legacy mode (real, virtual-8086, and protected modes) and long mode (compatibility and 64-bit modes). Details of certain kinds of complex behavior—such as control-flow changes in CALL, INT, or FXSAVE instructions—have cross-references in the instruction-detail pages to detailed descriptions in volumes 1 and 2.

Two instructions—CMPSD and MOVSD—use the same mnemonic for different instructions. Assemblers can distinguish them on the basis of the number and type of operands with which they are used.

2.2 Reference-Page Format

Figure 2-1 on page 37 shows the format of an instruction-detail page. The instruction mnemonic is shown in bold at the top-left, along with its name. In this example, *POPFD* is the mnemonic and *POP to EFLAGS Doubleword* is the name. Next, there is a general description of the instruction's operation. Many descriptions have cross-references to more detail in other parts of the manual.

Beneath the general description, the mnemonic is shown again, together with the related opcode(s) and a description summary. Related instructions are listed below this, followed by a table showing the flags that the instruction can affect. Finally, each instruction has a summary of the possible exceptions that can occur when executing the instruction. The columns labeled "Real" and "Virtual-8086" apply only to execution in legacy mode. The column labeled "Protected" applies both to legacy mode and long mode, because long mode is a superset of legacy protected mode.

The 128-bit and 64-bit media instructions also have diagrams illustrating the operation. A few instructions have examples or pseudocode describing the action.

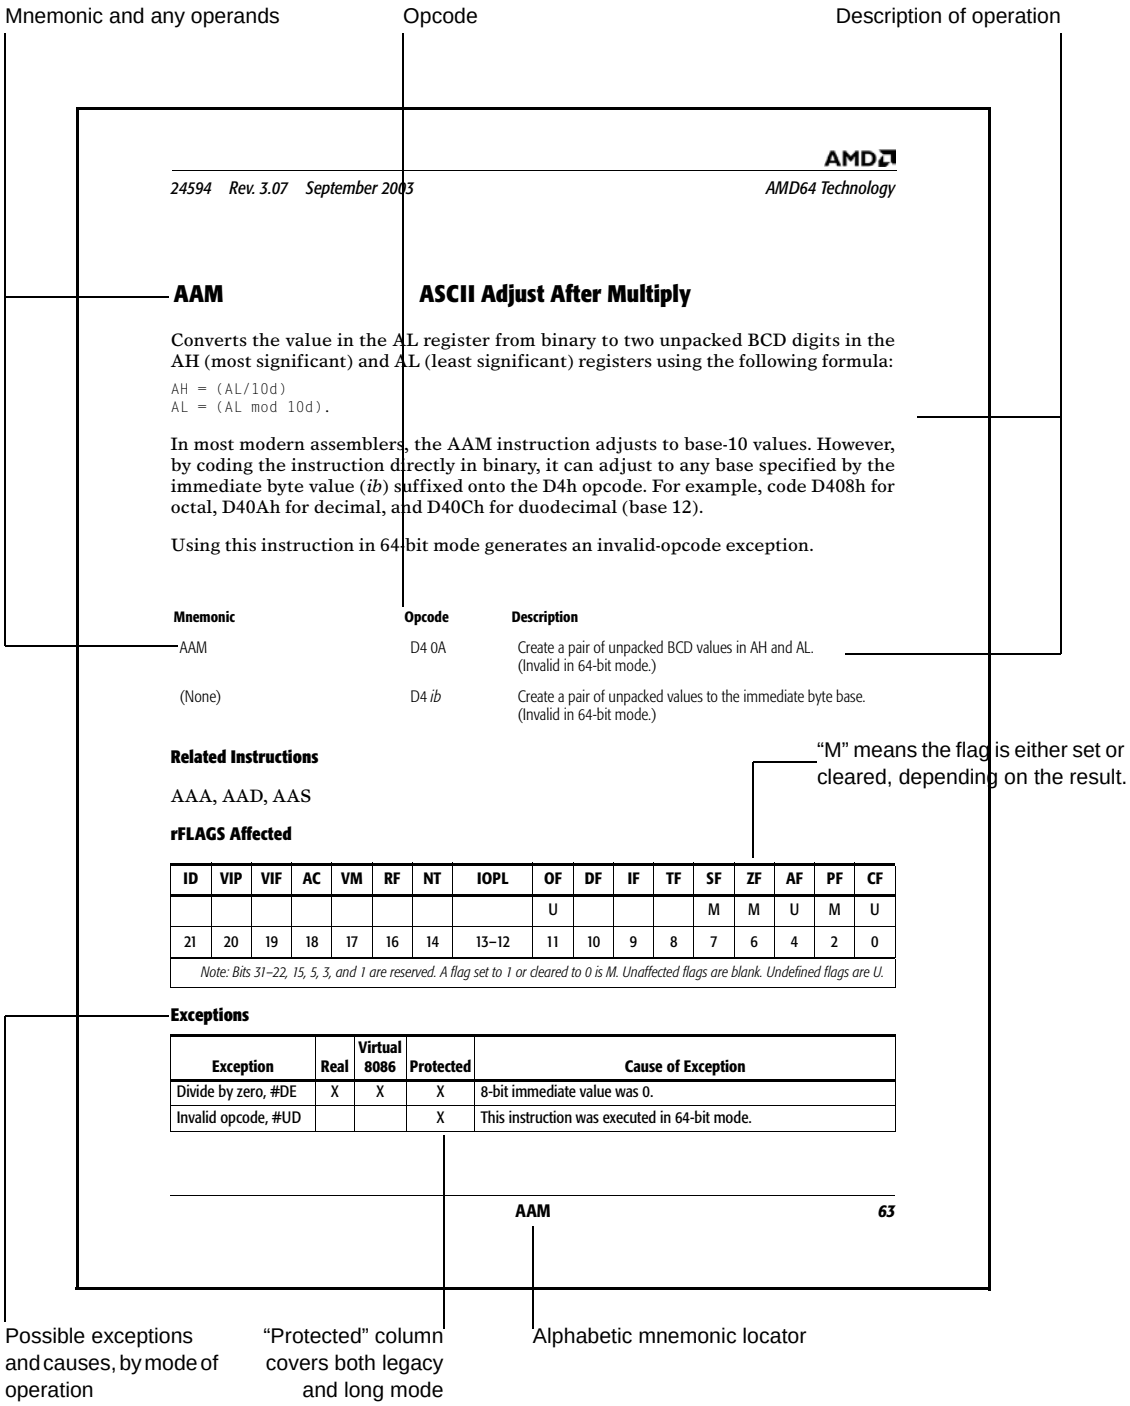

Figure 2-1. Format of Instruction-Detail Pages

2.3 Summary of Registers and Data Types

This section summarizes the registers available to software using the five instruction subsets described in “Instruction Groups” on page 35. For details on the organization and use of these registers, see their respective chapters in volumes 1 and 2.

2.3.1 General-Purpose Instructions

Registers. The size and number of general-purpose registers (GPRs) depends on the operating mode, as do the size of the flags and instruction-pointer registers. Figure 2-2 shows the registers available in legacy and compatibility modes.

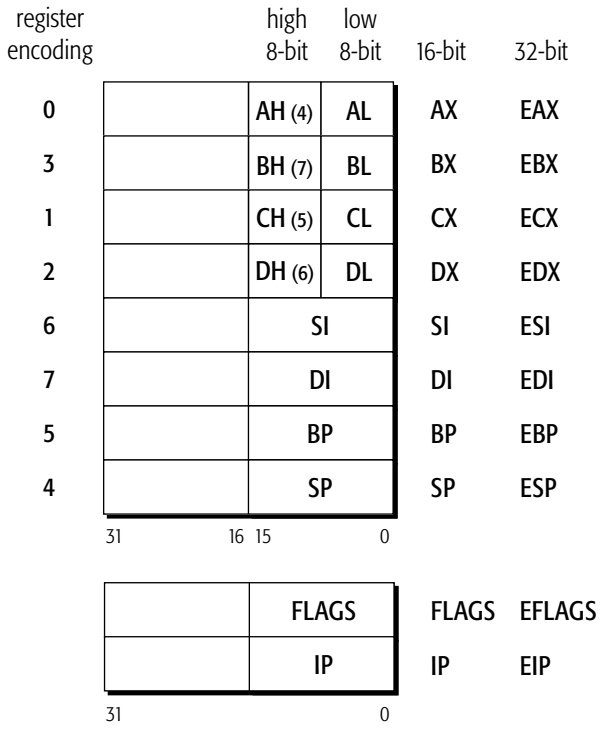

Figure 2-2. General Registers in Legacy and Compatibility Modes

Figure 2-3 on page 39 shows the registers accessible in 64-bit mode. Compared with legacy mode, registers become 64 bits wide, eight new data registers (R8–R15) are added and the low byte of all 16 GPRs is available for byte operations, and the four high-byte registers of legacy mode (AH, BH, CH, and DH) are not available if the REX prefix is used. The high 32 bits of doubleword operands are zero-extended to 64 bits, but the high bits of word and byte operands are not modified by operations in 64-

bit mode. The RFLAGS register is 64 bits wide, but the high 32 bits are reserved. They can be written with anything but they read as zeros (RAZ).

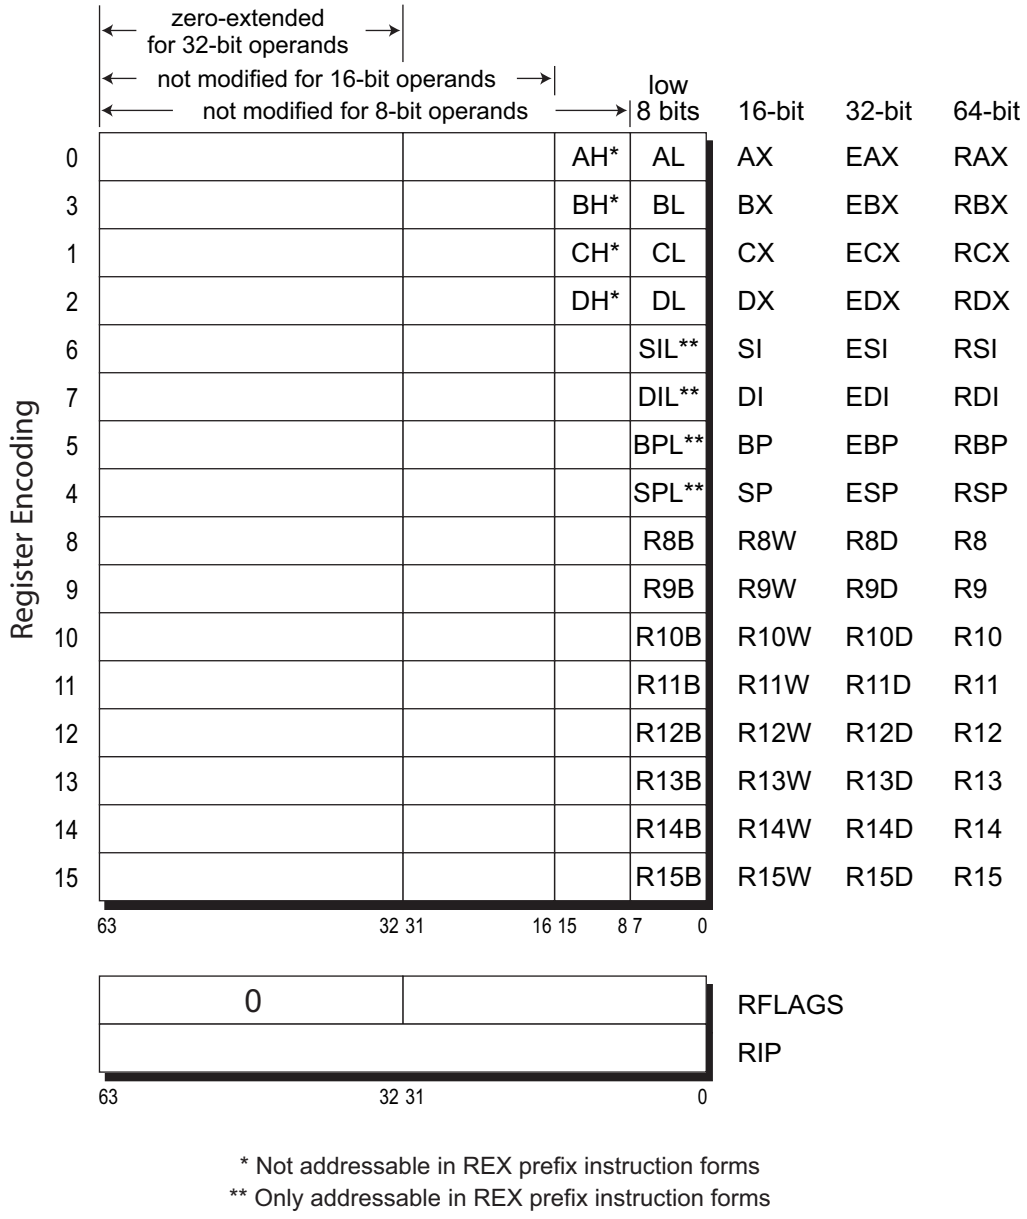

Figure 2-3. General Registers in 64-Bit Mode

For most instructions running in 64-bit mode, access to the extended GPRs requires a either a REX instruction modification prefix or extended encoding encoding using the VEX or XOP sequences (page 16).

Figure 2-4 shows the segment registers which, like the instruction pointer, are used by all instructions. In legacy and compatibility modes, all segments are accessible. In 64-bit mode, which uses the flat (non-segmented) memory model, only the CS, FS, and GS segments are recognized, whereas the contents of the DS, ES, and SS segment registers are ignored (the base for each of these segments is assumed to be zero, and neither their segment limit nor attributes are checked). For details, see "Segmented Virtual Memory" in Volume 2.

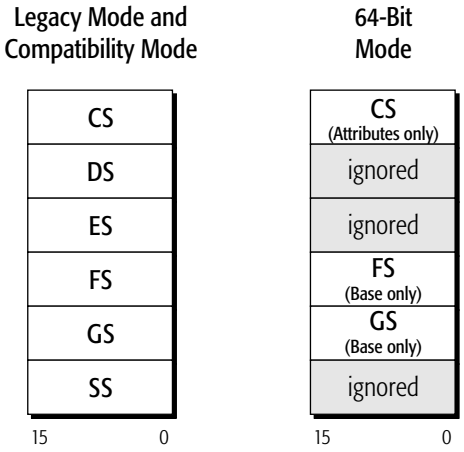

Figure 2-4. Segment Registers

Data Types. Figure 2-5 on page 41 shows the general-purpose data types. They are all scalar, integer data types. The 64-bit (quadword) data types are only available in 64-bit mode, and for most instructions they require a REX instruction prefix.

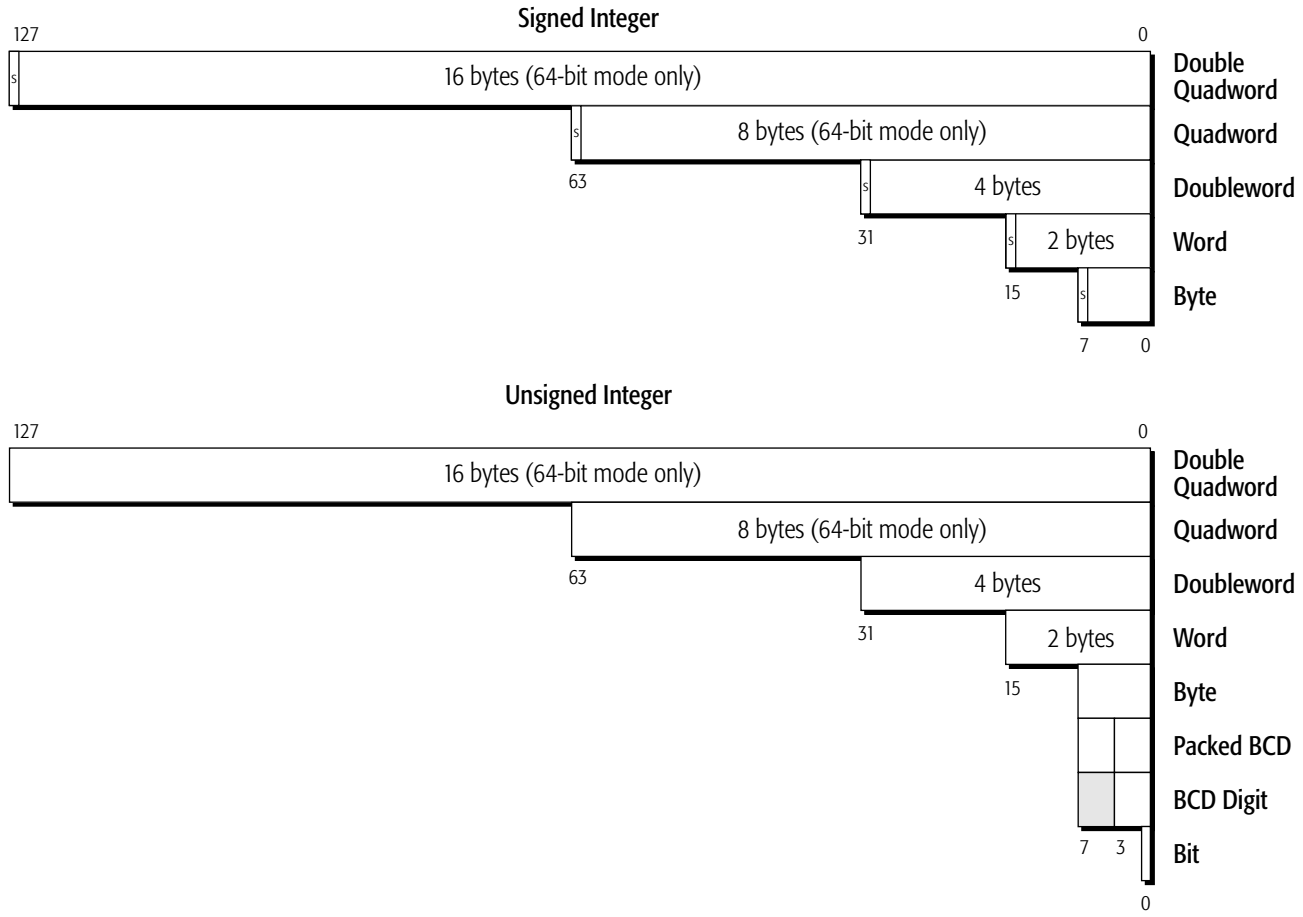

Figure 2-5. General-Purpose Data Types

2.3.2 System Instructions

Registers. The system instructions use several specialized registers shown in Figure 2-6 on page 42. System software uses these registers to, among other things, manage the processor's operating environment, define system resource characteristics, and monitor software execution. With the exception of the RFLAGS register, system registers can be read and written only from privileged software.

All system registers are 64 bits wide, except for the descriptor-table registers and the task register, which include 64-bit base-address fields and other fields.

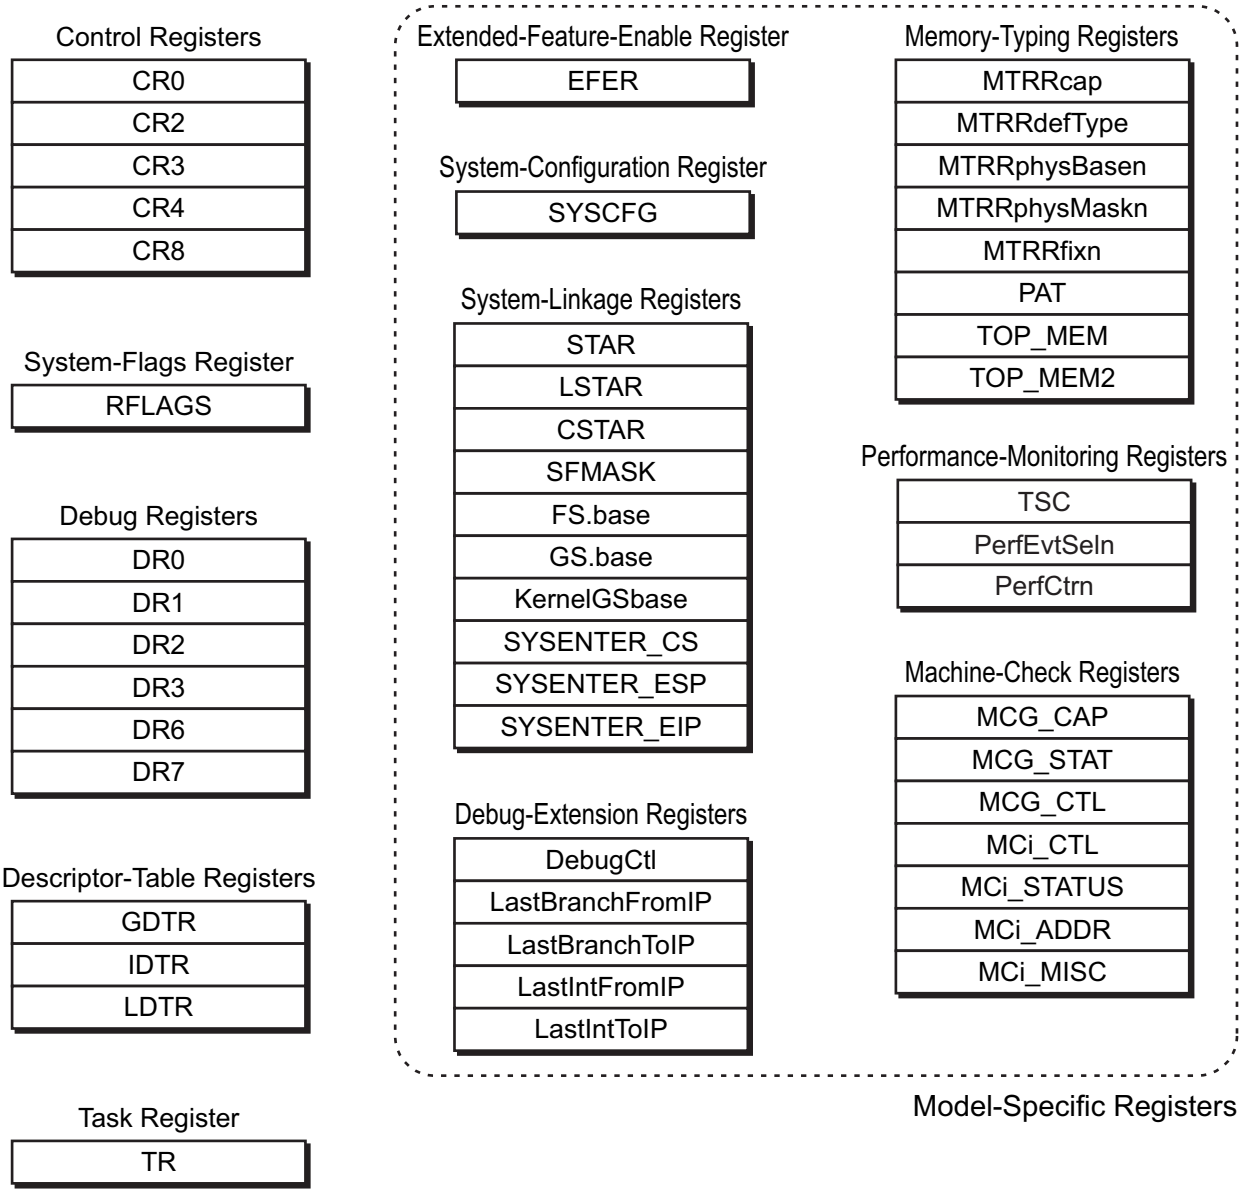

Figure 2-6. System Registers

Data Structures. Figure 2-7 on page 43 shows the system data structures. These are created and maintained by system software for use in protected mode. A processor running in protected mode uses these data structures to manage memory and protection, and to store program-state information when an interrupt or task switch occurs.

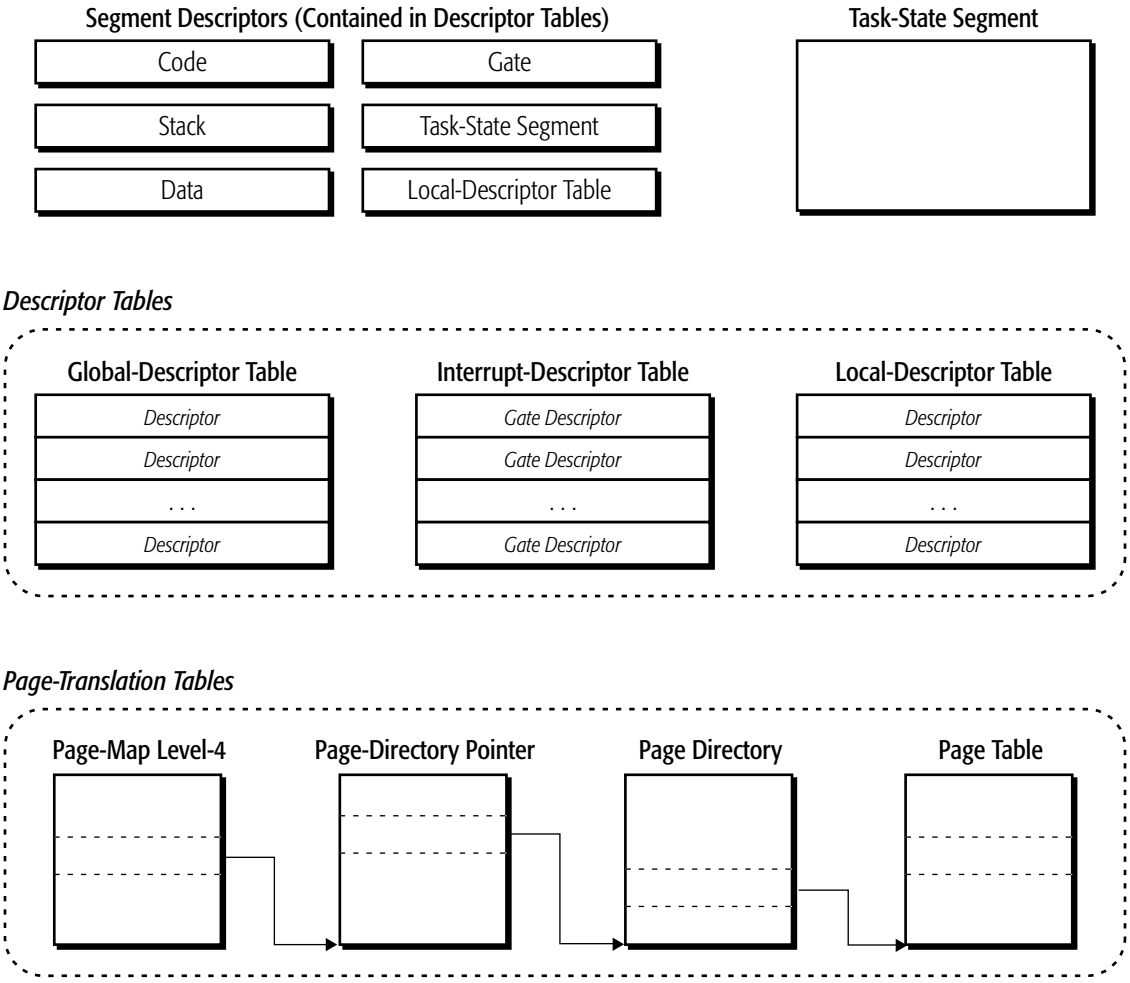

Figure 2-7. System Data Structures

2.3.3 SSE Instructions

Registers. The SSE instructions operate primarily on 128-bit and 256-bit floating-point vector operands located in the 256-bit YMM/XMM registers. Each 128-bit XMM register is defined as the lower octword of the corresponding YMM register. The number of available YMM/XMM data registers depends on the operating mode, as shown in Figure 2-8 below. In legacy and compatibility modes, eight YMM/XMM registers (YMM/XMM0–7) are available. In 64-bit mode, eight additional YMM/XMM data registers (YMM/XMM8–15) are available. These eight additional registers are addressed via the encoding extensions provided by the REX, VEX, and XOP prefixes.

The MXCSR register contains floating-point and other control and status flags used by the 128-bit media instructions. Some 128-bit media instructions also use the GPR (Figure 2-2 and Figure 2-3) and the MMX registers (Figure 2-12 on page 48) or set or clear flags in the rFLAGS register (see Figure 2-2 and Figure 2-3).

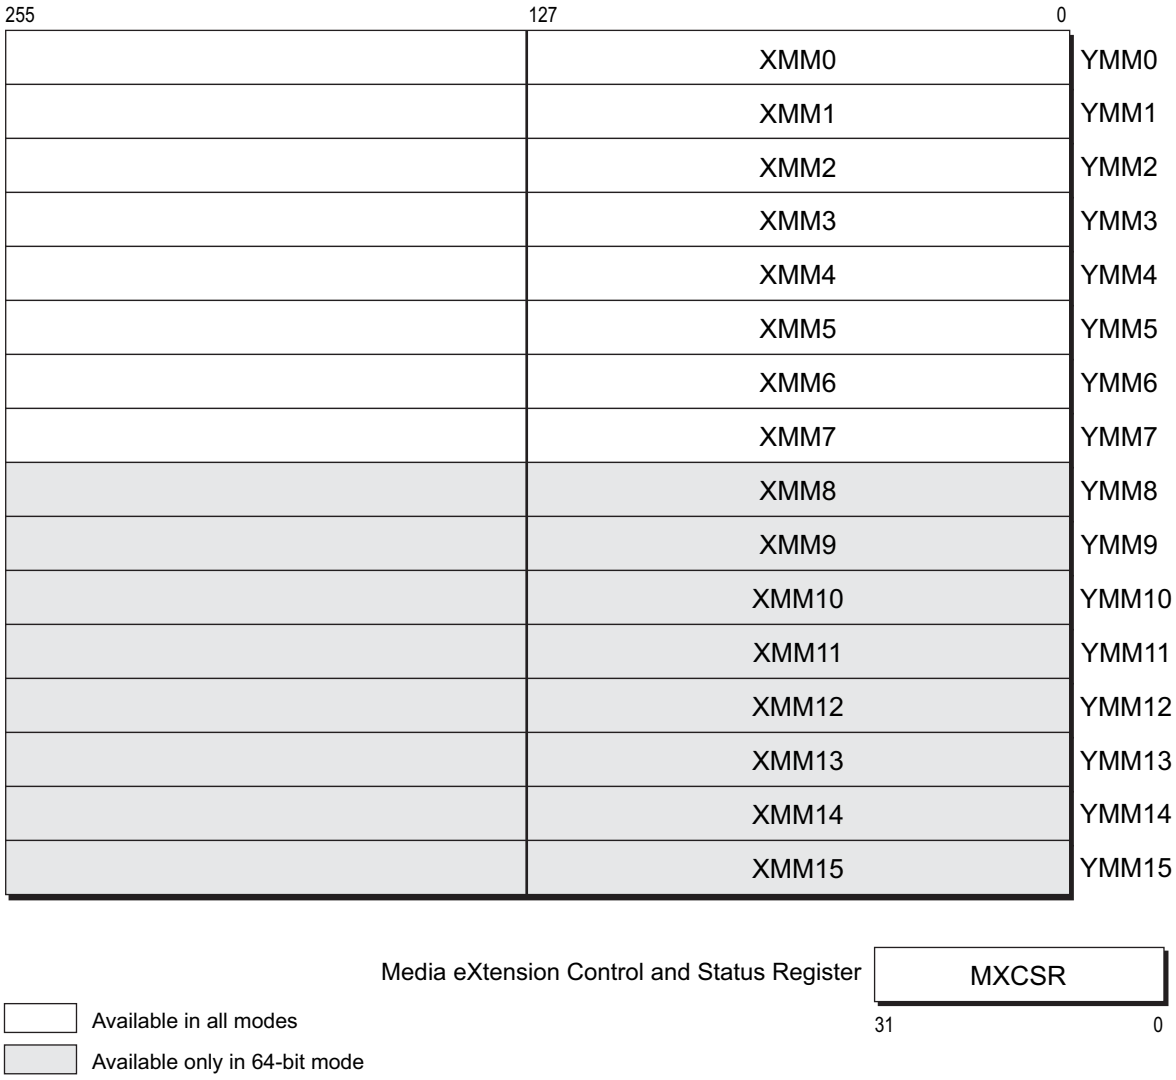

Figure 2-8. SSE Registers

Data Types. The SSE instruction set architecture provides support for 128-bit and 256-bit packed floating-point and integer data types as well as integer and floating-point scalars. Figure 2-9 below shows the 128-bit data types. Figure 2-10 on page 46 and Figure 2-11 on page 47 show the 256-bit data types. The floating-point data types include IEEE-754 single precision and double precision types.

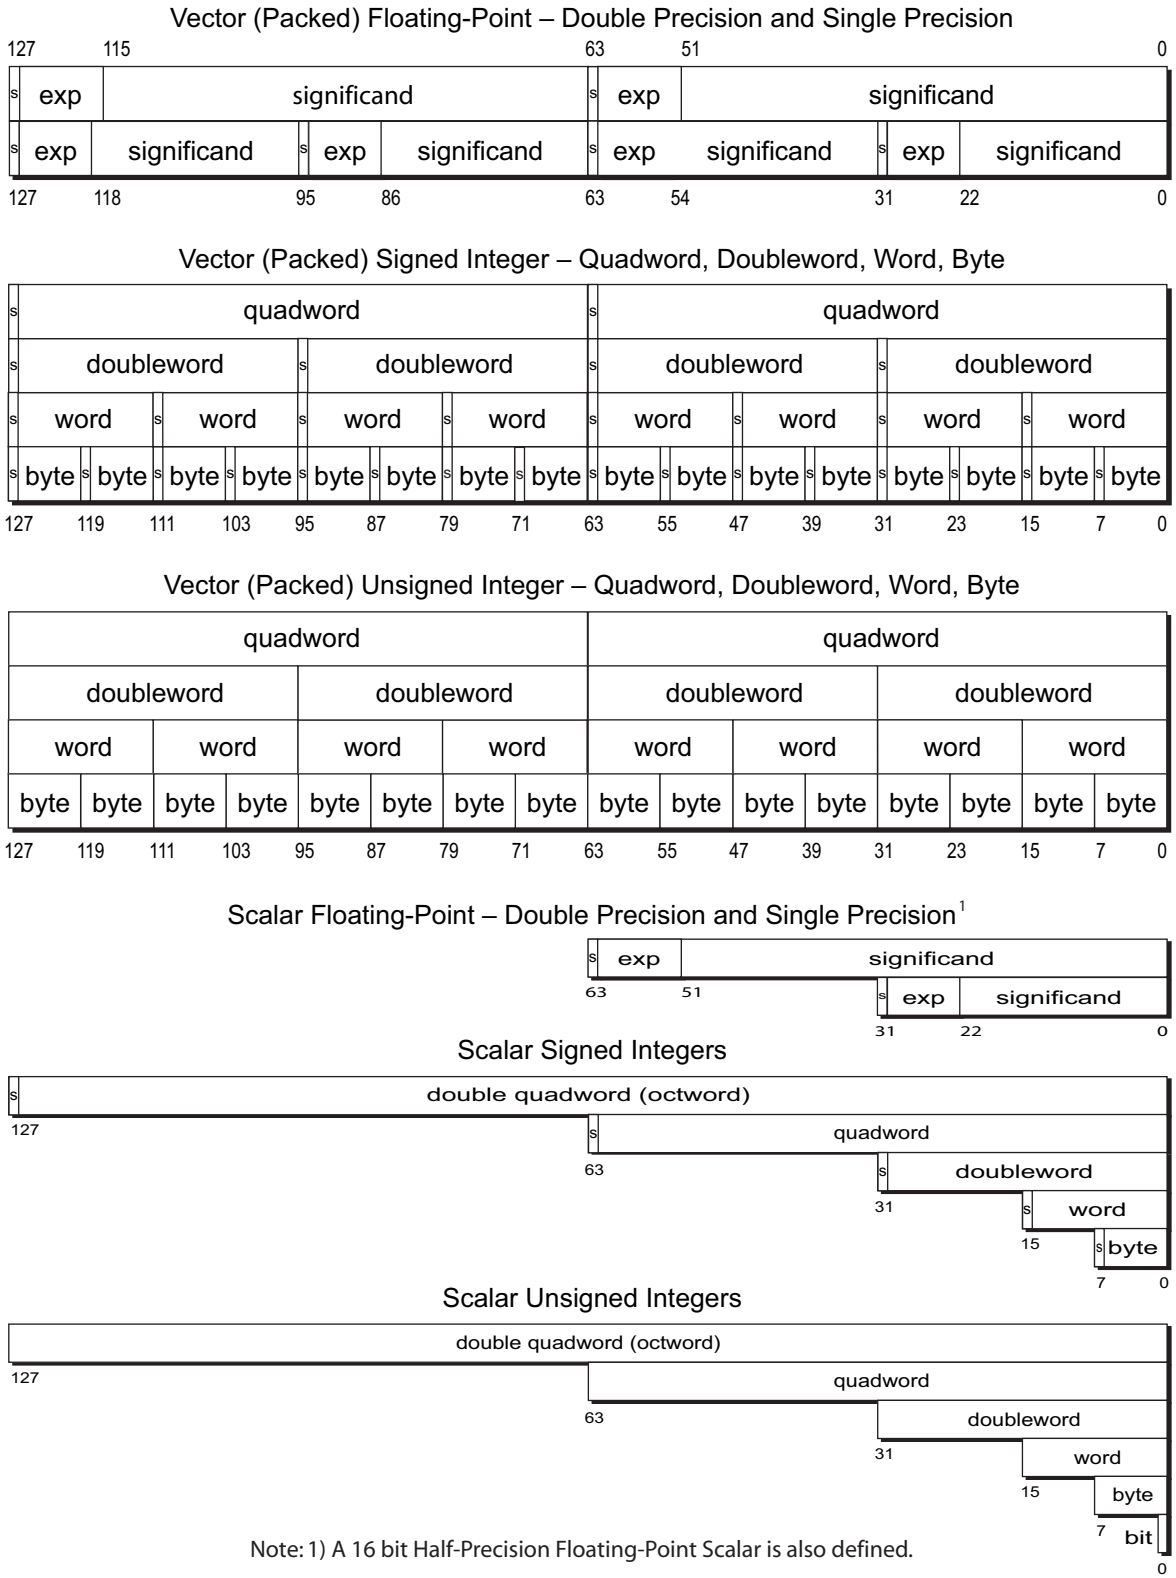

Figure 2-9. 128-Bit SSE Data Types

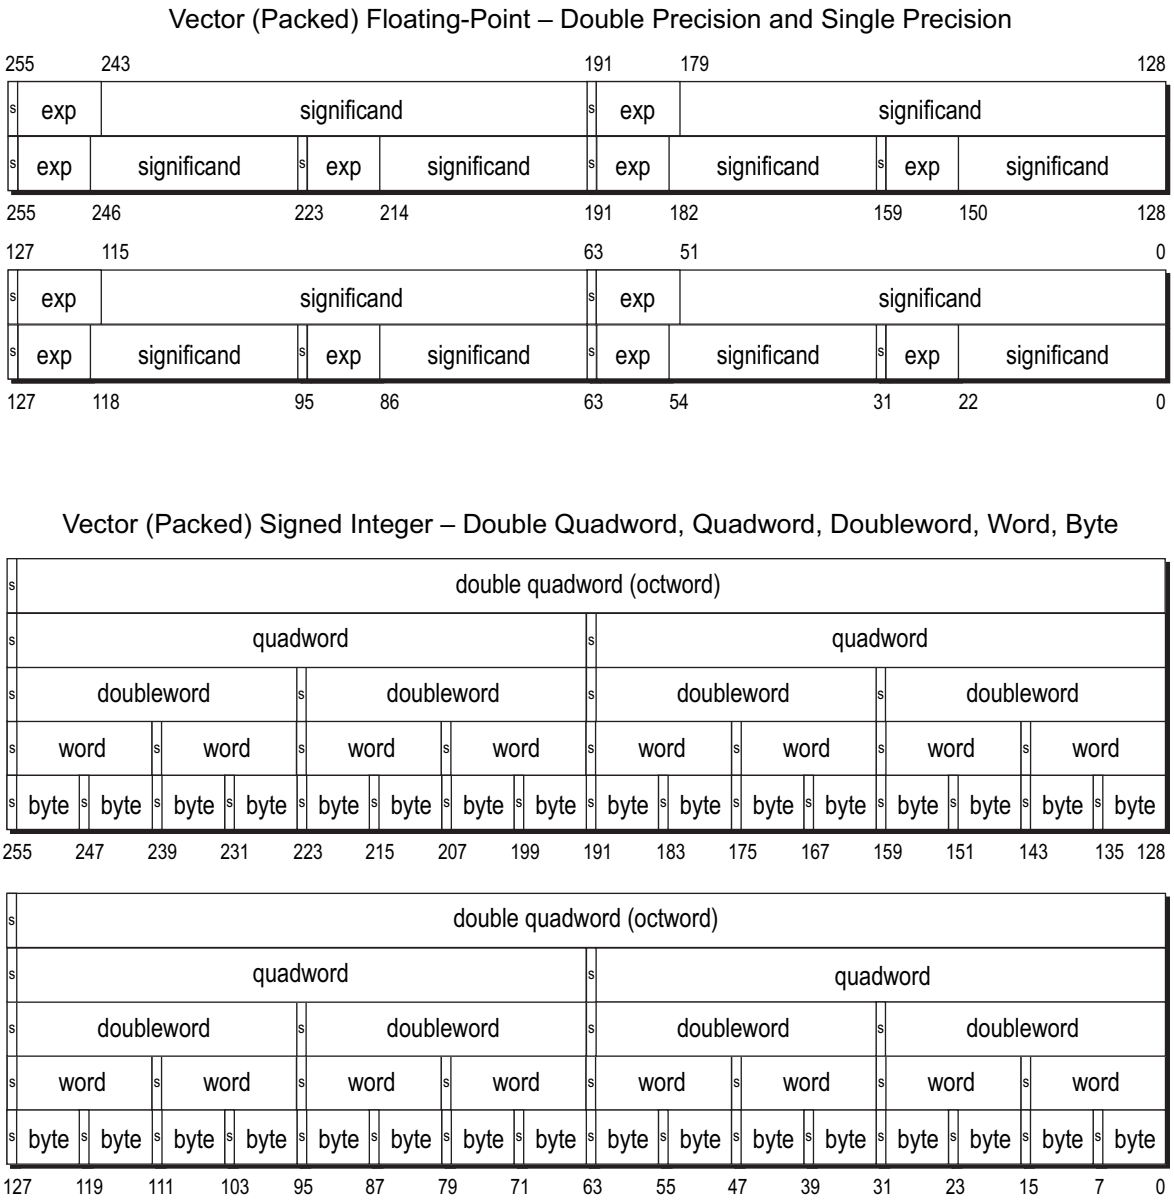

Figure 2-10. SSE 256-bit Data Types

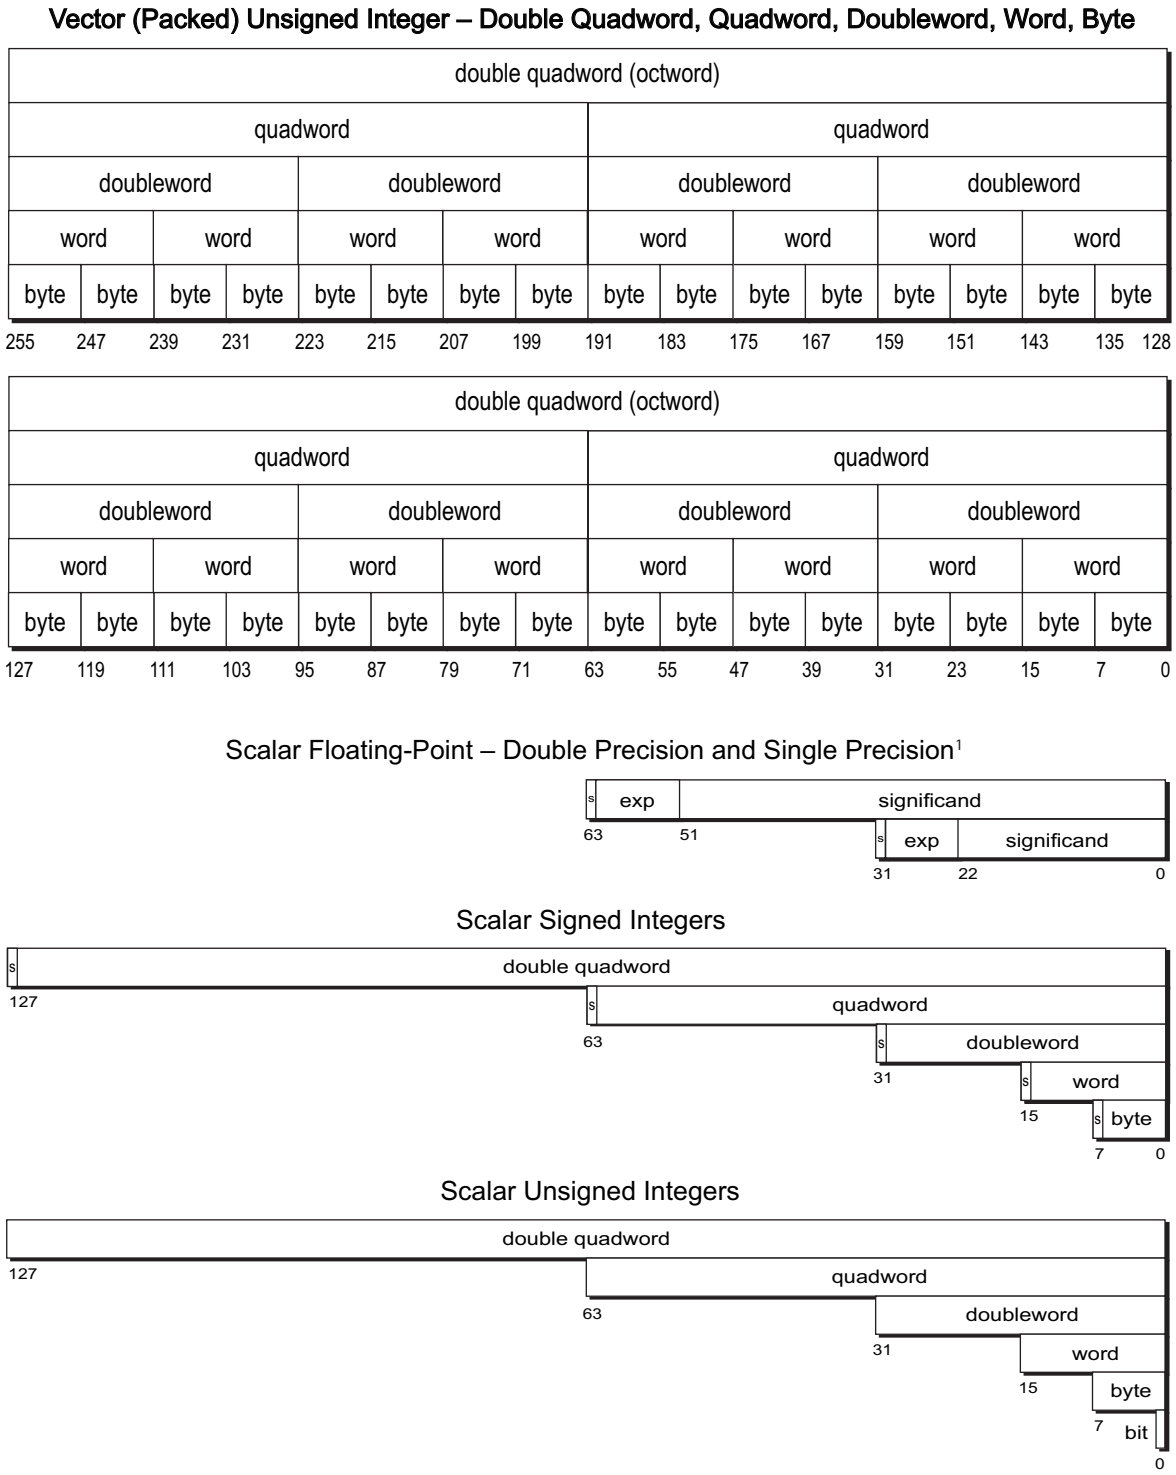

Note: 1) A 16 bit Half-Precision Floating-Point Scalar is also defined.

Figure 2-11. SSE 256-Bit Data Types (Continued)

2.3.4 64-Bit Media Instructions

Registers. The 64-bit media instructions use the eight 64-bit MMX registers, as shown in Figure 2-12. These registers are mapped onto the x87 floating-point registers, and 64-bit media instructions write the x87 tag word in a way that prevents an x87 instruction from using MMX data.

Some 64-bit media instructions also use the GPR (Figure 2-2 and Figure 2-3) and the XMM registers (Figure 2-8).

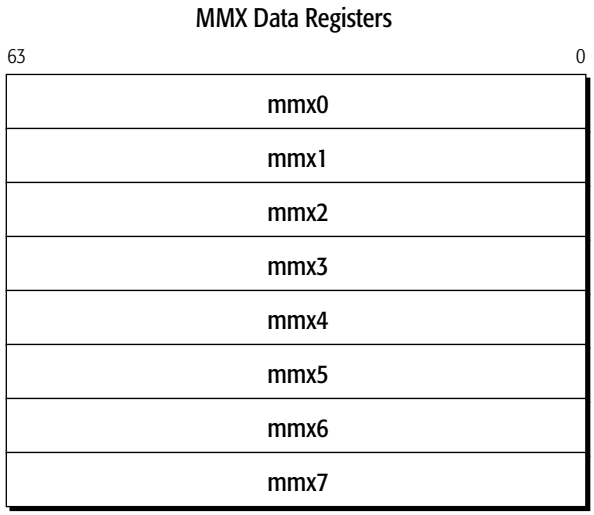

Figure 2-12. 64-Bit Media Registers

Data Types. Figure 2-13 on page 49 shows the 64-bit media data types. They include floating-point and integer vectors and integer scalars. The floating-point data type, used by 3DNow! instructions, consists of a packed vector or two IEEE-754 32-bit single-precision data types. Unlike other kinds of floating-point instructions, however, the 3DNow!™ instructions do not generate floating-point exceptions. For this reason, there is no register for reporting or controlling the status of exceptions in the 64-bit-media instruction subset.

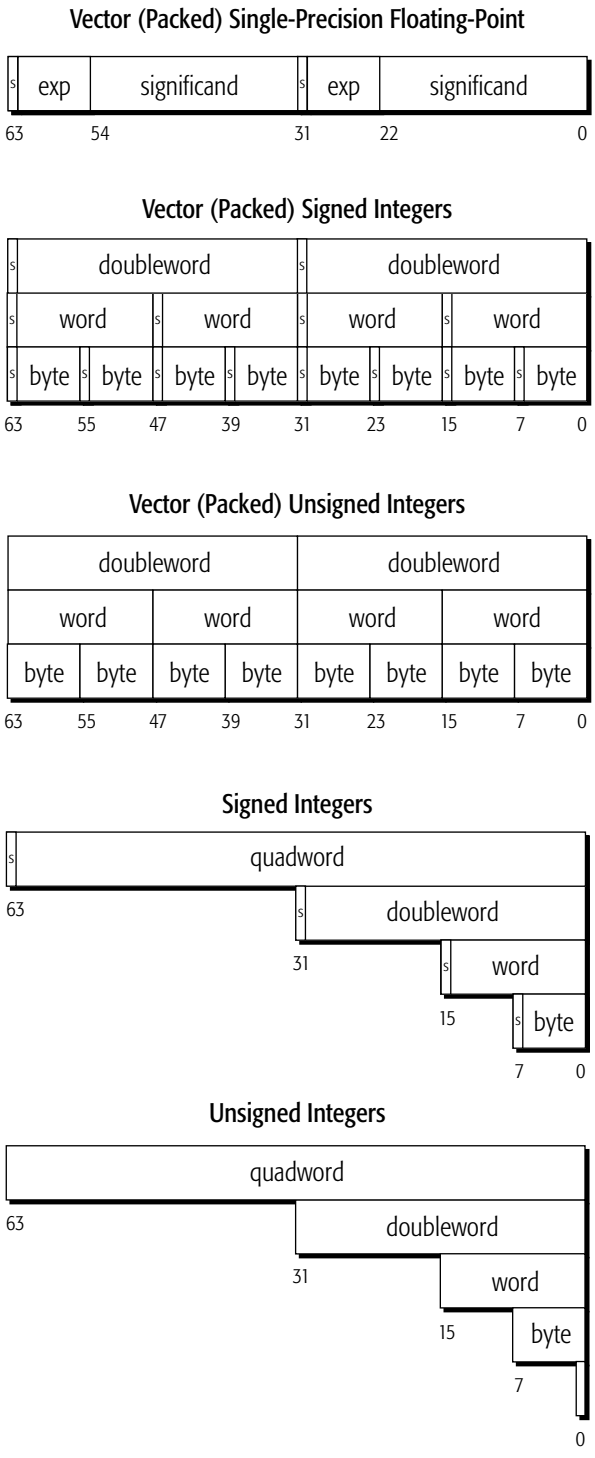

Figure 2-13. 64-Bit Media Data Types

2.3.5 x87 Floating-Point Instructions

Registers. The x87 floating-point instructions use the x87 registers shown in Figure 2-14. There are eight 80-bit data registers, three 16-bit registers that hold the x87 control word, status word, and tag word, and three registers (last instruction pointer, last opcode, last data pointer) that hold information about the last x87 operation.

The physical data registers are named FPR0–FPR7, although x87 software references these registers as a stack of registers, named ST(0)–ST(7). The x87 instructions store operands only in their own 80-bit floating-point registers or in memory. They do not access the GPR or XMM registers.

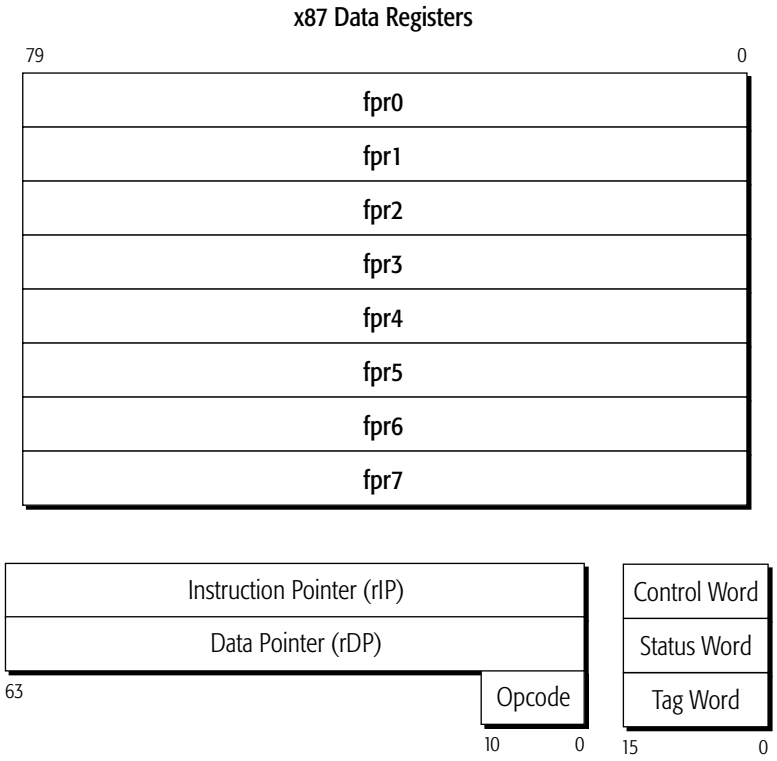

Figure 2-14. x87 Registers

Data Types. Figure 2-15 on page 51 shows all x87 data types. They include three floating-point formats (80-bit double-extended precision, 64-bit double precision, and 32-bit single precision), three signed-integer formats (quadword, doubleword, and word), and an 80-bit packed binary-coded decimal (BCD) format.

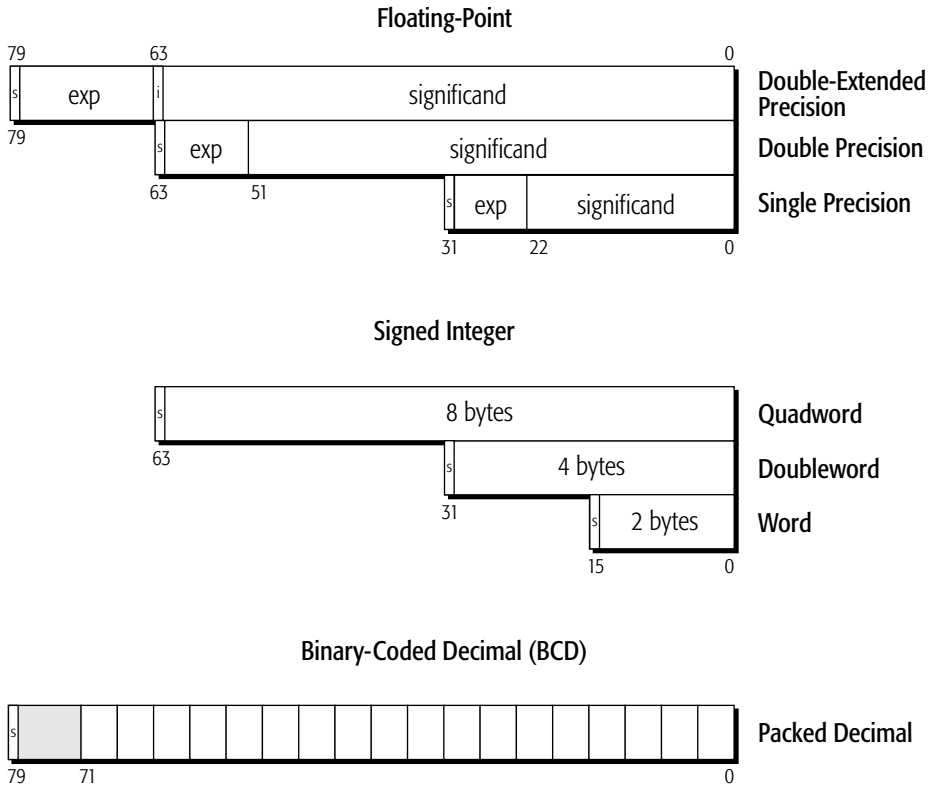

Figure 2-15. x87 Data Types

2.4 Summary of Exceptions

Table 2-1 on page 52 lists all possible exceptions. The table shows the interrupt-vector numbers, names, mnemonics, source, and possible causes. Exceptions that apply to specific instructions are documented with each instruction in the instruction-detail pages that follow.

Table 2-1. Interrupt-Vector Source and Cause

Vector	Interrupt (Exception)	Mnemonic	Source	Cause
0	Divide-By-Zero-Error	#DE	Software	DIV, IDIV, AAM instructions
1	Debug	#DB	Internal	Instruction accesses and data accesses
2	Non-Maskable-Interrupt	#NMI	External	External NMI signal
3	Breakpoint	#BP	Software	INT3 instruction
4	Overflow	#OF	Software	INTO instruction
5	Bound-Range	#BR	Software	BOUND instruction
6	Invalid-Opcode	#UD	Internal	Invalid instructions
7	Device-Not-Available	#NM	Internal	x87 instructions
8	Double-Fault	#DF	Internal	Interrupt during an interrupt
9	Coprocessor-Segment-Overrun	—	External	Unsupported (reserved)
10	Invalid-TSS	#TS	Internal	Task-state segment access and task switch
11	Segment-Not-Present	#NP	Internal	Segment access through a descriptor
12	Stack	#SS	Internal	SS register loads and stack references
13	General-Protection	#GP	Internal	Memory accesses and protection checks
14	Page-Fault	#PF	Internal	Memory accesses when paging enabled
15	Reserved	—		
16	Floating-Point Exception-Pending	#MF	Software	x87 floating-point and 64-bit media floating-point instructions
17	Alignment-Check	#AC	Internal	Memory accesses
18	Machine-Check	#MC	Internal External	Model specific
19	SIMD Floating-Point	#XF	Internal	128-bit media floating-point instructions
20	Reserved	—		
21	Control-Protection	#CP	Internal	Shadow Stack Protection checks
22—27	Reserved (Internal and External)	—		
28	Hypervisor Injection Exception	#HV	Software	Event injection
29	VMM Communication Exception	#VC	Internal	Virtualization event
30	SVM Security Exception	#SX	External	Security-sensitive events
31	Reserved (Internal and External)	—		
0—255	External Interrupts (Maskable)	#INTR	External	External interrupt signal
0—255	Software Interrupts	—	Software	INT*n* instruction

2.5 Notation

2.5.1 Mnemonic Syntax

Each instruction has a syntax that includes the mnemonic and any operands that the instruction can take. Figure 2-16 shows an example of a syntax in which the instruction takes two operands. In most instructions that take two operands, the first (left-most) operand is both a source operand (the first source operand) and the destination operand. The second (right-most) operand serves only as a source, not a destination.

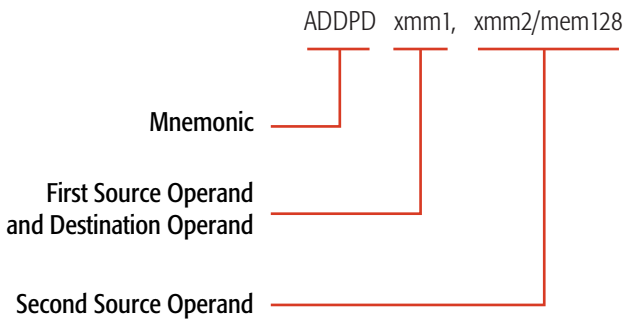

Figure 2-16. Syntax for Typical Two-Operand Instruction

The following notation is used to denote the size and type of source and destination operands:

- *cReg*—Control register.
- *dReg*—Debug register.
- *imm8*—Byte (8-bit) immediate.
- *imm16*—Word (16-bit) immediate.
- *imm16/32*—Word (16-bit) or doubleword (32-bit) immediate.
- *imm32*—Doubleword (32-bit) immediate.
- *imm32/64*—Doubleword (32-bit) or quadword (64-bit) immediate.
- *imm64*—Quadword (64-bit) immediate.
- *mem*—An operand of unspecified size in memory.
- *mem8*—Byte (8-bit) operand in memory.
- *mem16*—Word (16-bit) operand in memory.
- *mem16/32*—Word (16-bit) or doubleword (32-bit) operand in memory.
- *mem32*—Doubleword (32-bit) operand in memory.
- *mem32/48*—Doubleword (32-bit) or 48-bit operand in memory.
- *mem48*—48-bit operand in memory.

- *mem64*—Quadword (64-bit) operand in memory.
- *mem128*—Double quadword (128-bit) operand in memory.
- *mem16:16*—Two sequential word (16-bit) operands in memory.
- *mem16:32*—A doubleword (32-bit) operand followed by a word (16-bit) operand in memory.
- *mem32real*—Single-precision (32-bit) floating-point operand in memory.
- *mem16int*—Word (16-bit) integer operand in memory.
- *mem32int*—Doubleword (32-bit) integer operand in memory.
- *mem64real*—Double-precision (64-bit) floating-point operand in memory.
- *mem64int*—Quadword (64-bit) integer operand in memory.
- *mem80real*—Double-extended-precision (80-bit) floating-point operand in memory.
- *mem80dec*—80-bit packed BCD operand in memory, containing 18 4-bit BCD digits.
- *mem2env*—16-bit x87 control word or x87 status word.
- *mem14/28env*—14-byte or 28-byte x87 environment. The x87 environment consists of the x87 control word, x87 status word, x87 tag word, last non-control instruction pointer, last data pointer, and opcode of the last non-control instruction completed.
- *mem94/108env*—94-byte or 108-byte x87 environment and register stack.
- *mem512env*—512-byte environment for 128-bit media, 64-bit media, and x87 instructions.
- *mmx*—Quadword (64-bit) operand in an MMX register.
- *mmx1*—Quadword (64-bit) operand in an MMX register, specified as the left-most (first) operand in the instruction syntax.
- *mmx2*—Quadword (64-bit) operand in an MMX register, specified as the right-most (second) operand in the instruction syntax.
- *mmx/mem32*—Doubleword (32-bit) operand in an MMX register or memory.
- *mmx/mem64*—Quadword (64-bit) operand in an MMX register or memory.
- *mmx1/mem64*—Quadword (64-bit) operand in an MMX register or memory, specified as the left-most (first) operand in the instruction syntax.
- *mmx2/mem64*—Quadword (64-bit) operand in an MMX register or memory, specified as the right-most (second) operand in the instruction syntax.
- *moffset*—Direct memory offset that specifies an operand in memory.
- *moffset8*—Direct memory offset that specifies a byte (8-bit) operand in memory.
- *moffset16*—Direct memory offset that specifies a word (16-bit) operand in memory.
- *moffset32*—Direct memory offset that specifies a doubleword (32-bit) operand in memory.
- *moffset64*—Direct memory offset that specifies a quadword (64-bit) operand in memory.
- *pntr16:16*—Far pointer with 16-bit selector and 16-bit offset.
- *pntr16:32*—Far pointer with 16-bit selector and 32-bit offset.
- *reg*—Operand of unspecified size in a GPR register.

- *reg8*—Byte (8-bit) operand in a GPR register.
- *reg16*—Word (16-bit) operand in a GPR register.
- *reg16/32*—Word (16-bit) or doubleword (32-bit) operand in a GPR register.
- *reg32*—Doubleword (32-bit) operand in a GPR register.
- *reg64*—Quadword (64-bit) operand in a GPR register.
- *reg/mem8*—Byte (8-bit) operand in a GPR register or memory.
- *reg/mem16*—Word (16-bit) operand in a GPR register or memory.
- *reg/mem32*—Doubleword (32-bit) operand in a GPR register or memory.
- *reg/mem64*—Quadword (64-bit) operand in a GPR register or memory.
- *rel8off*—Signed 8-bit offset relative to the instruction pointer.
- *rel16off*—Signed 16-bit offset relative to the instruction pointer.
- *rel32off*—Signed 32-bit offset relative to the instruction pointer.
- *segReg or sReg*—Word (16-bit) operand in a segment register.
- *ST(0)*—x87 stack register 0.
- *ST(i)*—x87 stack register *i*, where *i* is between 0 and 7.
- *xmm*—Double quadword (128-bit) operand in an XMM register.
- *xmm1*—Double quadword (128-bit) operand in an XMM register, specified as the left-most (first) operand in the instruction syntax.
- *xmm2*—Double quadword (128-bit) operand in an XMM register, specified as the right-most (second) operand in the instruction syntax.
- *xmm/mem64*—Quadword (64-bit) operand in a 128-bit XMM register or memory.
- *xmm/mem128*—Double quadword (128-bit) operand in an XMM register or memory.
- *xmm1/mem128*—Double quadword (128-bit) operand in an XMM register or memory, specified as the left-most (first) operand in the instruction syntax.
- *xmm2/mem128*—Double quadword (128-bit) operand in an XMM register or memory, specified as the right-most (second) operand in the instruction syntax.
- *ymm*—Double octword (256-bit) operand in an YMM register.
- *ymm1*—Double octword (256-bit) operand in an YMM register, specified as the left-most (first) operand in the instruction syntax.
- *ymm2*—Double octword (256-bit) operand in an YMM register, specified as the right-most (second) operand in the instruction syntax.
- *ymm/mem64*—Quadword (64-bit) operand in a 256-bit YMM register or memory.
- *ymm/mem128*—Double quadword (128-bit) operand in an YMM register or memory.
- *ymm1/mem256*—Double octword (256-bit) operand in an YMM register or memory, specified as the left-most (first) operand in the instruction syntax.

- *ymm2/mem256*—Double octword (256-bit) operand in an YMM register or memory, specified as the right-most (second) operand in the instruction syntax.

2.5.2 Opcode Syntax

In addition to the notation shown above in "Mnemonic Syntax" on page 53, the following notation indicates the size and type of operands in the syntax of an instruction opcode:

- */digit*—Indicates that the ModRM byte specifies only one register or memory (r/m) operand. The digit is specified by the ModRM reg field and is used as an instruction-opcode extension. Valid digit values range from 0 to 7.
- */r*—Indicates that the ModRM byte specifies both a register operand and a reg/mem (register or memory) operand.
- *cb, cw, cd, cp*—Specifies a code-offset value and possibly a new code-segment register value. The value following the opcode is either one byte (cb), two bytes (cw), four bytes (cd), or six bytes (cp).
- *ib, iw, id, iq*—Specifies an immediate-operand value. The opcode determines whether the value is signed or unsigned. The value following the opcode, ModRM, or SIB byte is either one byte (ib), two bytes (iw), or four bytes (id). Word and doubleword values start with the low-order byte.
- *+rb, +rw, +rd, +rq*—Specifies a register value that is added to the hexadecimal byte on the left, forming a one-byte opcode. The result is an instruction that operates on the register specified by the register code. Valid register-code values are shown in Table 2-2.
- *m64*—Specifies a quadword (64-bit) operand in memory.
- *+i*—Specifies an x87 floating-point stack operand, ST(*i*). The value is used only with x87 floating-point instructions. It is added to the hexadecimal byte on the left, forming a one-byte opcode. Valid values range from 0 to 7.

Table 2-2. +rb, +rw, +rd, and +rq Register Value

REX.B Bit[1]	Value	Specified Register			
		+rb	+rw	+rd	+rq
0 or no REX Prefix	0	AL	AX	EAX	RAX
	1	CL	CX	ECX	RCX
	2	DL	DX	EDX	RDX
	3	BL	BX	EBX	RBX
	4	AH, SPL[1]	SP	ESP	RSP
	5	CH, BPL[1]	BP	EBP	RBP
	6	DH, SIL[1]	SI	ESI	RSI
	7	BH, DIL[1]	DI	EDI	RDI

1. See "REX Prefix" on page 14.

Table 2-2. +rb, +rw, +rd, and +rq Register Value (continued)

REX.B Bit[1]	Value	Specified Register			
		+rb	+rw	+rd	+rq
1	0	R8B	R8W	R8D	R8
	1	R9B	R9W	R9D	R9
	2	R10B	R10W	R10D	R10
	3	R11B	R11W	R11D	R11
	4	R12B	R12W	R12D	R12
	5	R13B	R13W	R13D	R13
	6	R14B	R14W	R14D	R14
	7	R15B	R15W	R15D	R15

1. *See “REX Prefix” on page 14.*

2.5.3 Pseudocode Definition

Pseudocode examples are given for the actions of several complex instructions (for example, see “CALL (Near)” on page 130). The following definitions apply to all such pseudocode examples:

```
////////////////////////////////////////////////////////////////////////////////
// Pseudo Code Definition
////////////////////////////////////////////////////////////////////////////////
//
// Comments start with double slashes.
//
// '=' can mean "is", or assignment based on context
// '==' is the equals comparison operator
//
////////////////////////////////////////////////////////////////////////////////
// Constants
////////////////////////////////////////////////////////////////////////////////

0               // numbers are in base-10 (decimal), unless followed by a suffix
0000_0001b      // a number in binary notation, underbars added for readability
FFE0_0000h      // a number expressed in hexadecimal notation

// in the following, '&&' is the logical AND operator. See "Logical Operators"
// below.
// reg[fld] identifies a field (one or more bits) within architected register
// or within a sub-element of a larger data structure. A dot separates the
// higher-level data structure name from the sub-element name.
//
CS.desc = Code Segment descriptor   // CS.desc has sub-elements: base, limit, attr
SS.desc = Stack Segment descriptor  // SS.desc has the same sub-elements
CS.desc.base = base subfield of CS.desc
CS = Code Segment Register
SS = Stack Segment Register
CPL = Current Privilege Level (0 <= CPL <= 3)
REAL_MODE = (CR0[PE] == 0)
```

```
PROTECTED_MODE = ((CR0[PE] == 1) && (RFLAGS[VM] == 0))
VIRTUAL_MODE = ((CR0[PE] == 1) && (RFLAGS[VM] == 1))
LEGACY_MODE = (EFER[LMA] == 0)
LONG_MODE = (EFER[LMA] == 1)
64BIT_MODE = ((EFER[LMA]==1) && (CS_desc.attr[L] == 1) && (CS_desc.attr[D] == 0))
COMPATIBILITY_MODE = (EFER[LMA] == 1) && (CS_desc.attr[L] == 0)
PAGING_ENABLED = (CR0[PG] == 1)
ALIGNMENT_CHECK_ENABLED = ((CR0[AM] == 1) && (RFLAGS[AC] == 1) && (CPL == 3))

OPERAND_SIZE = 16, 32, or 64   // size, in bits, of an operand
// OPERAND_SIZE depends on processor mode, the current code segment descriptor
// default operand size [D], presence of the operand size override prefix (66h)
// and, in 64-bit mode, the REX prefix.
// NOTE: Specific instructions take 8-bit operands, but for these instructions,
// operand size is fixed and the variable OPERAND_SIZE is not needed.

ADDRESS_SIZE = 16, 32, or 64   // size, in bits, of the effective address for
// memory reads. ADDRESS_SIZE depends processor mode, the current code segment
// descriptor default operand size [D], and the presence of the address size
// override prefix (67h)

STACK_SIZE = 16, 32, or 64     // size, in bits of stack operation operand
// STACK_SIZE depends on current code segment descriptor attribute D bit and
// the Stack Segment descriptor attribute B bit.

////////////////////////////////////////////////////////////////////////////////
// Architected Registers
////////////////////////////////////////////////////////////////////////////////
// Identified using abbreviated names assigned by the Architecture; can represent
//  the register or its contents depending on context.
RAX = the 64-bit contents of the general-purpose register
EAX = 32-bit contents of GPR EAX
AX = 16-bit contents of GPR AX
AL = lower 8 bits of GPR AX
AH = upper 8 bits of GPR AX

index_of(reg) = value used to encode the register.
index_of(AX) = 0000b
index_of(RAX) = 0000b

// in legacy and compatibility modes the msb of the index is fixed as 0

////////////////////////////////////////////////////////////////////////////////

////////////////////////////////////////////////////////////////////////////
// Arithmetic Operators
////////////////////////////////////////////////////////////////////////////
a + b    // integer addition
a - b    // integer subtraction
a * b    // integer multiplication
a / b    // integer division.  Result is the quotient
a % b    // modulo.  Result is the remainder after a is divided by b
// multiplication has precedence over addition where precedence is not explicitly
// indicated by grouping terms with parentheses

////////////////////////////////////////////////////////////////////////////
// Bitwise Operators
////////////////////////////////////////////////////////////////////////////
// temp, a, and b are values or register contents of the same size
temp = a AND b;   // Corresponding bits of a and b are logically ANDed together
```

```
temp = a OR b;    // Corresponding bits of a and b are logically ORed together
temp = a XOR b;   // Each bit of temp is the exclusive OR of the corresponding
                  // bits of a and b
temp = NOT a;     // Each bit of temp is the complement of the corresponding
                  // bit of a

// Concatenation
value = {field1,field2,100b};  //pack values of field1, field2 and 100b
size_of(value) = (size_of(field1) + size_of(field2) + 3)

////////////////////////////////////////////////////////////////////////////
// Logical Shift Operators
////////////////////////////////////////////////////////////////////////////
temp = a << b;    // Result is a shifted left by _b_ bit positions. Zeros are
                  // shifted into vacant positions. Bits shifted out are lost.
temp = a >> b;    // Result is a shifted right by _b_ bit positions. Zeros are
                  // shifted into vacant positions. Bits shifted out are lost.

////////////////////////////////////////////////////////////////////////////
// Logical Operators
////////////////////////////////////////////////////////////////////////////
// a boolean variable can assume one of two values (TRUE or FALSE)
// In these examples, FOO, BAR, CONE, and HEAD have been defined to be boolean
// variables
FOO && BAR  // Logical AND
FOO || BAR  // Logical OR
!FOO        // Logical complement (NOT)

////////////////////////////////////////////////////////////////////////////
// Comparison Operators
////////////////////////////////////////////////////////////////////////////
// a and b are integer values.  The result is a boolean value.
a == b      // if a and b are equal, the result is TRUE; otherwise it is FALSE.
a != b     // if a and b are not equal, the result is TRUE; otherwise it is FALSE.
a > b      // if a is greater than b, the result is TRUE; otherwise it is FALSE.
a < b      // if a is less than b, the result is TRUE; otherwise it is FALSE.
a >= b     // if a is greater than or equal to b, the result is TRUE; otherwise
           // it is FALSE.
a <= b     // if a is less than or equal to b, the result is TRUE; otherwise
           // it is FALSE.
////////////////////////////////////////////////////////////////////////////
// Logical Expressions
////////////////////////////////////////////////////////////////////////////
// Logical binary (two operand) and unary (one operand) operators can be combined
// with comparison operators to form more complex expressions.  Parentheses are
// used to enclose comparison terms and to show precedence. If precedence is not
// explicitly shown, logical AND has precedence over logical OR. Unary operators
// have precedence over binary operators.

FOO && (a < b) || !BAR  // evaluate the comparison a < b first, then
                        // AND this with FOO. Finally OR this intermediate result
```

```
                        // with the complement of BAR.

// Logical expressions can be English phrases that can be evaluated to be TRUE
// or FALSE. Statements assume knowledge of the system architecture (Volumes 1 and
// 2).

3 General-Purpose Instruction Reference

This chapter describes the function, mnemonic syntax, opcodes, affected flags, and possible exceptions generated by the general-purpose instructions. General-purpose instructions are used in basic software execution. Most of these instructions load, store, or operate on data located in the general-purpose registers (GPRs), in memory, or in both. The remaining instructions are used to alter the sequential flow of the program by branching to other locations within the program, or to entirely different programs. With the exception of the MOVD, MOVMSKPD and MOVMSKPS instructions, which operate on MMX/XMM registers, the instructions within the category of general-purpose instructions do not operate on any other register set.

Most general-purpose instructions are supported in all hardware implementations of the AMD64 architecture. However, some instructions in this group are optional and support must be determined by testing processor feature flags using the CPUID instruction. These instructions are listed in Table 3-1, along with the CPUID function, register and bit used to test for the presence of the instruction.

Table 3-1. Instruction Support Indicated by CPUID Feature Bits

Instruction	CPUID Function(s)	Register[Bit]	Feature Flag
ADCX, ADOX	0000_0007h (ECX=0)	EBX[19]	ADX
Bit Manipulation Instructions - group 1	0000_0007h (ECX=0)	EBX[3]	BMI1
Bit Manipulation Instructions - group 2	0000_0007h (ECX=0)	EBX[8]	BMI2
CLFLOPT	0000_0007_0	EBX[23]	CLFLOPT
CLWB	0000_0007h (ECX=0)	EBX[24]	CLWB
CLZERO	8000_0008h	EBX[0]	CLZERO
CMPXCHG8B	0000_0001h, 8000_0001h	EDX[8]	CMPXCHG8B
CMPXCHG16B	0000_0001h	ECX[13]	CMPXCHG16B
CMOV*cc* (Conditional Moves)	0000_0001h, 8000_0001h	EDX[15]	CMOV
CLFLUSH	0000_0001h	EDX[19]	CLFSH
CRC32	0000_0001h	ECX[20]	SSE42
LAHF, SAHF	8000_0001h	ECX[0]	LahfSahf
LZCNT	8000_0001h	ECX[5]	ABM
Long Mode and Long Mode instructions	8000_0001h	EDX[29]	LM
MCOMMIT	8000_0008h	EBX[8]	MCOMMIT
MFENCE, LFENCE	0000_0001h	EDX[26]	SSE2
MONITORX, MWAITX	8000_0001h	ECX[29]	MONITORX
MOVBE	0000_0001h	ECX[22]	MOVBE

Table 3-1. Instruction Support Indicated by CPUID Feature Bits (continued)

Instruction	CPUID Function(s)	Register[Bit]	Feature Flag
MOVD[1]	0000_0001h, 8000_0001h	EDX[23]	MMX
	0000_0001h	EDX[26]	SSE2
MOVNTI	0000_0001h	EDX[26]	SSE2
POPCNT	0000_0001h	ECX[23]	POPCNT
PREFETCH / PREFETCHW[2]	8000_0001h	ECX[8]	3DNowPrefetch
		EDX[29]	LM
		EDX[31]	3DNow
RDFSBASE, RDGSBASE WRFSBASE, WRGSBASE	0000_0007h (ECX=0)	EBX[0]	FSGSBASE
RDPRU	8000_0008h	EBX[4]	RDPRU
RDRAND	0000_0001h	ECX[30]	RDRAND
RDSEED	0000_0007h (ECX=0)	EBX[18]	RDSEED
RDPID	0000_0007h (ECX=0)	ECX[22]	RDPID
SFENCE	0000_0001h	EDX[25]	SSE
Trailing Bit Manipulation Instructions	8000_0001h	ECX[21]	TBM

Notes:

1. The MOVD variant that moves values to or from MMX registers is part of the MMX subset; the MOVD variant that moves data to or from XMM registers is part of the SSE2 subset.
2. Instruction is supported if any one of the listed feature flags is set.

For more information on using the CPUID instruction, see the reference page for the CPUID instruction on page 165. For a comprehensive list of all instruction support feature flags, see Appendix D, “Instruction Subsets and CPUID Feature Flags,” on page 587.

The general-purpose instructions can be used in legacy mode or 64-bit long mode. Compilation of general-purpose programs for execution in 64-bit long mode offers three primary advantages: access to the eight extended, 64-bit general-purpose registers (for a register set consisting of GPR0–GPR15), access to the 64-bit virtual address space, and access to the RIP-relative addressing mode.

For further information about the general-purpose instructions and register resources, see:

- “General-Purpose Programming” in Volume 1.
- “Summary of Registers and Data Types” on page 38.
- “Notation” on page 53.
- “Instruction Prefixes” on page 5.
- Appendix B, “General-Purpose Instructions in 64-Bit Mode.” In particular, see “General Rules for 64-Bit Mode” on page 555.

AAA ASCII Adjust After Addition

Adjusts the value in the AL register to an unpacked BCD value. Use the AAA instruction after using the ADD instruction to add two unpacked BCD numbers.

The instruction is coded without explicit operands:

```
AAA
```

If the value in the lower nibble of AL is greater than 9 or the AF flag is set to 1, the instruction increments the AH register, adds 6 to the AL register, and sets the CF and AF flags to 1. Otherwise, it does not change the AH register and clears the CF and AF flags to 0. In either case, AAA clears bits 7:4 of the AL register, leaving the correct decimal digit in bits 3:0.

This instruction also makes it possible to add ASCII numbers without having to mask off the upper nibble ‘3’.

MXCSR Flags Affected

Using this instruction in 64-bit mode generates an invalid-opcode exception.

Mnemonic	Opcode	Description
AAA	37	Create an unpacked BCD number. (Invalid in 64-bit mode.)

Exceptions

Exception	Real	Virtual 8086	Protected	Cause of Exception
Invalid opcode, #UD			X	This instruction was executed in 64-bit mode.

AAD ASCII Adjust Before Division

Converts two unpacked BCD digits in the AL (least significant) and AH (most significant) registers to a single binary value in the AL register.

The instruction is coded without explicit operands:

```
AAD
```

The instruction performs the following operation on the contents of AL and AH using the formula:

```
AL = ((10d * AH) + (AL))
```

After the conversion, AH is cleared to 00h.

In most modern assemblers, the AAD instruction adjusts from base-10 values. However, by coding the instruction directly in binary, it can adjust from any base specified by the immediate byte value (*ib*) suffixed onto the D5h opcode. For example, code D508h for octal, D50Ah for decimal, and D50Ch for duodecimal (base 12).

Using this instruction in 64-bit mode generates an invalid-opcode exception.

Mnemonic	Opcode	Description
AAD	D5 0A	Adjust two BCD digits in AL and AH. (Invalid in 64-bit mode.)
(None)	D5 *ib*	Adjust two BCD digits to the immediate byte base. (Invalid in 64-bit mode.)

Exceptions

Exception	Real	Virtual 8086	Protected	Cause of Exception
Invalid opcode, #UD			X	This instruction was executed in 64-bit mode.

AAM ASCII Adjust After Multiply

Converts the value in the AL register from binary to two unpacked BCD digits in the AH (most significant) and AL (least significant) registers.

The instruction is coded without explicit operands:

```
AAM
```

The instruction performs the following operation on the contents of AL and AH using the formula:

```
AH = (AL/10d)
AL = (AL mod 10d)
```

In most modern assemblers, the AAM instruction adjusts to base-10 values. However, by coding the instruction directly in binary, it can adjust to any base specified by the immediate byte value (*ib*) suffixed onto the D4h opcode. For example, code D408h for octal, D40Ah for decimal, and D40Ch for duodecimal (base 12).

Using this instruction in 64-bit mode generates an invalid-opcode exception.

Mnemonic	Opcode	Description
AAM	D4 0A	Create a pair of unpacked BCD values in AH and AL. (Invalid in 64-bit mode.)
(None)	D4 *ib*	Create a pair of unpacked values to the immediate byte base. (Invalid in 64-bit mode.)

Exceptions

Exception	Real	Virtual 8086	Protected	Cause of Exception
Divide by zero, #DE	X	X	X	8-bit immediate value was 0.
Invalid opcode, #UD			X	This instruction was executed in 64-bit mode.

AAS ASCII Adjust After Subtraction

Adjusts the value in the AL register to an unpacked BCD value. Use the AAS instruction after using the SUB instruction to subtract two unpacked BCD numbers.

The instruction is coded without explicit operands:

```
AAS
```

If the value in AL is greater than 9 or the AF flag is set to 1, the instruction decrements the value in AH, subtracts 6 from the AL register, and sets the CF and AF flags to 1. Otherwise, it clears the CF and AF flags and the AH register is unchanged. In either case, the instruction clears bits 7:4 of the AL register, leaving the correct decimal digit in bits 3:0.

Using this instruction in 64-bit mode generates an invalid-opcode exception.

Mnemonic	Opcode	Description
AAS	3F	Create an unpacked BCD number from the contents of the AL register. (Invalid in 64-bit mode.)

ADC Add with Carry

Adds the carry flag (CF), the value in a register or memory location (first operand), and an immediate value or the value in a register or memory location (second operand), and stores the result in the first operand location.

The instruction has two operands:

ADC *dest*, *src*

The instruction cannot add two memory operands. The CF flag indicates a pending carry from a previous addition operation. The instruction sign-extends an immediate value to the length of the destination register or memory location.

This instruction evaluates the result for both signed and unsigned data types and sets the OF and CF flags to indicate a carry in a signed or unsigned result, respectively. It sets the SF flag to indicate the sign of a signed result.

Use the ADC instruction after an ADD instruction as part of a multibyte or multiword addition.

The forms of the ADC instruction that write to memory support the LOCK prefix. For details about the LOCK prefix, see “Lock Prefix” on page 11.

Mnemonic	Opcode	Description
ADC AL, *imm8*	14 *ib*	Add *imm8* to AL + CF.

AND Logical AND

Performs a bit-wise logical and operation on the value in a register or memory location (first operand) and an immediate value or the value in a register or memory location (second operand), and stores the result in the first operand location. Both operands cannot be memory locations.

The instruction has two operands:

AND *dest*, *src*

The instruction sets each bit of the result to 1 if the corresponding bit of both operands is set; otherwise, it clears the bit to 0. The following table shows the truth table for the logical and operation:

X	Y	X and Y
0	0	0
0	1	0
1	0	0
1	1	1

The forms of the AND instruction that write to memory support the LOCK prefix. For details about the LOCK prefix, see “Lock Prefix” on page 11.

Mnemonic	Opcode	Description
AND AL, *imm8*	24 *ib*	and the contents of AL with an immediate 8-bit value and store the result in AL.

ANDN Logical And-Not

Performs a bit-wise logical and of the second source operand and the one's complement of the first source operand and stores the result into the destination operand.

This instruction has three operands:

ANDN *dest*, *src1*, *src2*

In 64-bit mode, the operand size is determined by the value of VEX.W. If VEX.W is 1, the operand size is 64-bit; if VEX.W is 0, the operand size is 32-bit. In 32-bit mode, VEX.W is ignored. 16-bit operands are not supported.

The destination operand (*dest*) is always a general purpose register.

The first source operand (*src1*) is a general purpose register and the second source operand (*src2*) is either a general purpose register or a memory operand.

This instruction implements the following operation:

```
not tmp, src1
and dest, tmp, src2
```

The flags are set according to the result of the and pseudo-operation.

The ANDN instruction is a BMI1 instruction. Support for this instruction is indicated by CPUID Fn0000_0007_EBX_x0[BMI1] = 1.

For more information on using the CPUID instruction, see the instruction reference page for the CPUID instruction on page 165. For a description of all feature flags related to instruction subset support, see Appendix D, “Instruction Subsets and CPUID Feature Flags,” on page 587.

Alignment check, #AC			X	An unaligned memory reference was performed while alignment checking was enabled.

BEXTR (register form) Bit Field Extract

Extracts a contiguous field of bits from the first source operand, as specified by the control field setting in the second source operand and puts the extracted field into the least significant bit positions of the destination. The remaining bits in the destination register are cleared to 0.

This instruction has three operands:

BEXTR *dest*, *src*, *cntl*

In 64-bit mode, the operand size is determined by the value of VEX.W. If VEX.W is 1, the operand size is 64-bit; if VEX.W is 0, the operand size is 32-bit. In 32-bit mode, VEX.W is ignored. 16-bit operands are not supported.

The destination (*dest*) is a general purpose register.

The source operand (*src*) is either a general purpose register or a memory operand.

The control (*cntl*) operand is a general purpose register that provides two fields describing the range of bits to extract:

- *lsb_index* (in bits 7:0)—specifies the index of the least significant bit of the field
- *length* (in bits 15:8)—specifies the number of bits in the field.

The position of the extracted field can be expressed as:

[*lsb_ index* + *length* – 1] : [*lsb_index*]

For example, if the *lsb_index* is 7 and *length* is 5, then bits 11:7 of the source will be copied to bits 4:0 of the destination, with the rest of the destination being zero-filled. Zeros are provided for any bit positions in the specified range that lie beyond the most significant bit of the source operand. A length value of zero results in all zeros being written to the destination.

This form of the BEXTR instruction is a BMI1 instruction. Support for this instruction is indicated by CPUID Fn0000_0007_EBX_x0[BMI1] = 1.

For more information on using the CPUID instruction, see the instruction reference page for the CPUID instruction on page 165. For a description of all feature flags related to instruction subset support, see Appendix D, “Instruction Subsets and CPUID Feature Flags,” on page 587.

Exceptions

Exception	Mode			Cause of Exception
	Real	Virtual 8086	Protected	
Invalid opcode, #UD	X	X		BMI instructions are only recognized in protected mode.
			X	BMI instructions are not supported, as indicated by CPUID Fn0000_0007_EBX_x0[BMI] = 0.
			X	VEX.L is 1.
Stack, #SS			X	A memory address exceeded the stack segment limit or was non-canonical.
General protection, #GP			X	A memory address exceeded a data segment limit or was non-canonical.
			X	A null data segment was used to reference memory.
Page fault, #PF			X	A page fault resulted from the execution of the instruction.
Alignment check, #AC			X	An unaligned memory reference was performed while alignment checking was enabled.

BEXTR (immediate form) Bit Field Extract

Extracts a contiguous field of bits from the first source operand, as specified by the control field setting in the second source operand and puts the extracted field into the least significant bit positions of the destination. The remaining bits in the destination register are cleared to 0.

This instruction has three operands:

BEXTR *dest*, *src*, *cntl*

In 64-bit mode, the operand size is determined by the value of XOP.W. If XOP.W is 1, the operand size is 64-bit; if XOP.W is 0, the operand size is 32-bit. In 32-bit mode, XOP.W is ignored. 16-bit operands are not supported.

The destination (*dest*) is a general purpose register.

The source operand (*src*) is either a general purpose register or a memory operand.

The control (*cntl*) operand is a 32-bit immediate value that provides two fields describing the range of bits to extract:

- *lsb_index* (in immediate operand bits 7:0)—specifies the index of the least significant bit of the field
- *length* (in immediate operand bits 15:8)—specifies the number of bits in the field.

The position of the extracted field can be expressed as:

[*lsb_ index* + *length* – 1] : [*lsb_index*]

For example, if the *lsb_index* is 7 and *length* is 5, then bits 11:7 of the source will be copied to bits 4:0 of the destination, with the rest of the destination being zero-filled. Zeros are provided for any bit positions in the specified range that lie beyond the most significant bit of the source operand. A length value of zero results in all zeros being written to the destination.

This form of the BEXTR instruction is a TBM instruction. Support for this instruction is indicated by CPUID Fn8000_0001_ECX[TBM] =1.

For more information on using the CPUID instruction, see the instruction reference page for the CPUID instruction on page 165. For a description of all feature flags related to instruction subset support, see Appendix D, “Instruction Subsets and CPUID Feature Flags,” on page 587.

BLCFILL Fill From Lowest Clear Bit

Finds the least significant zero bit in the source operand, clears all bits below that bit to 0 and writes the result to the destination. If there is no zero bit in the source operand, the destination is written with all zeros.

This instruction has two operands:

BLCFILL *dest*, *src*

In 64-bit mode, the operand size is determined by the value of XOP.W. If XOP.W is 1, the operand size is 64-bit; if XOP.W is 0, the operand size is 32-bit. In 32-bit mode, XOP.W is ignored. 16-bit operands are not supported.

The destination (*dest*) is a general purpose register.

The source operand (*src*) is a general purpose register or a memory operand.

The BLCFILL instruction effectively performs a bit-wise logical and of the source operand and the result of incrementing the source operand by 1 and stores the result to the destination register:

```
add tmp, src, 1
and dest,tmp, src
```

The value of the carry flag of rFLAGS is generated according to the result of the add pseudo-instruction and the remaining arithmetic flags are generated by the and pseudo-instruction.

The BLCFILL instruction is a TBM instruction. Support for this instruction is indicated by CPUID Fn8000_0001_ECX[TBM] = 1.

For more information on using the CPUID instruction, see the instruction reference page for the CPUID instruction on page 165. For a description of all feature flags related to instruction subset support, see Appendix D, “Instruction Subsets and CPUID Feature Flags,” on page 587.

BLCI Isolate Lowest Clear Bit

Finds the least significant zero bit in the source operand, sets all other bits to 1 and writes the result to the destination. If there is no zero bit in the source operand, the destination is written with all ones.

This instruction has two operands:

BLCI *dest*, *src*

In 64-bit mode, the operand size is determined by the value of XOP.W. If XOP.W is 1, the operand size is 64-bit; if XOP.W is 0, the operand size is 32-bit. In 32-bit mode, XOP.W is ignored. 16-bit operands are not supported.

The destination (*dest*) is a general purpose register.

The source operand (*src*) is a general purpose register or a memory operand.

The BLCI instruction effectively performs a bit-wise logical `or` of the source operand and the inverse of the result of incrementing the source operand by 1, and stores the result to the destination register:

```
add tmp,  src, 1
not tmp,  tmp
or  dest, tmp, src
```

The value of the carry flag of rFLAGS is generated according to the result of the `add` pseudo-instruction and the remaining arithmetic flags are generated by the `or` pseudo-instruction.

The BLCI instruction is a TBM instruction. Support for this instruction is indicated by CPUID Fn8000_0001_ECX[TBM] = 1.

For more information on using the CPUID instruction, see the instruction reference page for the CPUID instruction on page 165. For a description of all feature flags related to instruction subset support, see Appendix D, “Instruction Subsets and CPUID Feature Flags,” on page 587.

BLCIC Isolate Lowest Clear Bit and Complement

Finds the least significant zero bit in the source operand, sets that bit to 1, clears all other bits to 0 and writes the result to the destination. If there is no zero bit in the source operand, the destination is written with all zeros.

This instruction has two operands:

BLCIC dest, src

In 64-bit mode, the operand size is determined by the value of XOP.W. If XOP.W is 1, the operand size is 64-bit; if XOP.W is 0, the operand size is 32-bit. In 32-bit mode, XOP.W is ignored. 16-bit operands are not supported.

The destination (*dest*) is a general purpose register.

The source operand (*src*) is a general purpose register or a memory operand.

The BLCIC instruction effectively performs a bit-wise logical and of the negation of the source operand and the result of incrementing the source operand by 1, and stores the result to the destination register:

```
add tmp1, src, 1
not tmp2, src
and dest, tmp1,tmp2
```

The value of the carry flag of rFLAGS is generated according to the result of the add pseudo-instruction and the remaining arithmetic flags are generated by the and pseudo-instruction.

The BLCIC instruction is a TBM instruction. Support for this instruction is indicated by CPUID Fn8000_0001_ECX[TBM] = 1.

For more information on using the CPUID instruction, see the instruction reference page for the CPUID instruction on page 165. For a description of all feature flags related to instruction subset support, see Appendix D, “Instruction Subsets and CPUID Feature Flags,” on page 587.

BLCMSK Mask From Lowest Clear Bit

Finds the least significant zero bit in the source operand, sets that bit to 1, clears all bits above that bit to 0 and writes the result to the destination. If there is no zero bit in the source operand, the destination is written with all ones.

This instruction has two operands:

BLCMSK dest, src

In 64-bit mode, the operand size is determined by the value of XOP.W. If XOP.W is 1, the operand size is 64-bit; if XOP.W is 0, the operand size is 32-bit. In 32-bit mode, XOP.W is ignored. 16-bit operands are not supported.

The destination (*dest*) is a general purpose register.

The source operand (*src*) is a general purpose register or a memory operand.

The BLCMSK instruction effectively performs a bit-wise logical `xor` of the source operand and the result of incrementing the source operand by 1 and stores the result to the destination register:

```
add tmp1, src, 1
xor dest, tmp1,src
```

The value of the carry flag of rFLAGS is generated according to the result of the `add` pseudo-instruction and the remaining arithmetic flags are generated by the `xor` pseudo-instruction.

If the input is all ones, the output is a value with all bits set to 1.

The BLCMSK instruction is a TBM instruction. Support for this instruction is indicated by CPUID Fn8000_0001_ECX[TBM] = 1.

For more information on using the CPUID instruction, see the instruction reference page for the CPUID instruction on page 165. For a description of all feature flags related to instruction subset support, see Appendix D, “Instruction Subsets and CPUID Feature Flags,” on page 587.

BLCS Set Lowest Clear Bit

Finds the least significant zero bit in the source operand, sets that bit to 1 and writes the result to the destination. If there is no zero bit in the source operand, the source is copied to the destination (and CF in rFLAGS is set to 1).

This instruction has two operands:

BLCS dest, src

In 64-bit mode, the operand size is determined by the value of XOP.W. If XOP.W is 1, the operand size is 64-bit; if XOP.W is 0, the operand size is 32-bit. In 32-bit mode, XOP.W is ignored. 16-bit operands are not supported.

The destination (*dest*) is a general purpose register.

The source operand (*src*) is a general purpose register or a memory operand.

The BLCS instruction effectively performs a bit-wise logical `or` of the source operand and the result of incrementing the source operand by 1, and stores the result to the destination register:

```
add tmp,  src, 1
or  dest, tmp, src
```

The value of the carry flag of rFLAGS is generated by the `add` pseudo-instruction and the remaining arithmetic flags are generated by the `or` pseudo-instruction.

The BLCS instruction is a TBM instruction. Support for this instruction is indicated by CPUID Fn8000_0001_ECX[TBM] = 1.

For more information on using the CPUID instruction, see the instruction reference page for the CPUID instruction on page 165. For a description of all feature flags related to instruction subset support, see Appendix D, “Instruction Subsets and CPUID Feature Flags,” on page 587.

BLSFILL Fill From Lowest Set Bit

Finds the least significant one bit in the source operand, sets all bits below that bit to 1 and writes the result to the destination. If there is no one bit in the source operand, the destination is written with all ones.

This instruction has two operands:

BLSFILL dest, src

In 64-bit mode, the operand size is determined by the value of XOP.W. If XOP.W is 1, the operand size is 64-bit; if XOP.W is 0, the operand size is 32-bit. In 32-bit mode, XOP.W is ignored. 16-bit operands are not supported.

The destination (*dest*) is a general purpose register.

The source operand (*src*) is a general purpose register or a memory operand.

The BLSFILL instruction effectively performs a bit-wise logical `or` of the source operand and the result of subtracting 1 from the source operand, and stores the result to the destination register:

```
sub tmp,  src, 1
or  dest, tmp, src
```

The value of the carry flag of rFLAGs is generated by the `sub` pseudo-instruction and the remaining arithmetic flags are generated by the `or` pseudo-instruction.

The BLSFILL instruction is a TBM instruction. Support for this instruction is indicated by CPUID Fn8000_0001_ECX[TBM] = 1.

For more information on using the CPUID instruction, see the instruction reference page for the CPUID instruction on page 165. For a description of all feature flags related to instruction subset support, see Appendix D, “Instruction Subsets and CPUID Feature Flags,” on page 587.

BLSI Isolate Lowest Set Bit

Clears all bits in the source operand except for the least significant bit that is set to 1 and writes the result to the destination. If the source is all zeros, the destination is written with all zeros.

This instruction has two operands:

```
BLSI dest, src
```

In 64-bit mode, the operand size is determined by the value of VEX.W. If VEX.W is 1, the operand size is 64-bit; if VEX.W is 0, the operand size is 32-bit. In 32-bit mode, VEX.W is ignored. 16-bit operands are not supported.

The destination (*dest*) is a general purpose register.

The source operand (*src*) is either a general purpose register or a bit memory operand.

This instruction implements the following operation:

```
neg tmp, src1
and dst, tmp, src1
```

The value of the carry flag is generated by the `neg` pseudo-instruction and the remaining status flags are generated by the `and` pseudo-instruction.

The BLSI instruction is a BMI1 instruction. Support for this instruction is indicated by CPUID Fn0000_0007_EBX_x0[BMI1] = 1.

For more information on using the CPUID instruction, see the instruction reference page for the CPUID instruction on page 165. For a description of all feature flags related to instruction subset support, see Appendix D, “Instruction Subsets and CPUID Feature Flags,” on page 587.

Alignment check, #AC			X	An unaligned memory reference was performed while alignment checking was enabled.

BLSIC Isolate Lowest Set Bit and Complement

Finds the least significant bit that is set to 1 in the source operand, clears that bit to 0, sets all other bits to 1 and writes the result to the destination. If there is no one bit in the source operand, the destination is written with all ones.

This instruction has two operands:

BLSIC dest, src

In 64-bit mode, the operand size is determined by the value of XOP.W. If XOP.W is 1, the operand size is 64-bit; if XOP.W is 0, the operand size is 32-bit. In 32-bit mode, XOP.W is ignored. 16-bit operands are not supported.

The destination (*dest*) is a general purpose register.

The source operand (*src*) is a general purpose register or a memory operand.

The BLSIC instruction effectively performs a bit-wise logical `or` of the inverse of the source operand and the result of subtracting 1 from the source operand, and stores the result to the destination register:

```
sub tmp1, src, 1
not tmp2, src
or  dest, tmp1, tmp2
```

The value of the carry flag of rFLAGS is generated by the `sub` pseudo-instruction and the remaining arithmetic flags are generated by the `or` pseudo-instruction.

The BLSR instruction is a TBM instruction. Support for this instruction is indicated by CPUID Fn8000_0001_ECX[TBM] = 1.

For more information on using the CPUID instruction, see the instruction reference page for the CPUID instruction on page 165. For a description of all feature flags related to instruction subset support, see Appendix D, “Instruction Subsets and CPUID Feature Flags,” on page 587.

Alignment check, #AC			X	An unaligned memory reference was performed while alignment checking was enabled.

BLSMSK Mask From Lowest Set Bit

Forms a mask with bits set to 1 from bit 0 up to and including the least significant bit position that is set to 1 in the source operand and writes the mask to the destination. If the value of the source operand is zero, the destination is written with all ones.

This instruction has two operands:

BLSMSK *dest*, *src*

In 64-bit mode, the operand size is determined by the value of VEX.W. If VEX.W is 1, the operand size is 64-bit; if VEX.W is 0, the operand size is 32-bit. In 32-bit mode, VEX.W is ignored. 16-bit operands are not supported.

The destination (*dest*) is always a general purpose register.

The source operand (*src*) is either a general purpose register or a memory operand and the destination operand (*dest*) is a general purpose register.

This instruction implements the operation:

```
sub tmp, src1, 1
xor dst, tmp, src1
```

The value of the carry flag is generated by the `sub` pseudo-instruction and the remaining status flags are generated by the `xor` pseudo-instruction.

If the input is zero, the output is a value with all bits set to 1. If this is considered a corner case input, software may test the carry flag to detect the zero input value.

The BLSMSK instruction is a BMI1 instruction. Support for this instruction is indicated by CPUID Fn0000_0007_EBX_x0[BMI1] = 1.

For more information on using the CPUID instruction, see the instruction reference page for the CPUID instruction on page 165. For a description of all feature flags related to instruction subset support, see Appendix D, “Instruction Subsets and CPUID Feature Flags,” on page 587.

BLSR Reset Lowest Set Bit

Clears the least-significant bit that is set to 1 in the input operand and writes the modified operand to the destination.

This instruction has two operands:

BLSR *dest*, *src*

In 64-bit mode, the operand size is determined by the value of VEX.W. If VEX.W is 1, the operand size is 64-bit; if VEX.W is 0, the operand size is 32-bit. In 32-bit mode, VEX.W is ignored. 16-bit operands are not supported.

The destination (*dest*) is always a general purpose register.

The source operand (*src*) is either a general purpose register or a memory operand.

This instruction implements the operation:

```
sub tmp, src1, 1
and dst, tmp, src1
```

The value of the carry flag is generated by the `sub` pseudo-instruction and the remaining status flags are generated by the `and` pseudo-instruction.

The BLSR instruction is a BMI1 instruction. Support for this instruction is indicated by CPUID Fn0000_0007_EBX_x0[BMI1] = 1.

For more information on using the CPUID instruction, see the instruction reference page for the CPUID instruction on page 165. For a description of all feature flags related to instruction subset support, see Appendix D, “Instruction Subsets and CPUID Feature Flags,” on page 587.

BOUND Check Array Bound

Checks whether an array index (first operand) is within the bounds of an array (second operand). The array index is a signed integer in the specified register. If the operand-size attribute is 16, the array operand is a memory location containing a pair of signed word-integers; if the operand-size attribute is 32, the array operand is a pair of signed doubleword-integers. The first word or doubleword specifies the lower bound of the array and the second word or doubleword specifies the upper bound.

The array index must be greater than or equal to the lower bound and less than or equal to the upper bound. If the index is not within the specified bounds, the processor generates a BOUND range-exceeded exception (#BR).

The bounds of an array, consisting of two words or doublewords containing the lower and upper limits of the array, usually reside in a data structure just before the array itself, making the limits addressable through a constant offset from the beginning of the array. With the address of the array in a register, this practice reduces the number of bus cycles required to determine the effective address of the array bounds.

Using this instruction in 64-bit mode generates an invalid-opcode exception.

Mnemonic	Opcode	Description
BOUND *reg16*, *mem16&mem16*	62 */r*	Test whether a 16-bit array index is within the bounds specified by the two 16-bit values in mem16&mem16. (Invalid in 64-bit mode.)
BOUND *reg32*, *mem32&mem32*	62 */r*	Test whether a 32-bit array index is within the bounds specified by the two 32-bit values in mem32&mem32. (Invalid in 64-bit mode.)

BSF Bit Scan Forward

Searches the value in a register or a memory location (second operand) for the least-significant set bit. If a set bit is found, the instruction clears the zero flag (ZF) and stores the index of the least-significant set bit in a destination register (first operand). If the second operand contains 0, the instruction sets ZF to 1 and does not change the contents of the destination register. The bit index is an unsigned offset from bit 0 of the searched value.

Mnemonic	Opcode	Description
BSF *reg16*, *reg/mem16*	0F BC /r	Bit scan forward on the contents of *reg/mem16*.
BSF *reg32*, *reg/mem32*	0F BC /r	Bit scan forward on the contents of *reg/mem32*.

BSR Bit Scan Reverse

Searches the value in a register or a memory location (second operand) for the most-significant set bit. If a set bit is found, the instruction clears the zero flag (ZF) and stores the index of the most-significant set bit in a destination register (first operand). If the second operand contains 0, the instruction sets ZF to 1 and does not change the contents of the destination register. The bit index is an unsigned offset from bit 0 of the searched value.

Mnemonic	Opcode	Description
BSR *reg16*, *reg/mem16*	0F BD /r	Bit scan reverse on the contents of *reg/mem16*.
BSR *reg32*, *reg/mem32*	0F BD /r	Bit scan reverse on the contents of *reg/mem32*.

BSWAP Byte Swap

Reverses the byte order of the specified register. This action converts the contents of the register from little endian to big endian or vice versa. In a doubleword, bits 7:0 are exchanged with bits 31:24, and bits 15:8 are exchanged with bits 23:16. In a quadword, bits 7:0 are exchanged with bits 63:56, bits 15:8 with bits 55:48, bits 23:16 with bits 47:40, and bits 31:24 with bits 39:32. A subsequent use of the BSWAP instruction with the same operand restores the original value of the operand.

The result of applying the BSWAP instruction to a 16-bit register is undefined. To swap the bytes of a 16-bit register, use the XCHG instruction and specify the respective byte halves of the 16-bit register as the two operands. For example, to swap the bytes of AX, use `XCHG AL, AH`.

Mnemonic	Opcode	Description
BSWAP *reg32*	0F C8 +*rd*	Reverse the byte order of *reg32*.
BSWAP *reg64*	0F C8 +*rq*	Reverse the byte order of *reg64*.

BT Bit Test

Copies a bit, specified by a bit index in a register or 8-bit immediate value (second operand), from a bit string (first operand), also called the bit base, to the carry flag (CF) of the rFLAGS register.

If the bit base operand is a register, the instruction uses the modulo 16, 32, or 64 (depending on the operand size) of the bit index to select a bit in the register.

If the bit base operand is a memory location, bit 0 of the byte at the specified address is the bit base of the bit string. If the bit index is in a register, the instruction selects a bit position relative to the bit base in the range -2^{63} to $+2^{63} - 1$ if the operand size is 64, -2^{31} to $+2^{31} - 1$, if the operand size is 32, and -2^{15} to $+2^{15} - 1$ if the operand size is 16. If the bit index is in an immediate value, the bit selected is that value modulo 16, 32, or 64, depending on operand size.

When the instruction attempts to copy a bit from memory, it accesses 2, 4, or 8 bytes starting from the specified memory address for 16-bit, 32-bit, or 64-bit operand sizes, respectively, using the following formula:

Effective Address + ($NumBytes_i$ * (BitOffset DIV $NumBits_{i*8}$))

When using this bit addressing mechanism, avoid referencing areas of memory close to address space holes, such as references to memory-mapped I/O registers. Instead, use a MOV instruction to load a register from such an address and use a register form of the BT instruction to manipulate the data.

Mnemonic	Opcode	Description
BT *reg/mem16*, *reg16*	0F A3 /r	Copy the value of the selected bit to the carry flag.
BT *reg/mem32, reg32*	0F A3 /r	Copy the value of the selected bit to the carry flag.
BT *reg/mem64, reg64*	0F A3 /r	Copy the value of the selected bit to the carry flag.
BT *reg/mem16*, *imm8*	0F BA /4 *ib*	Copy the value of the selected bit to the carry flag.
BT *reg/mem32, imm8*	0F BA /4 *ib*	Copy the value of the selected bit to the carry flag.

BTC Bit Test and Complement

Copies a bit, specified by a bit index in a register or 8-bit immediate value (second operand), from a bit string (first operand), also called the bit base, to the carry flag (CF) of the rFLAGS register, and then complements (toggles) the bit in the bit string.

If the bit base operand is a register, the instruction uses the modulo 16, 32, or 64 (depending on the operand size) of the bit index to select a bit in the register.

If the bit base operand is a memory location, bit 0 of the byte at the specified address is the bit base of the bit string. If the bit index is in a register, the instruction selects a bit position relative to the bit base in the range -2^{63} to $+2^{63} - 1$ if the operand size is 64, -2^{31} to $+2^{31} - 1$, if the operand size is 32, and -2^{15} to $+2^{15} - 1$ if the operand size is 16. If the bit index is in an immediate value, the bit selected is that value modulo 16, 32, or 64, depending the operand size.

This instruction is useful for implementing semaphores in concurrent operating systems. Such an application should precede this instruction with the LOCK prefix. For details about the LOCK prefix, see “Lock Prefix” on page 11.

BTS Bit Test and Set

Copies a bit, specified by bit index in a register or 8-bit immediate value (second operand), from a bit string (first operand), also called the bit base, to the carry flag (CF) of the rFLAGS register, and then sets the bit in the bit string to 1.

If the bit base operand is a register, the instruction uses the modulo 16, 32, or 64 (depending on the operand size) of the bit index to select a bit in the register.

If the bit base operand is a memory location, bit 0 of the byte at the specified address is the bit base of the bit string. If the bit index is in a register, the instruction selects a bit position relative to the bit base in the range -2^{63} to $+2^{63} - 1$ if the operand size is 64, -2^{31} to $+2^{31} - 1$, if the operand size is 32, and -2^{15} to $+2^{15} - 1$ if the operand size is 16. If the bit index is in an immediate value, the bit selected is that value modulo 16, 32, or 64, depending on the operand size.

This instruction is useful for implementing semaphores in concurrent operating systems. Such applications should precede this instruction with the LOCK prefix. For details about the LOCK prefix, see “Lock Prefix” on page 11.

Mnemonic	Opcode	Description
BTS *reg/mem16*, *reg16*	0F AB /r	Copy the value of the selected bit to the carry flag, then set the selected bit.
BTS *reg/mem32, reg32*	0F AB /r	Copy the value of the selected bit to the carry flag, then set the selected bit.
BTS *reg/mem64, reg64*	0F AB /r	Copy the value of the selected bit to the carry flag, then set the selected bit.

Page fault, #PF		X	X	A page fault resulted from the execution of the instruction.
Alignment check, #AC		X	X	An unaligned memory reference was performed while alignment checking was enabled.

BZHI Zero High Bits

Copies bits, left to right, from the first source operand starting with the bit position specified by the second source operand (*index*), writes these bits to the destination, and clears all the bits in positions greater than or equal to *index*.

This instruction has three operands:

BZHI *dest*, *src, index*

In 64-bit mode, the operand size (*op_size*) is determined by the value of VEX.W. If VEX.W is 1, the operand size is 64 bits; if VEX.W is 0, the operand size is 32 bits. In 32-bit mode, VEX.W is ignored. 16-bit operands are not supported.

The destination (*dest*) is a general purpose register. The first source operand (*src*) is either a general purpose register or a memory operand. The second source operand is a general purpose register. Bits [7:0] of this register, treated as an unsigned 8-bit integer, specify the index of the most-significant bit of the first source operand to be copied to the corresponding bit of the destination. Bits [*op_size*-1:*index*] of the destination are cleared.

If the value of *index* is greater than or equal to the operand size, *index* is set to (*op_size*-1). In this case, the CF flag is set.

This instruction is a BMI2 instruction. Support for this instruction is indicated by CPUID Fn0000_0007_EBX_x0[BMI2] = 1.

For more information on using the CPUID instruction, see the instruction reference page for the CPUID instruction on page 165. For a description of all feature flags related to instruction subset support, see Appendix D, “Instruction Subsets and CPUID Feature Flags,” on page 587.

			X	A null data segment was used to reference memory.
Page fault, #PF			X	A page fault resulted from the execution of the instruction.
Alignment check, #AC			X	An unaligned memory reference was performed while alignment checking was enabled.

CALL (Near) Near Procedure Call

Pushes the offset of the next instruction onto the stack and branches to the target address, which contains the first instruction of the called procedure. The target operand can specify a register, a memory location, or a label. A procedure accessed by a near CALL is located in the same code segment as the CALL instruction.

If the CALL target is specified by a register or memory location, then a 16-, 32-, or 64-bit rIP is read from the operand, depending on the operand size. A 16- or 32-bit rIP is zero-extended to 64 bits.

If the CALL target is specified by a displacement, the signed displacement is added to the rIP (of the following instruction), and the result is truncated to 16, 32, or 64 bits, depending on the operand size. The signed displacement is 16 or 32 bits, depending on the operand size.

In all cases, the rIP of the instruction after the CALL is pushed on the stack, and the size of the stack push (16, 32, or 64 bits) depends on the operand size of the CALL instruction.

For near calls in 64-bit mode, the operand size defaults to 64 bits. The E8 opcode results in RIP = RIP + 32-bit signed displacement and the FF /2 opcode results in RIP = 64-bit offset from register or memory. No prefix is available to encode a 32-bit operand size in 64-bit mode.

At the end of the called procedure, RET is used to return control to the instruction following the original CALL. When RET is executed, the rIP is popped off the stack, which returns control to the instruction after the CALL.

See CALL (Far) for information on far calls—calls to procedures located outside of the current code segment. For details about control-flow instructions, see “Control Transfers” in Volume 1, and “Control-Transfer Privilege Checks” in Volume 2.

Mnemonic	Opcode	Description
CALL *rel16off*	E8 *iw*	Near call with the target specified by a 16-bit relative displacement.
CALL *rel32off*	E8 *id*	Near call with the target specified by a 32-bit relative displacement.
CALL *reg/mem16*	FF /2	Near call with the target specified by *reg/mem16*.
CALL *reg/mem32*	FF /2	Near call with the target specified by *reg/mem32*. (There is no prefix for encoding this in 64-bit mode.)
CALL *reg/mem64*	FF /2	Near call with the target specified by *reg/mem64*.

For details about control-flow instructions, see “Control Transfers” in Volume 1, and “Control-Transfer Privilege Checks” in Volume 2.

CALL (Far) Far Procedure Call

Pushes procedure linking information onto the stack and branches to the target address, which contains the first instruction of the called procedure. The operand specifies a target selector and offset.

The instruction can specify the target directly, by including the far pointer in the immediate and displacement fields of the instruction, or indirectly, by referencing a far pointer in memory. In 64-bit mode, only indirect far calls are allowed; executing a direct far call (opcode 9A) generates an undefined opcode exception. For both direct and indirect far calls, if the CALL (Far) operand-size is 16 bits, the instruction's operand is a 16-bit offset followed by a 16-bit selector. If the operand-size is 32 or 64 bits, the operand is a 32-bit offset followed by a 16-bit selector.

The target selector used by the instruction can be a code selector in all modes. Additionally, the target selector can reference a call gate in protected mode, or a task gate or TSS selector in legacy protected mode.

- *Target is a code selector*—The CS:rIP of the next instruction is pushed to the stack, using operand-size stack pushes. Then code is executed from the target CS:rIP. In this case, the target offset can only be a 16- or 32-bit value, depending on operand-size, and is zero-extended to 64 bits. No CPL change is allowed.
- *Target is a call gate*—The call gate specifies the actual target code segment and offset. Call gates allow calls to the same or more privileged code. If the target segment is at the same CPL as the current code segment, the CS:rIP of the next instruction is pushed to the stack.

  If the CALL (Far) changes privilege level, then a stack-switch occurs, using an inner-level stack pointer from the TSS. The CS:rIP of the next instruction is pushed to the new stack. If the mode is legacy mode and the param-count field in the call gate is non-zero, then up to 31 operands are copied from the caller's stack to the new stack. Finally, the caller's SS:rSP is pushed to the new stack.

  When calling through a call gate, the stack pushes are 16-, 32-, or 64-bits, depending on the size of the call gate. The size of the target rIP is also 16, 32, or 64 bits, depending on the size of the call gate. If the target rIP is less than 64 bits, it is zero-extended to 64 bits. Long mode only allows 64-bit call gates that must point to 64-bit code segments.
- *Target is a task gate or a TSS*—If the mode is legacy protected mode, then a task switch occurs. See “Hardware Task-Management in Legacy Mode” in volume 2 for details about task switches. Hardware task switches are not supported in long mode.

See CALL (Near) for information on near calls—calls to procedures located inside the current code segment. For details about control-flow instructions, see “Control Transfers” in Volume 1, and “Control-Transfer Privilege Checks” in Volume 2.

Mnemonic	Opcode	Description
CALL FAR *pntr16:16*	9A *cd*	Far call direct, with the target specified by a far pointer contained in the instruction. (Invalid in 64-bit mode.)
CALL FAR *pntr16:32*	9A *cp*	Far call direct, with the target specified by a far pointer contained in the instruction. (Invalid in 64-bit mode.)
CALL FAR *mem16:16*	FF /3	Far call indirect, with the target specified by a far pointer in memory.
CALL FAR *mem16:32*	FF /3	Far call indirect, with the target specified by a far pointer in memory.

CBW
CWDE
CDQE
Convert to Sign-Extended

Copies the sign bit in the AL or eAX register to the upper bits of the rAX register. The effect of this instruction is to convert a signed byte, word, or doubleword in the AL or eAX register into a signed word, doubleword, or quadword in the rAX register. This action helps avoid overflow problems in signed number arithmetic.

The CDQE mnemonic is meaningful only in 64-bit mode.

Mnemonic	Opcode	Description
CBW	98	Sign-extend AL into AX.
CWDE	98	Sign-extend AX into EAX.
CDQE	98	Sign-extend EAX into RAX.

Convert to Sign-Extended

Copies the sign bit in the rAX register to all bits of the rDX register. The effect of this instruction is to convert a signed word, doubleword, or quadword in the rAX register into a signed doubleword, quadword, or double-quadword in the rDX:rAX registers. This action helps avoid overflow problems in signed number arithmetic.

The CQO mnemonic is meaningful only in 64-bit mode.

Mnemonic	Opcode	Description
CWD	99	Sign-extend AX into DX:AX.
CDQ	99	Sign-extend EAX into EDX:EAX.
CQO	99	Sign-extend RAX into RDX:RAX.

CLD Clear Direction Flag

Clears the direction flag (DF) in the rFLAGS register to zero. If the DF flag is 0, each iteration of a string instruction increments the data pointer (index registers rSI or rDI). If the DF flag is 1, the string instruction decrements the pointer. Use the CLD instruction before a string instruction to make the data pointer increment.

Mnemonic	Opcode	Description
CLD	FC	Clear the direction flag (DF) to zero.

CLFLUSH Cache Line Flush

Flushes the cache line specified by the *mem8* linear-address. The instruction checks all levels of the cache hierarchy—internal caches and external caches—and invalidates the cache line in every cache in which it is found. If a cache contains a dirty copy of the cache line (that is, the cache line is in the *modified* or *owned* MOESI state), the line is written back to memory before it is invalidated. The instruction sets the cache-line MOESI state to *invalid*.

The instruction also checks the physical address corresponding to the linear-address operand against the processor's write-combining buffers. If the write-combining buffer holds data intended for that physical address, the instruction writes the entire contents of the buffer to memory. This occurs even though the data is not cached in the cache hierarchy. In a multiprocessor system, the instruction checks the write-combining buffers only on the processor that executed the CLFLUSH instruction.

On processors that do not support the CLFLUSHOPT instruction, (CPUID Fn 0000_0007_EBX_x0[CLFLOPT]=0), the CLFLUSH instruction is weakly ordered with respect to other instructions that operate on memory. Speculative loads initiated by the processor, or specified explicitly using cache-prefetch instructions, can be reordered around a CLFLUSH instruction. Such reordering can invalidate a speculatively prefetched cache line, unintentionally defeating the prefetch operation. The only way to avoid this situation is to use the MFENCE instruction after the CLFLUSH instruction to force strong-ordering of the CLFLUSH instruction with respect to subsequent memory operations. The CLFLUSH instruction may also take effect on a cache line while stores from previous store instructions are still pending in the store buffer. To ensure that such stores are included in the cache line that is flushed, use an MFENCE instruction ahead of the CLFLUSH instruction. Such stores would otherwise cause the line to be re-cached and modified after the CLFLUSH completed. The LFENCE, SFENCE, and serializing instructions are *not* ordered with respect to CLFLUSH.

On processors that support CLFLUSHOPT, (CPUID Fn 0000_0007_EBX_x0[CLFLOPT]=1), CLFLUSH is ordered with respect to locked operations, fence instructions, and CLFLUSHOPT, CLFLUSH and write instructions that touch the same cache line. CLFLUSH is not ordered with CLFLUSHOPT, CLFLUSH and write instructions to other cache lines.

The CLFLUSH instruction behaves like a load instruction with respect to setting the page-table accessed and dirty bits. That is, it sets the page-table accessed bit to 1, but does not set the page-table dirty bit.

The CLFLUSH instruction executes at any privilege level. CLFLUSH performs all the segmentation and paging checks that a 1-byte read would perform, except that it also allows references to execute-only segments.

The CLFLUSH instruction is supported if the feature flag CPUID Fn0000_0001_EDX[CLFSH] is set. The 8-bit field CPUID Fn 0000_0001_EBX[CLFlush] returns the size of the cacheline in quadwords.

For more information on using the CPUID instruction, see the instruction reference page for the CPUID instruction on page 165. For a description of all feature flags related to instruction subset support, see Appendix D, "Instruction Subsets and CPUID Feature Flags," on page 587.

Mnemonic	Opcode	Description
CLFLUSH *mem8*	0F AE /7	flush cache line containing *mem8.*

CLFLUSHOPT Optimized Cache Line Flush

Flushes the cache line specified by the mem8 linear-address. The instruction checks all levels of the cache hierarchy-internal caches and external caches-and invalidates the cache line in every cache in which it is found. If a cache contains a dirty copy of the cache line (that is, the cache line is in the modified or owned MOESI state), the line is written back to memory before it is invalidated. The instruction sets the cache-line MOESI state to invalid.

The instruction also checks the physical address corresponding to the linear-address operand against the processor's write-combining buffers. If the write-combining buffer holds data intended for that physical address, the instruction writes the entire contents of the buffer to memory. This occurs even though the data is not cached in the cache hierarchy. In a multiprocessor system, the instruction checks the write-combining buffers only on the processor that executed the CLFLUSHOPT instruction.

The CLFLUSHOPT instruction is ordered with respect to fence instructions and locked operations. CLFLUSHOPT is also ordered with writes, CLFLUSH, and CLFLUSHOPT instructions that reference the same cache line as the CLFLUSHOPT. CLFLUSHOPT is not ordered with writes, CLFLUSH, and CLFLUSHOPT to other cache lines. To enforce ordering in that situation, a SFENCE instruction or stronger should be used.

Speculative loads initiated by the processor, or specified explicitly using cache-prefetch instructions, can be reordered around a CLFLUSHOPT instruction. Such reordering can invalidate a speculatively prefetched cache line, unintentionally defeating the prefetch operation.

The only way to avoid this situation is to use the MFENCE instruction after the CLFLUSHOPT instruction to force strong ordering of the CLFLUSHOPT instruction with respect to subsequent memory operations.

The CLFLUSHOPT instruction behaves like a load instruction with respect to setting the page-table accessed and dirty bits. That is, it sets the page-table accessed bit to 1, but does not set the page-table dirty bit.

The CLFLUSHOPT instruction executes at any privilege level. CLFLUSHOPT performs all the segmentation and paging checks that a 1-byte read would perform, except that it also allows references to execute-only segments.

The CLFLUSHOPT instruction is supported if the feature flag CPUID Fn0000_0007_EBX_x0[CLFLOPT]is set. The 8-bit field CPUID Fn 0000_0001_EBX[CLFlush] returns the size of the cacheline in quadwords.

Mnemonic	Opcode	Description
CLFLUSHOPT mem8	66 0F AE /7	Flush cache line containing mem8

CLWB Cache Line Write Back and Retain

Flushes the cache line specified by the *mem8* linear address. The instruction checks all levels of the cache hierarchy—internal caches and external caches—and causes the cache line, if dirty, to be written to memory. The cache line may be retained in the cache where found in a non-dirty state.

The CLWB instruction is weakly ordered with respect to other instructions that operate on memory. Speculative loads initiated by the processor, or specified explicitly using cache prefetch instructions, can be reordered around a CLWB instruction. CLWB is ordered naturally with older stores to the same address on the same logical processor. To create strict ordering of CLWB use a store-ordering instruction such as SFENCE.

The CLWB instruction behaves like a load instruction with respect to setting the page table accessed and dirty bits. That is, it sets the page table accessed bit to 1, but does not set the page table dirty bit.

The CLWB instruction executes at any privilege level. CLWB performs all the segmentation and paging checks that a 1-byte read would perform, except that it also allows references to execute only segments.

The CLWB instruction is supported if the feature flag CPUID Fn0000_0007-EBX[24]=1.

The 8-bit field CPUID Fn 0000_0001_EBX[CLFlush] returns the size of the cacheline in quadwords.

Mnemonic	Opcode	Description
CLWB	66 0F AE /6	Cache line write-back.

CLZERO Zero Cache Line

Clears the cache line specified by the logical address in rAX by writing a zero to every byte in the line. The instruction uses an implied non temporal memory type, similar to a streaming store, and uses the write combining protocol to minimize cache pollution.

CLZERO is weakly-ordered with respect to other instructions that operate on memory. Software should use an SFENCE or stronger to enforce memory ordering of CLZERO with respect to other store instructions.

The CLZERO instruction executes at any privilege level. CLZERO performs all the segmentation and paging checks that a store of the specified cache line would perform.

The CLZERO instruction is supported if the feature flag CPUID Fn8000_0008_EBX[CLZERO] is set. The 8-bit field CPUID Fn 0000_0001_EBX[CLFlush] returns the size of the cacheline in quadwords.

CMOV*cc* Conditional Move

Conditionally moves a 16-bit, 32-bit, or 64-bit value in memory or a general-purpose register (second operand) into a register (first operand), depending upon the settings of condition flags in the rFLAGS register. If the condition is not satisfied, the destination register is not modified. For the memory-based forms of CMOVcc, memory-related exceptions may be reported even if the condition is false. In 64-bit mode, CMOVcc with a 32-bit operand size will clear the upper 32 bits of the destination register even if the condition is false.

The mnemonics of CMOVcc instructions denote the condition that must be satisfied. Most assemblers provide instruction mnemonics with A (above) and B (below) tags to supply the semantics for manipulating unsigned integers. Those with G (greater than) and L (less than) tags deal with signed integers. Many opcodes may be represented by synonymous mnemonics. For example, the CMOVL instruction is synonymous with the CMOVNGE instruction and denote the instruction with the opcode 0F 4C.

The feature flag CPUID Fn0000_0001_EDX[CMOV] or CPUID Fn8000_0001_EDX[CMOV] =1 indicates support for CMOV*cc* instructions on a particular processor implementation.

For more information on using the CPUID instruction, see the instruction reference page for the CPUID instruction on page 165. For a description of all feature flags related to instruction subset support, see Appendix D, “Instruction Subsets and CPUID Feature Flags,” on page 587.

CMP Compare

Compares the contents of a register or memory location (first operand) with an immediate value or the contents of a register or memory location (second operand), and sets or clears the status flags in the rFLAGS register to reflect the results. To perform the comparison, the instruction subtracts the second operand from the first operand and sets the status flags in the same manner as the SUB instruction, but does not alter the first operand. If the second operand is an immediate value, the instruction sign-extends the value to the length of the first operand.

Use the CMP instruction to set the condition codes for a subsequent conditional jump (J*cc*), conditional move (CMOV*cc*), or conditional SET*cc* instruction. Appendix F, “Instruction Effects on RFLAGS” shows how instructions affect the rFLAGS status flags.

Mnemonic	Opcode	Description
CMP AL, *imm8*	3C *ib*	Compare an 8-bit immediate value with the contents of the AL register.
CMP AX, *imm16*	3D *iw*	Compare a 16-bit immediate value with the contents of the AX register.
CMP EAX, *imm32*	3D *id*	Compare a 32-bit immediate value with the contents of the EAX register.
CMP RAX, *imm32*	3D *id*	Compare a 32-bit immediate value with the contents of the RAX register.
CMP *reg/mem8*, *imm8*	80 /7 *ib*	Compare an 8-bit immediate value with the contents of an 8-bit register or memory operand.
CMP *reg/mem16*, *imm16*	81 /7 *iw*	Compare a 16-bit immediate value with the contents of a 16-bit register or memory operand.
CMP *reg/mem32*, *imm32*	81 /7 *id*	Compare a 32-bit immediate value with the contents of a 32-bit register or memory operand.
CMP *reg/mem64*, *imm32*	81 /7 *id*	Compare a 32-bit signed immediate value with the contents of a 64-bit register or memory operand.

Compare Strings

Compares the bytes, words, doublewords, or quadwords pointed to by the rSI and rDI registers, sets or clears the status flags of the rFLAGS register to reflect the results, and then increments or decrements the rSI and rDI registers according to the state of the DF flag in the rFLAGS register. To perform the comparison, the instruction subtracts the second operand from the first operand and sets the status flags in the same manner as the SUB instruction, but does not alter the first operand. The two operands must be the same size.

If the DF flag is 0, the instruction increments rSI and rDI; otherwise, it decrements the pointers. It increments or decrements the pointers by 1, 2, 4, or 8, depending on the size of the operands.

The forms of the CMPSx instruction with explicit operands address the first operand at *seg*:[rSI]. The value of *seg* defaults to the DS segment, but may be overridden by a segment prefix. These instructions always address the second operand at ES:[rDI]. ES may not be overridden. The explicit operands serve only to specify the type (size) of the values being compared and the segment used by the first operand.

The no-operands forms of the instruction use the DS:[rSI] and ES:[rDI] registers to point to the values to be compared. The mnemonic determines the size of the operands.

Do not confuse this CMPSD instruction with the same-mnemonic CMPSD (compare scalar double-precision floating-point) instruction in the 128-bit media instruction set. Assemblers can distinguish the instructions by the number and type of operands.

For block comparisons, the CMPS instruction supports the REPE or REPZ prefixes (they are synonyms) and the REPNE or REPNZ prefixes (they are synonyms). For details about the REP prefixes, see “Repeat Prefixes” on page 12. If a conditional jump instruction like JL follows a CMPS*x* instruction, the jump occurs if the value of the *seg*:[rSI] operand is less than the ES:[rDI] operand. This action allows lexicographical comparisons of string or array elements. A CMPS*x* instruction can also operate inside a loop controlled by the LOOP*cc* instruction.

Mnemonic	Opcode	Description
CMPS *mem8*, *mem8*	A6	Compare the byte at DS:rSI with the byte at ES:rDI and then increment or decrement rSI and rDI.
CMPS *mem16*, *mem16*	A7	Compare the word at DS:rSI with the word at ES:rDI and then increment or decrement rSI and rDI.
CMPS *mem32*, *mem32*	A7	Compare the doubleword at DS:rSI with the doubleword at ES:rDI and then increment or decrement rSI and rDI.
CMPS *mem64*, *mem64*	A7	Compare the quadword at DS:rSI with the quadword at ES:rDI and then increment or decrement rSI and rDI.

Mnemonic	Opcode	Description
CMPSB	A6	Compare the byte at DS:rSI with the byte at ES:rDI and then increment or decrement rSI and rDI.
CMPSW	A7	Compare the word at DS:rSI with the word at ES:rDI and then increment or decrement rSI and rDI.
CMPSD	A7	Compare the doubleword at DS:rSI with the doubleword at ES:rDI and then increment or decrement rSI and rDI.
CMPSQ	A7	Compare the quadword at DS:rSI with the quadword at ES:rDI and then increment or decrement rSI and rDI.

CMPXCHG Compare and Exchange

Compares the value in the AL, AX, EAX, or RAX register with the value in a register or a memory location (first operand). If the two values are equal, the instruction copies the value in the second operand to the first operand and sets the ZF flag in the rFLAGS register to 1. Otherwise, it copies the value in the first operand to the AL, AX, EAX, or RAX register and clears the ZF flag to 0.

The OF, SF, AF, PF, and CF flags are set to reflect the results of the compare.

When the first operand is a memory operand, CMPXCHG always does a read-modify-write on the memory operand. If the compared operands were unequal, CMPXCHG writes the same value to the memory operand that was read.

The forms of the CMPXCHG instruction that write to memory support the LOCK prefix. For details about the LOCK prefix, see “Lock Prefix” on page 11.

Mnemonic	Opcode	Description
CMPXCHG *reg/mem8*, *reg8*	0F B0 */r*	Compare AL register with an 8-bit register or memory location. If equal, copy the second operand to the first operand. Otherwise, copy the first operand to AL.
CMPXCHG *reg/mem16*, *reg16*	0F B1 */r*	Compare AX register with a 16-bit register or memory location. If equal, copy the second operand to the first operand. Otherwise, copy the first operand to AX.
CMPXCHG *reg/mem32*, *reg32*	0F B1 */r*	Compare EAX register with a 32-bit register or memory location. If equal, copy the second operand to the first operand. Otherwise, copy the first operand to EAX.
CMPXCHG *reg/mem64*, *reg64*	0F B1 */r*	Compare RAX register with a 64-bit register or memory location. If equal, copy the second operand to the first operand. Otherwise, copy the first operand to RAX.

CMPXCHG8B Compare and Exchange Eight Bytes
CMPXCHG16B Compare and Exchange Sixteen Bytes

Compares the value in the rDX:rAX registers with a 64-bit or 128-bit value in the specified memory location. If the values are equal, the instruction copies the value in the rCX:rBX registers to the memory location and sets the zero flag (ZF) of the rFLAGS register to 1. Otherwise, it copies the value in memory to the rDX:rAX registers and clears ZF to 0.

If the effective operand size is 16-bit or 32-bit, the CMPXCHG8B instruction is used. This instruction uses the EDX:EAX and ECX:EBX register operands and a 64-bit memory operand. If the effective operand size is 64-bit, the CMPXCHG16B instruction is used; this instruction uses RDX:RAX register operands and a 128-bit memory operand.

The CMPXCHG8B and CMPXCHG16B instructions always do a read-modify-write on the memory operand. If the compared operands were unequal, the instructions write the same value to the memory operand that was read.

The CMPXCHG8B and CMPXCHG16B instructions support the LOCK prefix. For details about the LOCK prefix, see “Lock Prefix” on page 11.

Support for the CMPXCHG8B and CMPXCHG16B instructions is implementation dependent. Support for the CMPXCHG8B instruction is indicated by CPUID Fn0000_0001_EDX[CMPXCHG8B] or Fn8000_0001_EDX[CMPXCHG8B] = 1. Support for the CMPXCHG16B instruction is indicated by CPUID Fn0000_0001_ECX[CMPXCHG16B] = 1.

For more information on using the CPUID instruction, see the instruction reference page for the CPUID instruction on page 165. For a description of all feature flags related to instruction subset support, see Appendix D, “Instruction Subsets and CPUID Feature Flags,” on page 587.

The memory operand used by CMPXCHG16B must be 16-byte aligned or else a general-protection exception is generated.

Mnemonic	Opcode	Description
CMPXCHG8B *mem64*	0F C7 /1 *m64*	Compare EDX:EAX register to 64-bit memory location. If equal, set the zero flag (ZF) to 1 and copy the ECX:EBX register to the memory location. Otherwise, copy the memory location to EDX:EAX and clear the zero flag.
CMPXCHG16B *mem128*	0F C7 /1 *m128*	Compare RDX:RAX register to 128-bit memory location. If equal, set the zero flag (ZF) to 1 and copy the RCX:RBX register to the memory location. Otherwise, copy the memory location to RDX:RAX and clear the zero flag.

CPUID Processor Identification

Provides information about the processor and its capabilities through a number of different functions. Software should load the number of the CPUID function to execute into the EAX register before executing the CPUID instruction. The processor returns information in the EAX, EBX, ECX, and EDX registers; the contents and format of these registers depend on the function.

The architecture supports CPUID information about *standard functions* and *extended functions*. The standard functions have numbers in the 0000_*xxxx*h series (for example, standard function 1). To determine the largest standard function number that a processor supports, execute CPUID function 0.

The extended functions have numbers in the 8000_*xxxx*h series (for example, extended function 8000_0001h). To determine the largest extended function number that a processor supports, execute CPUID extended function 8000_0000h. If the value returned in EAX is greater than 8000_0000h, the processor supports extended functions.

Software operating at any privilege level can execute the CPUID instruction to collect this information. In 64-bit mode, this instruction works the same as in legacy mode except that it zero-extends 32-bit register results to 64 bits.

CPUID is a serializing instruction.

Mnemonic	Opcode	Description
CPUID	0F A2	Returns information about the processor and its capabilities. EAX specifies the function number, and the data is returned in EAX, EBX, ECX, EDX.

Testing for the CPUID Instruction

To avoid an invalid-opcode exception (#UD) on those processor implementations that do not support the CPUID instruction, software must first test to determine if the CPUID instruction is supported. Support for the CPUID instruction is indicated by the ability to write the ID bit in the rFLAGS register. Normally, 32-bit software uses the PUSHFD and POPFD instructions in an attempt to write rFLAGS.ID. After reading the updated rFLAGS.ID bit, a comparison determines if the operation changed its value. If the value changed, the processor executing the code supports the CPUID instruction. If the value did not change, rFLAGS.ID is not writable, and the processor does not support the CPUID instruction.

The following code sample shows how to test for the presence of the CPUID instruction using 32-bit code.

```
pushfd                      ; save EFLAGS
pop     eax                 ; store EFLAGS in EAX
mov     ebx, eax            ; save in EBX for later testing
xor     eax, 00200000h      ; toggle bit 21
push    eax                 ; push to stack
popfd                       ; save changed EAX to EFLAGS
```

```
pushfd                  ; push EFLAGS to TOS
pop     eax             ; store EFLAGS in EAX
cmp     eax, ebx        ; see if bit 21 has changed
jz      NO_CPUID        ; if no change, no CPUID
```

Standard Function 0 and Extended Function 8000_0000h

CPUID standard function 0 loads the EAX register with the largest CPUID *standard* function number supported by the processor implementation; similarly, CPUID extended function 8000_0000h loads the EAX register with the largest *extended* function number supported.

Standard function 0 and extended function 8000_0000h both load a 12-character string into the EBX, EDX, and ECX registers identifying the processor vendor. For AMD processors, the string is `AuthenticAMD`. This string informs software that it should follow the AMD CPUID definition for subsequent CPUID function calls. If the function returns another vendor's string, software must use that vendor's CPUID definition when interpreting the results of subsequent CPUID function calls. Table 3-2 shows the contents of the EBX, EDX, and ECX registers after executing function 0 on an AMD processor.

Table 3-2. Processor Vendor Return Values

Register	Return Value	ASCII Characters
EBX	6874_7541h	"h t u A"
EDX	6974_6E65h	"i t n e"
ECX	444D_4163h	"D M A c"

For a description of all feature flags related to instruction subset support, see Appendix D, "Instruction Subsets and CPUID Feature Flags," on page 587. For a description of all defined feature numbers and return values, see Appendix E, "Obtaining Processor Information Via the CPUID Instruction," on page 593.

CRC32 CRC32 Cyclical Redundancy Check

Performs one step of a 32-bit cyclic redundancy check.

The first source, which is also the destination, is a doubleword value in either a 32-bit or 64-bit GPR depending on the presence of a REX prefix and the value of the REX.W bit. The second source is a GPR or memory location of width 8, 16, or 32 bits. A vector of width 40, 48, or 64 bits is derived from the two operands as follows:

1. The low-order 32 bits of the first operand is bit-wise inverted and shifted left by the width of the second operand.
2. The second operand is bit-wise inverted and shifted left by 32 bits
3. The results of steps 1 and 2 are `xor`ed.

This vector is interpreted as a polynomial of degree 40, 48, or 64 over the field of two elements (i.e., bit *i* is interpreted as the coefficient of X^i). This polynomial is divided by the polynomial of degree 32 that is similarly represented by the vector 11EDC6F41h. (The division admits an efficient iterative implementation based on the `xor` operation.) The remainder is encoded as a 32-bit vector, which is bit-wise inverted and written to the destination. In the case of a 64-bit destination, the upper 32 bits are cleared.

In an application of the CRC algorithm, a data block is partitioned into byte, word, or doubleword segments and CRC32 is executed iteratively, once for each segment.

CRC32 is a SSE4.2 instruction. Support for SSE4.2 instructions is indicated by CPUID Fn0000_0001_ECX[SSE42] = 1.

For more information on using the CPUID instruction, see the instruction reference page for the CPUID instruction on page 165. For a description of all feature flags related to instruction subset support, see Appendix D, “Instruction Subsets and CPUID Feature Flags,” on page 587.

Instruction Encoding

Mnemonic	Encoding	Notes
CRC32 *reg32*, *reg/mem8*	F2 0F 38 F0 /r	Perform CRC32 operation on 8-bit values

Alignment check, #AC		X	X	An unaligned memory reference was performed while alignment checking was enabled.

DAA Decimal Adjust after Addition

Adjusts the value in the AL register into a packed BCD result and sets the CF and AF flags in the rFLAGS register to indicate a decimal carry out of either nibble of AL.

Use this instruction to adjust the result of a byte ADD instruction that performed the binary addition of one 2-digit packed BCD values to another.

The instruction performs the adjustment by adding 06h to AL if the lower nibble is greater than 9 or if AF = 1. Then 60h is added to AL if the original AL was greater than 99h or if CF = 1.

If the lower nibble of AL was adjusted, the AF flag is set to 1. Otherwise AF is not modified. If the upper nibble of AL was adjusted, the CF flag is set to 1. Otherwise, CF is not modified. SF, ZF, and PF are set according to the final value of AL.

Using this instruction in 64-bit mode generates an invalid-opcode (#UD) exception.

Mnemonic	Opcode	Description
DAA	27	Decimal adjust AL. (Invalid in 64-bit mode.)

rFLAGS Affected

Exceptions

Exception	Real	Virtual 8086	Protected	Cause of Exception
Invalid opcode, #UD			X	This instruction was executed in 64-bit mode.

DAS Decimal Adjust after Subtraction

Adjusts the value in the AL register into a packed BCD result and sets the CF and AF flags in the rFLAGS register to indicate a decimal borrow.

Use this instruction to adjust the result of a byte SUB instruction that performed a binary subtraction of one 2-digit, packed BCD value from another.

This instruction performs the adjustment by subtracting 06h from AL if the lower nibble is greater than 9 or if AF = 1. Then 60h is subtracted from AL if the original AL was greater than 99h or if CF = 1.

If the adjustment changes the lower nibble of AL, the AF flag is set to 1; otherwise AF is not modified. If the adjustment results in a borrow for either nibble of AL, the CF flag is set to 1; otherwise CF is not modified. The SF, ZF, and PF flags are set according to the final value of AL.

Using this instruction in 64-bit mode generates an invalid-opcode (#UD) exception.

Mnemonic	Opcode	Description
DAS	2F	Decimal adjusts AL after subtraction. (Invalid in 64-bit mode.)

DEC Decrement by 1

Subtracts 1 from the specified register or memory location. The CF flag is not affected.

The one-byte forms of this instruction (opcodes 48 through 4F) are used as REX prefixes in 64-bit mode. See “REX Prefix” on page 14.

The forms of the DEC instruction that write to memory support the LOCK prefix. For details about the LOCK prefix, see “Lock Prefix” on page 11.

To perform a decrement operation that updates the CF flag, use a SUB instruction with an immediate operand of 1.

Mnemonic	Opcode	Description
DEC *reg/mem8*	FE /1	Decrement the contents of an 8-bit register or memory location by 1.
DEC *reg/mem16*	FF /1	Decrement the contents of a 16-bit register or memory location by 1.
DEC *reg/mem32*	FF /1	Decrement the contents of a 32-bit register or memory location by 1.
DEC *reg/mem64*	FF /1	Decrement the contents of a 64-bit register or memory location by 1.
DEC *reg16*	48 +*rw*	Decrement the contents of a 16-bit register by 1. (See “REX Prefix” on page 14.)
DEC *reg32*	48 +*rd*	Decrement the contents of a 32-bit register by 1. (See “REX Prefix” on page 14.)

Stack, #SS	X	X	X	A memory address exceeded the stack segment limit or was non-canonical.
General protection, #GP	X	X	X	A memory address exceeded the data segment limit or was non-canonical.
			X	The destination operand was in a non-writable segment.
			X	A null data segment was used to reference memory.
Page fault, #PF		X	X	A page fault resulted from the execution of the instruction.
Alignment check, #AC		X	X	An unaligned memory reference was performed while alignment checking was enabled.

DIV Unsigned Divide

Divides the unsigned value in a register by the unsigned value in the specified register or memory location. The register to be divided depends on the size of the divisor.

When dividing a word, the dividend is in the AX register. The instruction stores the quotient in the AL register and the remainder in the AH register.

When dividing a doubleword, quadword, or double quadword, the most-significant word of the dividend is in the rDX register and the least-significant word is in the rAX register. After the division, the instruction stores the quotient in the rAX register and the remainder in the rDX register.

The following table summarizes the action of this instruction:

Division Size	Dividend	Divisor	Quotient	Remainder	Maximum Quotient
Word/byte	AX	reg/mem8	AL	AH	255
Doubleword/word	DX:AX	reg/mem16	AX	DX	65,535
Quadword/doubleword	EDX:EAX	reg/mem32	EAX	EDX	$2^{32} - 1$
Double quadword/ quadword	RDX:RAX	reg/mem64	RAX	RDX	$2^{64} - 1$

The instruction truncates non-integral results towards 0 and the remainder is always less than the divisor. An overflow generates a #DE (divide error) exception, rather than setting the CF flag.

Division by zero generates a divide-by-zero exception.

Mnemonic	Opcode	Description
DIV *reg/mem8*	F6 /6	Perform unsigned division of AX by the contents of an 8-bit register or memory location and store the quotient in AL and the remainder in AH.
DIV *reg/mem16*	F7 /6	Perform unsigned division of DX:AX by the contents of a 16-bit register or memory operand store the quotient in AX and the remainder in DX.
DIV *reg/mem32*	F7 /6	Perform unsigned division of EDX:EAX by the contents of a 32-bit register or memory location and store the quotient in EAX and the remainder in EDX.
DIV *reg/mem64*	F7 /6	Perform unsigned division of RDX:RAX by the contents of a 64-bit register or memory location and store the quotient in RAX and the remainder in RDX.

ENTER Create Procedure Stack Frame

Creates a stack frame for a procedure.

The first operand specifies the size of the stack frame allocated by the instruction.

The second operand specifies the nesting level (0 to 31—the value is automatically masked to 5 bits). For nesting levels of 1 or greater, the processor copies earlier stack frame pointers before adjusting the stack pointer. This action provides a called procedure with access points to other nested stack frames.

The 32-bit `enter N, 0` (a nesting level of 0) instruction is equivalent to the following 32-bit instruction sequence:

```
push  ebp         ; save current EBP
mov   ebp, esp    ; set stack frame pointer value
sub   esp, N      ; allocate space for local variables
```

The ENTER and LEAVE instructions provide support for block structured languages. The LEAVE instruction releases the stack frame on returning from a procedure.

In 64-bit mode, the operand size of ENTER defaults to 64 bits, and there is no prefix available for encoding a 32-bit operand size.

Mnemonic	Opcode	Description
ENTER *imm16*, 0	C8 *iw* 00	Create a procedure stack frame.
ENTER *imm16*, 1	C8 *iw* 01	Create a nested stack frame for a procedure.

Alignment check, #AC		X	X	An unaligned memory reference was performed while alignment checking was enabled.

IDIV Signed Divide

Divides the signed value in a register by the signed value in the specified register or memory location. The register to be divided depends on the size of the divisor.

When dividing a word, the dividend is in the AX register. The instruction stores the quotient in the AL register and the remainder in the AH register.

When dividing a doubleword, quadword, or double quadword, the most-significant word of the dividend is in the rDX register and the least-significant word is in the rAX register. After the division, the instruction stores the quotient in the rAX register and the remainder in the rDX register.

The following table summarizes the action of this instruction:

Division Size	Dividend	Divisor	Quotient	Remainder	Quotient Range
Word/byte	AX	reg/mem8	AL	AH	–128 to +127
Doubleword/word	DX:AX	reg/mem16	AX	DX	–32,768 to +32,767
Quadword/doubleword	EDX:EAX	reg/mem32	EAX	EDX	-2^{31} to $2^{31}-1$
Double quadword/ quadword	RDX:RAX	reg/mem64	RAX	RDX	-2^{63} to $2^{63}-1$

The instruction truncates non-integral results towards 0. The sign of the remainder is always the same as the sign of the dividend, and the absolute value of the remainder is less than the absolute value of the divisor. An overflow generates a #DE (divide error) exception, rather than setting the OF flag.

To avoid overflow problems, precede this instruction with a CBW, CWD, CDQ, or CQO instruction to sign-extend the dividend.

Mnemonic	Opcode	Description
IDIV *reg/mem8*	F6 /7	Perform signed division of AX by the contents of an 8-bit register or memory location and store the quotient in AL and the remainder in AH.
IDIV *reg/mem16*	F7 /7	Perform signed division of DX:AX by the contents of a 16-bit register or memory location and store the quotient in AX and the remainder in DX.
IDIV *reg/mem32*	F7 /7	Perform signed division of EDX:EAX by the contents of a 32-bit register or memory location and store the quotient in EAX and the remainder in EDX.
IDIV *reg/mem64*	F7 /7	Perform signed division of RDX:RAX by the contents of a 64-bit register or memory location and store the quotient in RAX and the remainder in RDX.

Page fault, #PF		X	X	A page fault resulted from the execution of the instruction.
Alignment check, #AC		X	X	An unaligned memory reference was performed while alignment checking was enabled.

IMUL Signed Multiply

Multiplies two signed operands. The number of operands determines the form of the instruction.

If a single operand is specified, the instruction multiplies the value in the specified general-purpose register or memory location by the value in the AL, AX, EAX, or RAX register (depending on the operand size) and stores the product in AX, DX:AX, EDX:EAX, or RDX:RAX, respectively.

If two operands are specified, the instruction multiplies the value in a general-purpose register (first operand) by an immediate value or the value in a general-purpose register or memory location (second operand) and stores the product in the first operand location.

If three operands are specified, the instruction multiplies the value in a general-purpose register or memory location (second operand), by an immediate value (third operand) and stores the product in a register (first operand).

The IMUL instruction sign-extends an immediate operand to the length of the other register/memory operand.

The CF and OF flags are set if, due to integer overflow, the double-width multiplication result cannot be represented in the half-width destination register. Otherwise the CF and OF flags are cleared.

Mnemonic	Opcode	Description
IMUL *reg/mem8*	F6 /5	Multiply the contents of AL by the contents of an 8-bit memory or register operand and put the signed result in AX.
IMUL *reg/mem16*	F7 /5	Multiply the contents of AX by the contents of a 16-bit memory or register operand and put the signed result in DX:AX.

IN Input from Port

Transfers a byte, word, or doubleword from an I/O port to the AL, AX, or EAX register. The port address is specified either by an 8-bit immediate value (00h to FFh) encoded in the instruction or a 16-bit value contained in the DX register (0000h to FFFFh). The processor's I/O address space is distinct from system memory addressing.

For two opcodes (E4h and ECh), the data size of the port is fixed at 8 bits. For the other opcodes (E5h and EDh), the effective operand-size determines the port size. If the effective operand size is 64 bits, IN reads only 32 bits from the I/O port.

If the CPL is higher than IOPL, or the mode is virtual mode, IN checks the I/O permission bitmap in the TSS before allowing access to the I/O port. (See Volume 2 for details on the TSS I/O permission bitmap.)

Mnemonic	Opcode	Description
IN AL, *imm8*	E4 *ib*	Input a byte from the port at the address specified by *imm8* and put it into the AL register.
IN AX, *imm8*	E5 *ib*	Input a word from the port at the address specified by *imm8* and put it into the AX register.
IN EAX, *imm8*	E5 *ib*	Input a doubleword from the port at the address specified by *imm8* and put it into the EAX register.
IN AL, DX	EC	Input a byte from the port at the address specified by the DX register and put it into the AL register.
IN AX, DX	ED	Input a word from the port at the address specified by the DX register and put it into the AX register.
IN EAX, DX	ED	Input a doubleword from the port at the address specified by the DX register and put it into the EAX register.

Exceptions

Exception	Real	Virtual 8086	Protected	Cause of Exception
General protection, #GP		X		One or more I/O permission bits were set in the TSS for the accessed port.
			X	The CPL was greater than the IOPL and one or more I/O permission bits were set in the TSS for the accessed port.
Page fault, #PF		X	X	A page fault resulted from the execution of the instruction.

INC Increment by 1

Adds 1 to the specified register or memory location. The CF flag is not affected, even if the operand is incremented to 0000.

The one-byte forms of this instruction (opcodes 40 through 47) are used as REX prefixes in 64-bit mode. See “REX Prefix” on page 14.

The forms of the INC instruction that write to memory support the LOCK prefix. For details about the LOCK prefix, see “Lock Prefix” on page 11.

To perform an increment operation that updates the CF flag, use an ADD instruction with an immediate operand of 1.

Mnemonic	Opcode	Description
INC *reg/mem8*	FE /0	Increment the contents of an 8-bit register or memory location by 1.
INC *reg/mem16*	FF /0	Increment the contents of a 16-bit register or memory location by 1.
INC *reg/mem32*	FF /0	Increment the contents of a 32-bit register or memory location by 1.
INC *reg/mem64*	FF /0	Increment the contents of a 64-bit register or memory location by 1.
INC *reg16*	40 +*rw*	Increment the contents of a 16-bit register by 1. (These opcodes are used as REX prefixes in 64-bit mode. See “REX Prefix” on page 14.)
INC *reg32*	40 +*rd*	Increment the contents of a 32-bit register by 1. (These opcodes are used as REX prefixes in 64-bit mode. See “REX Prefix” on page 14.)

INS
INSB
INSW
INSD

Input String

Transfers data from the I/O port specified in the DX register to an input buffer specified in the rDI register and increments or decrements the rDI register according to the setting of the DF flag in the rFLAGS register.

If the DF flag is 0, the instruction increments rDI by 1, 2, or 4, depending on the number of bytes read. If the DF flag is 1, it decrements the pointer by 1, 2, or 4.

In 16-bit and 32-bit mode, the INS instruction always uses ES as the data segment. The ES segment cannot be overridden with a segment override prefix. In 64-bit mode, INS always uses the unsegmented memory space.

The INS instructions use the explicit memory operand (first operand) to determine the size of the I/O port, but always use ES:[rDI] for the location of the input buffer. The explicit register operand (second operand) specifies the I/O port address and must always be DX.

The INSB, INSW, and INSD instructions copy byte, word, and doubleword data, respectively, from the I/O port (0000h to FFFFh) specified in the DX register to the input buffer specified in the ES:rDI registers.

If the operand size is 64-bits, the instruction behaves as if the operand size were 32-bits.

If the CPL is higher than the IOPL or the mode is virtual mode, INS*x* checks the I/O permission bitmap in the TSS before allowing access to the I/O port. (See volume 2 for details on the TSS I/O permission bitmap.)

The INSx instructions support the REP prefix for block input of rCX bytes, words, or doublewords. For details about the REP prefix, see “Repeat Prefixes” on page 12.

Mnemonic	Opcode	Description
INS *mem8*, DX	6C	Input a byte from the port specified by DX, put it into the memory location specified in ES:rDI, and then increment or decrement rDI.
INS *mem16*, DX	6D	Input a word from the port specified by DX register, put it into the memory location specified in ES:rDI, and then increment or decrement rDI.
INS *mem32*, DX	6D	Input a doubleword from the port specified by DX, put it into the memory location specified in ES:rDI, and then increment or decrement rDI.
INSB	6C	Input a byte from the port specified by DX, put it into the memory location specified in ES:rDI, and then increment or decrement rDI.

Mnemonic	Opcode	Description
INSW	6D	Input a word from the port specified by DX, put it into the memory location specified in ES:rDI, and then increment or decrement rDI.
INSD	6D	Input a doubleword from the port specified by DX, put it into the memory location specified in ES:rDI, and then increment or decrement rDI.

INT Interrupt to Vector

Transfers execution to the interrupt handler specified by an 8-bit unsigned immediate value. This value is an interrupt vector number (00h to FFh), which the processor uses as an index into the interrupt-descriptor table (IDT).

For detailed descriptions of the steps performed by INT*n* instructions, see the following:

- *Legacy-Mode Interrupts:* "Virtual-8086 Mode Interrupt Control Transfers" in Volume 2.
- *Long-Mode Interrupts:* "Long-Mode Interrupt Control Transfers" in Volume 2.

See also the descriptions of the INT3 instruction on page 381 and the INTO instruction on page 195.

Mnemonic	Opcode	Description
INT *imm8*	CD *ib*	Call interrupt service routine specified by interrupt vector *imm8*.

rFLAGS Affected

If a task switch occurs, all flags are modified. Otherwise settings are as follows:

ID	VIP	VIF	AC	VM	RF	NT	IOPL	OF	DF	IF	TF	SF	ZF	AF	PF	CF
		M	M	M	0	M				M	0					
21	20	19	18	17	16	14	13:12	11	10	9	8	7	6	4	2	0

Note: *Bits 31:22, 15, 5, 3, and 1 are reserved. A flag set to 1 or cleared to 0 is M (modified). Unaffected flags are blank. Undefined flags are U.*

Exceptions

Exception	Real	Virtual 8086	Protected	Cause of Exception
Invalid TSS, #TS (selector)		X	X	As part of a stack switch, the target stack segment selector or rSP in the TSS was beyond the TSS limit.
		X	X	As part of a stack switch, the target stack segment selector in the TSS was a null selector.
		X	X	As part of a stack switch, the target stack segment selector's TI bit was set, but the LDT selector was a null selector.
		X	X	As part of a stack switch, the target stack segment selector in the TSS was beyond the limit of the GDT or LDT descriptor table.
		X	X	As part of a stack switch, the target stack segment selector in the TSS contained a RPL that was not equal to its DPL.
		X	X	As part of a stack switch, the target stack segment selector in the TSS contained a DPL that was not equal to the CPL of the code segment selector.
		X	X	As part of a stack switch, the target stack segment selector in the TSS was not a writable segment.
Segment not present, #NP (selector)		X	X	The accessed code segment, interrupt gate, trap gate, task gate, or TSS was not present.
Stack, #SS	X	X	X	A memory address exceeded the stack segment limit or was non-canonical, and no stack switch occurred.
Stack, #SS (selector)		X	X	After a stack switch, a memory address exceeded the stack segment limit or was non-canonical.
		X	X	As part of a stack switch, the SS register was loaded with a non-null segment selector and the segment was marked not present.

Exception	Real	Virtual 8086	Protected	Cause of Exception
General protection, #GP	X	X	X	A memory address exceeded a data segment limit or was non-canonical.
	X	X	X	The target offset exceeded the code segment limit or was non-canonical.
		X		The IOPL was less than 3 and CR4.VME was 0.
		X		IOPL was less than 3, CR4.VME was 1, and the corresponding bit in the VME interrupt redirection bitmap was 1.
General protection, #GP (selector)	X	X	X	The interrupt vector was beyond the limit of IDT.
		X	X	The descriptor in the IDT was not an interrupt, trap, or task gate in legacy mode or not a 64-bit interrupt or trap gate in long mode.
		X	X	The DPL of the interrupt, trap, or task gate descriptor was less than the CPL.
		X	X	The segment selector specified by the interrupt or trap gate had its TI bit set, but the LDT selector was a null selector.
		X	X	The segment descriptor specified by the interrupt or trap gate exceeded the descriptor table limit or was a null selector.
		X	X	The segment descriptor specified by the interrupt or trap gate was not a code segment in legacy mode, or not a 64-bit code segment in long mode.
			X	The DPL of the segment specified by the interrupt or trap gate was greater than the CPL.
		X		The DPL of the segment specified by the interrupt or trap gate pointed was not 0 or it was a conforming segment.
Page fault, #PF		X	X	A page fault resulted from the execution of the instruction.
Alignment check, #AC		X	X	An unaligned memory reference was performed while alignment checking was enabled.

INTO Interrupt to Overflow Vector

Checks the overflow flag (OF) in the rFLAGS register and calls the overflow exception (#OF) handler if the OF flag is set to 1. This instruction has no effect if the OF flag is cleared to 0. The INTO instruction detects overflow in signed number addition. See *AMD64 Architecture Programmer's Manual Volume 1: Application Programming* for more information on the OF flag.

Using this instruction in 64-bit mode generates an invalid-opcode exception.

For detailed descriptions of the steps performed by INT instructions, see the following:

- *Legacy-Mode Interrupts:* "Legacy Protected-Mode Interrupt Control Transfers" in Volume 2.
- *Long-Mode Interrupts:* "Long-Mode Interrupt Control Transfers" in Volume 2.

Mnemonic	Opcode	Description
INTO	CE	Call overflow exception if the overflow flag is set. (Invalid in 64-bit mode.)

Action

```
IF (64BIT_MODE)
   EXCEPTION[#UD]
IF (RFLAGS.OF == 1)     // #OF is a trap, and pushes the rIP of the instruction
   EXCEPTION [#OF]     // following INTO.
EXIT
```

Exceptions

Exception	Real	Virtual 8086	Protected	Cause of Exception
Overflow, #OF	X	X	X	The INTO instruction was executed with 0F set to 1.
Invalid opcode, #UD			X	Instruction was executed in 64-bit mode.

Jcc Jump on Condition

Checks the status flags in the rFLAGS register and, if the flags meet the condition specified by the condition code in the mnemonic (*cc*), jumps to the target instruction located at the specified relative offset. Otherwise, execution continues with the instruction following the J*cc* instruction.

Unlike the unconditional jump (JMP), conditional jump instructions have only two forms—*short* and *near conditional jumps*. Different opcodes correspond to different forms of one instruction. For example, the JO instruction (jump if overflow) has opcode 0Fh 80h for its near form and 70h for its short form, but the mnemonic is the same for both forms. The only difference is that the near form has a 16- or 32-bit relative displacement, while the short form always has an 8-bit relative displacement.

Mnemonics are provided to deal with the programming semantics of both signed and unsigned numbers. Instructions tagged A (above) and B (below) are intended for use in unsigned integer code; those tagged G (greater) and L (less) are intended for use in signed integer code.

If the jump is taken, the signed displacement is added to the rIP (of the following instruction) and the result is truncated to 16, 32, or 64 bits, depending on operand size.

In 64-bit mode, the operand size defaults to 64 bits. The processor sign-extends the 8-bit or 32-bit displacement value to 64 bits before adding it to the RIP.

These instructions cannot perform far jumps (to other code segments). To create a far-conditional-jump code sequence corresponding to a high-level language statement like:

```
IF A == B THEN GOTO FarLabel
```

where FarLabel is located in another code segment, use the opposite condition in a conditional short jump before an unconditional far jump. Such a code sequence might look like:

```
      cmp   A,B               ; compare operands
      jne   NextInstr         ; continue program if not equal
      jmp   far FarLabel      ; far jump if operands are equal

   NextInstr:                 ; continue program
```

For details about control-flow instructions, see “Control Transfers” in Volume 1, and “Control-Transfer Privilege Checks” in Volume 2.

rFLAGS Affected

None

Exceptions

Exception	Real	Virtual 8086	Protected	Cause of Exception
General protection, #GP	X	X	X	The target offset exceeded the code segment limit or was non-canonical.

JCXZ
JECXZ
JRCXZ
Jump if rCX Zero

Checks the contents of the count register (rCX) and, if 0, jumps to the target instruction located at the specified 8-bit relative offset. Otherwise, execution continues with the instruction following the J*r*CXZ instruction.

The size of the count register (CX, ECX, or RCX) depends on the address-size attribute of the JrCXZ instruction. Therefore, JRCXZ can only be executed in 64-bit mode and JCXZ cannot be executed in 64-bit mode.

If the jump is taken, the signed displacement is added to the rIP (of the following instruction) and the result is truncated to 16, 32, or 64 bits, depending on operand size.

In 64-bit mode, the operand size defaults to 64 bits. The processor sign-extends the 8-bit displacement value to 64 bits before adding it to the RIP.

For details about control-flow instructions, see “Control Transfers” in Volume 1, and “Control-Transfer Privilege Checks” in Volume 2.

Mnemonic	Opcode	Description
JCXZ *rel8off*	E3 *cb*	Jump short if the 16-bit count register (CX) is zero.
JECXZ *rel8off*	E3 *cb*	Jump short if the 32-bit count register (ECX) is zero.
JRCXZ *rel8off*	E3 *cb*	Jump short if the 64-bit count register (RCX) is zero.

General protection, #GP	X	X	X	The target offset exceeded the code segment limit or was non-canonical

JMP (Near) Near Jump

Unconditionally transfers control to a new address without saving the current rIP value. This form of the instruction jumps to an address in the current code segment and is called a *near jump*. The target operand can specify a register, a memory location, or a label.

If the JMP target is specified in a register or memory location, then a 16-, 32-, or 64-bit rIP is read from the operand, depending on operand size. This rIP is zero-extended to 64 bits.

If the JMP target is specified by a displacement in the instruction, the signed displacement is added to the rIP (of the following instruction), and the result is truncated to 16, 32, or 64 bits depending on operand size. The signed displacement can be 8 bits, 16 bits, or 32 bits, depending on the opcode and the operand size.

For near jumps in 64-bit mode, the operand size defaults to 64 bits. The E9 opcode results in RIP = RIP + 32-bit signed displacement, and the FF /4 opcode results in RIP = 64-bit offset from register or memory. No prefix is available to encode a 32-bit operand size in 64-bit mode.

See JMP (Far) for information on far jumps—jumps to procedures located outside of the current code segment. For details about control-flow instructions, see “Control Transfers” in Volume 1, and “Control-Transfer Privilege Checks” in Volume 2.

Mnemonic	Opcode	Description
JMP *rel8off*	EB *cb*	Short jump with the target specified by an 8-bit signed displacement.
JMP *rel16off*	E9 *cw*	Near jump with the target specified by a 16-bit signed displacement.

Alignment check, #AC		X	X	An unaligned memory reference was performed while alignment checking was enabled.

JMP (Far) Far Jump

Unconditionally transfers control to a new address without saving the current CS:rIP values. This form of the instruction jumps to an address outside the current code segment and is called a *far jump*. The operand specifies a target selector and offset.

The target operand can be specified by the instruction directly, by containing the far pointer in the jmp far opcode itself, or indirectly, by referencing a far pointer in memory. In 64-bit mode, only indirect far jumps are allowed, executing a direct far jmp (opcode EA) will generate an undefined opcode exception. For both direct and indirect far jumps, if the JMP (Far) operand-size is 16 bits, the instruction's operand is a 16-bit selector followed by a 16-bit offset. If the operand-size is 32 or 64 bits, the operand is a 16-bit selector followed by a 32-bit offset.

In all modes, the target selector used by the instruction can be a code selector. Additionally, the target selector can also be a call gate in protected mode, or a task gate or TSS selector in legacy protected mode.

- *Target is a code segment*—Control is transferred to the target CS:rIP. In this case, the target offset can only be a 16 or 32 bit value, depending on operand-size, and is zero-extended to 64 bits; 64-bit offsets are only available via call gates. No CPL change is allowed.
- *Target is a call gate*—The call gate specifies the actual target code segment and offset, and control is transferred to the target CS:rIP. When jumping through a call gate, the size of the target rIP is 16, 32, or 64 bits, depending on the size of the call gate. If the target rIP is less than 64 bits, it's zero-extended to 64 bits. In long mode, only 64-bit call gates are allowed, and they must point to 64-bit code segments. No CPL change is allowed.
- *Target is a task gate or a TSS*—If the mode is legacy protected mode, then a task switch occurs. See “Hardware Task-Management in Legacy Mode” in volume 2 for details about task switches. Hardware task switches are not supported in long mode.

See JMP (Near) for information on near jumps—jumps to procedures located inside the current code segment. For details about control-flow instructions, see “Control Transfers” in Volume 1, and “Control-Transfer Privilege Checks” in Volume 2.

Mnemonic	Opcode	Description
JMP FAR *pntr16:16*	EA *cd*	Far jump direct, with the target specified by a far pointer contained in the instruction. (Invalid in 64-bit mode.)

LAHF Load Status Flags into AH Register

Loads the lower 8 bits of the rFLAGS register, including sign flag (SF), zero flag (ZF), auxiliary carry flag (AF), parity flag (PF), and carry flag (CF), into the AH register.

The instruction sets the reserved bits 1, 3, and 5 of the rFLAGS register to 1, 0, and 0, respectively, in the AH register.

The LAHF instruction is available in 64-bit mode if CPUID Fn8000_0001_ECX[LahfSahf] = 1. It is always available in the other operating modes (including compatibility mode)

For more information on using the CPUID instruction, see the instruction reference page for the CPUID instruction on page 165. For a description of all feature flags related to instruction subset support, see Appendix D, “Instruction Subsets and CPUID Feature Flags,” on page 587.

Mnemonic	Opcode	Description
LAHF	9F	Load the SF, ZF, AF, PF, and CF flags into the AH register.

Load Far Pointer

Loads a far pointer from a memory location (second operand) into a segment register (mnemonic) and general-purpose register (first operand). The instruction stores the 16-bit segment selector of the pointer into the segment register and the 16-bit or 32-bit offset portion into the general-purpose register. The operand-size attribute determines whether the pointer loaded is 32 or 48 bits in length. A 64-bit operand is not supported.

These instructions load associated segment-descriptor information into the hidden portion of the specified segment register.

Mnemonic	Opcode	Description
LDS *reg16, mem16:16*	C5 */r*	Load DS:reg16 with a far pointer from memory. [Redefined as VEX (2-byte prefix) in 64-bit mode.]
LDS *reg32, mem16:32*	C5 */r*	Load DS:reg32 with a far pointer from memory. [Redefined as VEX (2-byte prefix) in 64-bit mode.]
LES *reg16, mem16:16*	C4 */r*	Load ES:reg16 with a far pointer from memory. [Redefined as VEX (3-byte prefix) in 64-bit mode.]
LES *reg32, mem16:32*	C4 */r*	Load ES:reg32 with a far pointer from memory. [Redefined as VEX (3-byte prefix) in 64-bit mode.]
LFS *reg16, mem16:16*	0F B4 */r*	Load FS:reg16 with a 32-bit far pointer from memory.
LFS *reg32, mem16:32*	0F B4 */r*	Load FS:reg32 with a 48-bit far pointer from memory.
LGS *reg16, mem16:16*	0F B5 */r*	Load GS:reg16 with a 32-bit far pointer from memory.
LGS *reg32, mem16:32*	0F B5 */r*	Load GS:reg32 with a 48-bit far pointer from memory.
LSS *reg16, mem16:16*	0F B2 */r*	Load SS:*reg16* with a 32-bit far pointer from memory.
LSS *reg32, mem16:32*	0F B2 */r*	Load SS:*reg32* with a 48-bit far pointer from memory.

LEA Load Effective Address

Computes the effective address of a memory location (second operand) and stores it in a general-purpose register (first operand).

The address size of the memory location and the size of the register determine the specific action taken by the instruction, as follows:

- If the address size and the register size are the same, the instruction stores the effective address as computed.
- If the address size is longer than the register size, the instruction truncates the effective address to the size of the register.
- If the address size is shorter than the register size, the instruction zero-extends the effective address to the size of the register.

If the second operand is a register, an undefined-opcode exception occurs.

The LEA instruction is related to the MOV instruction, which copies data from a memory location to a register, but LEA takes the address of the source operand, whereas MOV takes the contents of the memory location specified by the source operand. In the simplest cases, LEA can be replaced with MOV. For example:

```
lea eax, [ebx]
```

has the same effect as:

```
mov eax, ebx
```

However, LEA allows software to use any valid ModRM and SIB addressing mode for the source operand. For example:

```
lea eax, [ebx+edi]
```

loads the sum of the EBX and EDI registers into the EAX register. This could not be accomplished by a single MOV instruction.

The LEA instruction has a limited capability to perform multiplication of operands in general-purpose registers using scaled-index addressing. For example:

```
lea eax, [ebx+ebx*8]
```

loads the value of the EBX register, multiplied by 9, into the EAX register. Possible values of multipliers are 2, 4, 8, 3, 5, and 9.

The LEA instruction is widely used in string-processing and array-processing to initialize an index register (rSI or rDI) before performing string instructions such as MOVSx. It is also used to initialize the rBX register before performing the XLAT instruction in programs that perform character translations. In data structures, the LEA instruction can calculate addresses of operands stored in memory, and in particular, addresses of array or string elements.

Mnemonic	Opcode	Description
LEA *reg16*, *mem*	8D */r*	Store effective address in a 16-bit register.
LEA *reg32, mem*	8D */r*	Store effective address in a 32-bit register.
LEA *reg64, mem*	8D */r*	Store effective address in a 64-bit register.

LEAVE Delete Procedure Stack Frame

Releases a stack frame created by a previous ENTER instruction. To release the frame, it copies the frame pointer (in the rBP register) to the stack pointer register (rSP), and then pops the old frame pointer from the stack into the rBP register, thus restoring the stack frame of the calling procedure.

The 32-bit LEAVE instruction is equivalent to the following 32-bit operation:

```
MOV ESP,EBP
POP EBP
```

To return program control to the calling procedure, execute a RET instruction after the LEAVE instruction.

In 64-bit mode, the LEAVE operand size defaults to 64 bits, and there is no prefix available for encoding a 32-bit operand size.

Mnemonic	Opcode	Description
LEAVE	C9	Set the stack pointer register SP to the value in the BP register and pop BP.
LEAVE	C9	Set the stack pointer register ESP to the value in the EBP register and pop EBP. (No prefix for encoding this in 64-bit mode.)
LEAVE	C9	Set the stack pointer register RSP to the value in the RBP register and pop RBP.

LFENCE Load Fence

Acts as a barrier to force strong memory ordering (serialization) between load instructions preceding the LFENCE and load instructions that follow the LFENCE. Loads from differing memory types may be performed out of order, in particular between WC/WC+ and other memory types. The LFENCE instruction assures that the system completes all previous loads before executing subsequent loads.

The LFENCE instruction is weakly-ordered with respect to store instructions, data and instruction prefetches, and the SFENCE instruction. Speculative loads initiated by the processor, or specified explicitly using cache-prefetch instructions, can be reordered around an LFENCE.

In addition to load instructions, the LFENCE instruction is strongly ordered with respect to other LFENCE instructions, as well as MFENCE and other serializing instructions. Further details on the use of MFENCE to order accesses among differing memory types may be found in *AMD64 Architecture Programmer's Manual Volume 2: System Programming*, section 7.4 "Memory Types" on page 172.

LFENCE is an SSE2 instruction. Support for SSE2 instructions is indicated by CPUID Fn0000_0001_EDX[SSE2] = 1.

In some systems, LFENCE may be configured to be dispatch serializing. In systems where CPUID Fn8000_0021_EAX[LFenceAlwaysSerializing](bit 2) = 1, LFENCE is always dispatch serializing.

For more information on using the CPUID instruction, see the instruction reference page for the CPUID instruction on page 165. For a description of all feature flags related to instruction subset support, see Appendix D, "Instruction Subsets and CPUID Feature Flags," on page 587.

LLWPCB Load Lightweight Profiling Control Block Address

Parses the Lightweight Profiling Control Block at the address contained in the specified register. If the LWPCB is valid, writes the address into the LWP_CBADDR MSR and enables Lightweight Profiling.

See Volume 2, Chapter 13, for an overview of the lightweight profiling facility.

The LWPCB must be in memory that is readable and writable in user mode. For better performance, it should be aligned on a 64-byte boundary in memory and placed so that it does not cross a page boundary, though neither of these suggestions is required.

The LWPCB address in the register is truncated to 32 bits if the operand size is 32.

Action

1. If LWP is not available or if the machine is not in protected mode, LLWPCB immediately causes a #UD exception.
2. If LWP is already enabled, the processor flushes the LWP state to memory in the old LWPCB. See description of the SLWPCB instruction on page 340 for details on saving the active LWP state.

   If the flush causes a #PF exception, LWP remains enabled with the old LWPCB still active. Note that the flush is done before LWP attempts to access the new LWPCB.
3. If the specified LWPCB address is 0, LWP is disabled and the execution of LLWPCB is complete.
4. The LWPCB address is non-zero. LLWPCB validates it as follows:
   - If any part of the LWPCB or the ring buffer is beyond the data segment limit, LLWPCB causes a #GP exception.
   - If the ring buffer size is below the implementation’s minimum ring buffer size, LLWPCB causes a #GP exception.
   - While doing these checks, LWP reads and writes the LWPCB, which may cause a #PF exception.

   If any of these exceptions occurs, LLWPCB aborts and LWP is left disabled. Usually, the operating system will handle a #PF exception by making the memory available and returning to retry the LLWPCB instruction. The #GP exceptions indicate application programming errors.
5. LWP converts the LWPCB address and the ring buffer address to linear address form by adding the DS base address and stores the addresses internally.
6. LWP examines the LWPCB.Flags field to determine which events should be enabled and whether threshold interrupts should be taken. It clears the bits for any features that are not available and stores the result back to LWPCB.Flags to inform the application of the actual LWP state.
7. For each event being enabled, LWP examines the EventInterval*n* value and, if necessary, sets it to an implementation-defined minimum. (The minimum event interval for LWPVAL is zero.) It loads its internal counter for the event from the value in EventCounter*n*. A zero or negative value

in EventCounter*n* means that the next event of that type will cause an event record to be stored. To count every j^{th} event, a program should set EventInterval*n* to *j-1* and EventCounter*n* to some starting value (where *j-1* is a good initial count). If the counter value is larger than the interval, the first event record will be stored after a larger number of events than subsequent records.

8. LWP is started. The execution of LLWPCB is complete.

Notes

If none of the bits in the LWPCB.Flags specifies an available event, LLWPCB still enables LWP to allow the use of the LWPINS instruction. However, no other event records will be stored.

A program can temporarily disable LWP by executing SLWPCB to obtain the current LWPCB address, saving that value, and then executing LLWPCB with a register containing 0. It can later re-enable LWP by executing LLWPCB with a register containing the saved address.

When LWP is enabled, it is typically an error to execute LLWPCB with the address of the active LWPCB. When the hardware flushes the existing LWP state into the LWPCB, it may overwrite fields that the application may have set to new LWP parameter values. The flushed values will then be loaded as LWP is restarted. To reuse an LWPCB, an application should stop LWP by passing a zero to LLWPCB, then prepare the LWPCB with new parameters and execute LLWPCB again to restart LWP.

Internally, LWP keeps the linear address of the LWPCB and the ring buffer. If the application changes the value of DS, LWP will continue to collect samples even if the new DS value would no longer allow access the LWPCB or the ring buffer. However, a #GP fault will occur if the application uses XRSTOR to restore LWP state saved by XSAVE. Programs should avoid using XSAVE/XRSTOR on LWP state if DS has changed. This only applies when the CPL != 0; kernel mode operation of XRSTOR is unaffected by changes to DS. See instruction listing for XSAVE in Volume 4 for details.

Operating system and hypervisor code that runs when CPL ≠ 3 should use XSAVE and XRSTOR to control LWP rather than using LLWPCB. Use WRMSR to write 0 to the LWP_CBADDR MSR to immediately stop LWP without saving its current state.

It is possible to execute LLWPCB when the CPL != 3 or when SMM is active, but the system software must ensure that the LWPCB and the entire ring buffer are properly mapped into writable memory in order to avoid a #PF or #GP fault. Furthermore, if LWP is enabled when a kernel executes LLWPCB, both the old and new control blocks and ring buffers must be accessible. Using LLWPCB in these situations is not recommended.

LLWPCB is an LWP instruction. Support for LWP instructions is indicated by CPUID Fn8000_0001_ECX[LWP] = 1.

For more information on using the CPUID instruction, see the instruction reference page for the CPUID instruction on page 165. For a description of all feature flags related to instruction subset support, see Appendix D, “Instruction Subsets and CPUID Feature Flags,” on page 587.

Instruction Encoding

Mnemonic	Encoding			
	XOP	RXB.map_select	W.vvvv.L.pp	Opcode
LLWPCB *reg32*	8F	$\overline{\text{RXB}}$.09	0.1111.0.00	12 /0
LLWPCB *reg64*	8F	$\overline{\text{RXB}}$.09	1.1111.0.00	12 /0

ModRM.reg augments the opcode and is assigned the value 0. ModRM.r/m (augmented by XOP.R) specifies the register containing the effective address of the LWPCB. ModRM.mod is 11b.

LODS
LODSB
LODSW
LODSD
LODSQ

Load String

Copies the byte, word, doubleword, or quadword in the memory location pointed to by the DS:rSI registers to the AL, AX, EAX, or RAX register, depending on the size of the operand, and then increments or decrements the rSI register according to the state of the DF flag in the rFLAGS register.

If the DF flag is 0, the instruction increments rSI; otherwise, it decrements rSI. It increments or decrements rSI by 1, 2, 4, or 8, depending on the number of bytes being loaded.

The forms of the LODS instruction with an explicit operand address the operand at *seg*:[rSI]. The value of *seg* defaults to the DS segment, but may be overridden by a segment prefix. The explicit operand serves only to specify the type (size) of the value being copied and the specific registers used.

The no-operands forms of the instruction always use the DS:[rSI] registers to point to the value to be copied (they do not allow a segment prefix). The mnemonic determines the size of the operand and the specific registers used.

The LODS*x* instructions support the REP prefixes. For details about the REP prefixes, see “Repeat Prefixes” on page 12. More often, software uses the LODS*x* instruction inside a loop controlled by a LOOP*cc* instruction as a more efficient replacement for instructions like:

```
mov eax, dword ptr ds:[esi]
add esi, 4
```

The LODSQ instruction can only be used in 64-bit mode.

Mnemonic	Opcode	Description
LODS *mem8*	AC	Load byte at DS:rSI into AL and then increment or decrement rSI.
LODS *mem16*	AD	Load word at DS:rSI into AX and then increment or decrement rSI.
LODS *mem32*	AD	Load doubleword at DS:rSI into EAX and then increment or decrement rSI.
LODS *mem64*	AD	Load quadword at DS:rSI into RAX and then increment or decrement rSI.
LODSB	AC	Load byte at DS:rSI into AL and then increment or decrement rSI.
LODSW	AD	Load the word at DS:rSI into AX and then increment or decrement rSI.

Mnemonic	Opcode	Description
LODSD	AD	Load doubleword at DS:rSI into EAX and then increment or decrement rSI.
LODSQ	AD	Load quadword at DS:rSI into RAX and then increment or decrement rSI.

LOOP
LOOPE
LOOPNE
LOOPNZ
LOOPZ

Loop

Decrements the count register (rCX) by 1, then, if rCX is not 0 and the ZF flag meets the condition specified by the mnemonic, it jumps to the target instruction specified by the signed 8-bit relative offset. Otherwise, it continues with the next instruction after the LOOP*cc* instruction.

The size of the count register used (CX, ECX, or RCX) depends on the address-size attribute of the LOOP*cc* instruction.

The LOOP instruction ignores the state of the ZF flag.

The LOOPE and LOOPZ instructions jump if rCX is not 0 and the ZF flag is set to 1. In other words, the instruction exits the loop (falls through to the next instruction) if rCX becomes 0 or ZF = 0.

The LOOPNE and LOOPNZ instructions jump if rCX is not 0 and ZF flag is cleared to 0. In other words, the instruction exits the loop if rCX becomes 0 or ZF = 1.

The LOOP*cc* instruction does not change the state of the ZF flag. Typically, the loop contains a compare instruction to set or clear the ZF flag.

If the jump is taken, the signed displacement is added to the rIP (of the following instruction) and the result is truncated to 16, 32, or 64 bits, depending on operand size.

In 64-bit mode, the operand size defaults to 64 bits without the need for a REX prefix, and the processor sign-extends the 8-bit offset before adding it to the RIP.

Mnemonic	Opcode	Description
LOOP *rel8off*	E2 *cb*	Decrement rCX, then jump short if rCX is not 0.
LOOPE *rel8off*	E1 *cb*	Decrement rCX, then jump short if rCX is not 0 and ZF is 1.

LWPINS Lightweight Profiling Insert Record

Inserts programmed event record into the LWP event ring buffer in memory and advances the ring buffer pointer.

Refer to the description of the programmed event record in Volume 2, Chapter 13. The record has an EventId of 255. The value in the register specified by vvvv (first operand) is stored in the Data2 field at bytes 23–16 (zero extended if the operand size is 32). The value in a register or memory location (second operand) is stored in the Data1 field at bytes 7–4. The immediate value (third operand) is truncated to 16 bits and stored in the Flags field at bytes 3–2.

If the ring buffer is not full, or if LWP is running in Continuous Mode, the head pointer is advanced and the CF flag is cleared. If the ring buffer threshold is exceeded and threshold interrupts are enabled, an interrupt is signaled. If LWP is in Continuous Mode and the new head pointer equals the tail pointer, the MissedEvents counter is incremented to indicate that the buffer wrapped.

If the ring buffer is full and LWP is running in Synchronized Mode, the event record overwrites the last record in the buffer, the MissedEvents counter in the LWPCB is incremented, the head pointer is not advanced, and the CF flag is set.

LWPINS generates an invalid opcode exception (#UD) if the machine is not in protected mode or if LWP is not available.

LWPINS simply clears CF if LWP is not enabled. This allows LWPINS instructions to be harmlessly ignored if profiling is turned off.

It is possible to execute LWPINS when the CPL $\neq 3$ or when SMM is active, but the system software must ensure that the memory operand (if present), the LWPCB, and the entire ring buffer are properly mapped into writable memory in order to avoid a #PF or #GP fault. Using LWPINS in these situations is not recommended.

LWPINS can be used by a program to mark significant events in the ring buffer as they occur. For instance, a program might capture information on changes in the process' address space such as library loads and unloads, or changes in the execution environment such as a change in the state of a user-mode thread of control.

Note that when the LWPINS instruction finishes writing a event record in the event ring buffer, it counts as an instruction retired. If the Instructions Retired event is active, this might cause that counter to become negative and immediately store another event record with the same instruction address (but different EventId values).

LWPINS is an LWP instruction. Support for LWP instructions is indicated by CPUID Fn8000_0001_ECX[LWP] = 1.

For more information on using the CPUID instruction, see the instruction reference page for the CPUID instruction on page 165. For a description of all feature flags related to instruction subset support, see Appendix D, "Instruction Subsets and CPUID Feature Flags," on page 587.

Instruction Encoding

Mnemonic	Encoding			
	XOP	RXB.map_select	W.vvvv.L.pp	Opcode
LWPINS *reg32.vvvv, reg/mem32, imm32*	8F	$\overline{\text{RXB}}$.0A	0.$\overline{\text{src1}}$.0.00	12 /0 /imm32
LWPINS *reg64.vvvv, reg/mem32, imm32*	8F	$\overline{\text{RXB}}$.0A	1.$\overline{\text{src1}}$.0.00	12 /0 /imm32

ModRM.reg augments the opcode and is assigned the value 0. The {mod, r/m} field of the ModRM byte (augmented by XOP.R) encodes the second operand. A 4-byte immediate field follows ModRM.

Exceptions

Exception	Real	Virtual 8086	Protected	Cause of Exception
Invalid opcode, #UD	X	X	X	LWP instructions are not supported, as indicated by CPUID Fn8000_0001_ECX[LWP] = 0.
	X	X		The system is not in protected mode.
			X	LWP is not available.
Page fault, #PF			X	A page fault resulted from reading or writing the LWPCB.
			X	A page fault resulted from writing the event to the ring buffer.
			X	A page fault resulted from reading a modrm operand from memory.
General protection, #GP			X	A modrm operand in memory exceeded the segment limit.

LWPVAL Lightweight Profiling Insert Value

Decrements the event counter associated with the programmed value sample event (see “Programmed Value Sample” in Volume 2, Chapter 13). If the resulting counter value is negative, inserts an event record into the LWP event ring buffer in memory and advances the ring buffer pointer.

Refer to the description of the programmed value sample record in Volume 2, Chapter 13. The event record has an EventId of 1. The value in the register specified by vvvv (first operand) is stored in the Data2 field at bytes 23–16 (zero extended if the operand size is 32). The value in a register or memory location (second operand) is stored in the Data1 field at bytes 7–4. The immediate value (third operand) is truncated to 16 bits and stored in the Flags field at bytes 3–2.

If the programmed value sample record is not written to the event ring buffer, the memory location of the second operand (assuming it is memory-based) is not accessed.

If the ring buffer is not full or if LWP is running in continuous mode, the head pointer is advanced and the event counter is reset to the interval for the event (subject to randomization). If the ring buffer threshold is exceeded and threshold interrupts are enabled, an interrupt is signaled. If LWP is in Continuous Mode and the new head pointer equals the tail pointer, the MissedEvents counter is incremented to indicate that the buffer wrapped.

If the ring buffer is full and LWP is running in Synchronized Mode, the event record overwrites the last record in the buffer, the MissedEvents counter in the LWPCB is incremented, and the head pointer is not advanced.

LWPVAL generates an invalid opcode exception (#UD) if the machine is not in protected mode or if LWP is not available.

LWPVAL does nothing if LWP is not enabled or if the Programmed Value Sample event is not enabled in LWPCB.Flags. This allows LWPVAL instructions to be harmlessly ignored if profiling is turned off.

It is possible to execute LWPVAL when the CPL != 3 or when SMM is active, but the system software must ensure that the memory operand (if present), the LWPCB, and the entire ring buffer are properly mapped into writable memory in order to avoid a #PF or #GP fault. Using LWPVAL in these situations is not recommended.

LWPVAL can be used by a program to perform value profiling. This is the technique of sampling the value of some program variable at a predetermined frequency. For example, a managed runtime might use LWPVAL to sample the value of the divisor for a frequently executed divide instruction in order to determine whether to generate specialized code for a common division. It might sample the target location of an indirect branch or call to see if one destination is more frequent than others. Since LWPVAL does not modify any registers or condition codes, it can be inserted harmlessly between any instructions.

Note

When LWPVAL completes (whether or not it stored an event record in the event ring buffer), it counts as an instruction retired. If the Instructions Retired event is active, this might cause that counter to become negative and immediately store an event record. If LWPVAL also stored an event record, the buffer will contain two records with the same instruction address (but different EventId values).

LWPVAL is an LWP instruction. Support for LWP instructions is indicated by CPUID Fn8000_0001_ECX[LWP] = 1.

For more information on using the CPUID instruction, see the instruction reference page for the CPUID instruction on page 165. For a description of all feature flags related to instruction subset support, see Appendix D, “Instruction Subsets and CPUID Feature Flags,” on page 587.

Instruction Encoding

Mnemonic	Encoding			
	XOP	RXB.map_select	W.vvvv.L.pp	Opcode
LWPVAL *reg32.vvvv, reg/mem32, imm32*	8F	$\overline{\text{RXB}}$.0A	0.$\overline{\text{src1}}$.0.00	12 /1 /imm32
LWPVAL *reg64.vvvv, reg/mem32, imm32*	8F	$\overline{\text{RXB}}$.0A	1.$\overline{\text{src1}}$.0.00	12 /1 /imm32

ModRM.reg augments the opcode and is assigned the value 001b. The {mod, r/m} field of the ModRM byte (augmented by XOP.R) encodes the second operand. A four-byte immediate field follows ModRM.

LZCNT Count Leading Zeros

Counts the number of leading zero bits in the 16-, 32-, or 64-bit general purpose register or memory source operand. Counting starts downward from the most significant bit and stops when the highest bit having a value of 1 is encountered or when the least significant bit is encountered. The count is written to the destination register.

This instruction has two operands:

LZCNT dest, src

If the input operand is zero, CF is set to 1 and the size (in bits) of the input operand is written to the destination register. Otherwise, CF is cleared.

If the most significant bit is a one, the ZF flag is set to 1, zero is written to the destination register. Otherwise, ZF is cleared.

LZCNT is an Advanced Bit Manipulation (ABM) instruction. Support for the LZCNT instruction is indicated by CPUID Fn8000_0001_ECX[ABM] = 1. If the LZCNT instruction is not available, the encoding is interpreted as the BSR instruction. Software MUST check the CPUID bit once per program or library initialization before using the LZCNT instruction, or inconsistent behavior may result.

For more information on using the CPUID instruction, see the instruction reference page for the CPUID instruction on page 165. For a description of all feature flags related to instruction subset support, see Appendix D, “Instruction Subsets and CPUID Feature Flags,” on page 587.

MCOMMIT Commit Stores to Memory

MCOMMIT provides a fencing and error detection capability for stores to system memory components that have delayed error reporting. Execution of MCOMMIT ensures that any preceding stores in the thread to such memory components have completed (target locations written, unless inhibited by an error condition) and that any errors encountered by those stores have been signaled to associated error logging resources. If any such errors are present, MCOMMIT will clear rFLAGS.CF to zero, otherwise it will set rFLAGS.CF to one.

These errors are specific to the design of the platform and are reported only via MCOMMIT and in associated error logging registers on the platform; they are not visible to the Machine Check Architecture. Execution of MCOMMIT does not change any state in the error logging resources. Any error indications will need to be cleared by privileged software before MCOMMIT can return an error-free indication. Details on the error logging mechanisms may be found in the Processor Programming Reference manual for any product that supports this technology and the MCOMMIT instruction.

The MCOMMIT instruction is supported if the feature flag CPUID Fn8000_0008_EBX[MCOMMIT] =1 (bit 8). The MCOMMIT instruction must be explicitly enabled by the OS by setting EFER.MCOMMIT=1 (EFER bit 17), otherwise attempted execution of MCOMMIT will result in a #UD exception.

MCOMMIT uses the same ordering rules as the SFENCE instruction. It may be executed at any privilege level.

MFENCE Memory Fence

Acts as a barrier to force strong memory ordering (serialization) between load and store instructions preceding the MFENCE, and load and store instructions that follow the MFENCE. The processor may perform loads out of program order with respect to non-conflicting stores for certain memory types. The MFENCE instruction ensures that the system completes all previous memory accesses before executing subsequent accesses.

The MFENCE instruction is weakly-ordered with respect to data and instruction prefetches. Speculative loads initiated by the processor, or specified explicitly using cache-prefetch instructions, can be reordered around an MFENCE.

In addition to load and store instructions, the MFENCE instruction is strongly ordered with respect to other MFENCE instructions, LFENCE instructions, SFENCE instructions, serializing instructions, and CLFLUSH instructions. Further details on the use of MFENCE to order accesses among differing memory types may be found in *AMD64 Architecture Programmer's Manual Volume 2: System Programming*, see 7.4 "Memory Types" on page 172.

The MFENCE instruction is a serializing instruction.

MFENCE is an SSE2 instruction. Support for SSE2 instructions is indicated by CPUID Fn0000_0001_EDX[SSE2] = 1.

For more information on using the CPUID instruction, see the instruction reference page for the CPUID instruction on page 165. For a description of all feature flags related to instruction subset support, see Appendix D, "Instruction Subsets and CPUID Feature Flags," on page 587.

Invalid opcode, #UD	X	X	X	SSE2 instructions are not supported, as indicated by CPUID Fn0000_0001_EDX[SSE2] = 0.

MONITORX Setup Monitor Address

Establishes a linear address range of memory for hardware to monitor and puts the processor in the monitor event pending state. When in the monitor event pending state, the monitoring hardware detects stores to the specified linear address range and causes the processor to exit the monitor event pending state. The MWAIT and MWAITX instructions use the state of the monitor hardware.

The address range should be a write-back memory type. Executing MONITORX on an address range for a non-write-back memory type is not guaranteed to cause the processor to enter the monitor event pending state. The size of the linear address range that is established by the MONITORX instruction can be determined by CPUID function 0000_0005h.

The rAX register provides the effective address. The DS segment is the default segment used to create the linear address. Segment overrides may be used with the MONITORX instruction.

The ECX register specifies optional extensions for the MONITORX instruction. There are currently no extensions defined and setting any bits in ECX will result in a #GP exception. The ECX register operand is implicitly 32-bits.

The EDX register specifies optional hints for the MONITORX instruction. There are currently no hints defined and EDX is ignored by the processor. The EDX register operand is implicitly 32-bits.

The MONITORX instruction can be executed at any privilege level and MSR `C001_0015h[MonMwaitUserEn]` has no effect on MONITORX.

MONITORX performs the same segmentation and paging checks as a 1-byte read.

Support for the MONITORX instruction is indicated by CPUID Fn8000_0001_ECX[MONITORX] (bit 29) = 1.

Software must check the CPUID bit once per program or library initialization before using the MONITORX instruction, or inconsistent behavior may result.

The following pseudo-code shows typical usage of a MONITORX/MWAITX pair:

```
EAX = Linear_Address_to_Monitor;
ECX = 0; // Extensions
EDX = 0; // Hints
while (!matching_store_done){
      MONITORX EAX, ECX, EDX
IF (!matching_store_done) {
      MWAITX EAX, ECX
                }
}
```

MOV Move

Copies an immediate value or the value in a general-purpose register, segment register, or memory location (second operand) to a general-purpose register, segment register, or memory location. The source and destination must be the same size (byte, word, doubleword, or quadword) and cannot both be memory locations.

In opcodes A0 through A3, the memory offsets (called *moffsets*) are address sized. In 64-bit mode, memory offsets default to 64 bits. Opcodes A0–A3, in 64-bit mode, are the only cases that support a 64-bit offset value. (In all other cases, offsets and displacements are a maximum of 32 bits.) The B8 through BF (B8 +*rq*) opcodes, in 64-bit mode, are the only cases that support a 64-bit immediate value (in all other cases, immediate values are a maximum of 32 bits).

When reading segment-registers with a 32-bit operand size, the processor zero-extends the 16-bit selector results to 32 bits. When reading segment-registers with a 64-bit operand size, the processor zero-extends the 16-bit selector to 64 bits. If the destination operand specifies a segment register (DS, ES, FS, GS, or SS), the source operand must be a valid segment selector.

It is possible to move a null segment selector value (0000–0003h) into the DS, ES, FS, or GS register. This action does not cause a general protection fault, but a subsequent reference to such a segment *does* cause a #GP exception. For more information about segment selectors, see “Segment Selectors and Registers” in Volume 2.

When the MOV instruction is used to load the SS register, the processor blocks external interrupts until after the execution of the following instruction. This action allows the following instruction to be a MOV instruction to load a stack pointer into the ESP register (`MOV ESP,val`) before an interrupt occurs. However, the LSS instruction provides a more efficient method of loading SS and ESP.

Attempting to use the MOV instruction to load the CS register generates an invalid opcode exception (#UD). Use the far JMP, CALL, or RET instructions to load the CS register.

To initialize a register to 0, rather than using a MOV instruction, it may be more efficient to use the XOR instruction with identical destination and source operands.

Mnemonic	Opcode	Description
MOV *reg/mem8*, *reg8*	88 */r*	Move the contents of an 8-bit register to an 8-bit destination register or memory operand.
MOV *reg/mem16*, *reg16*	89 */r*	Move the contents of a 16-bit register to a 16-bit destination register or memory operand.
MOV *reg/mem32*, *reg32*	89 */r*	Move the contents of a 32-bit register to a 32-bit destination register or memory operand.
MOV *reg/mem64*, *reg64*	89 */r*	Move the contents of a 64-bit register to a 64-bit destination register or memory operand.
MOV *reg8*, *reg/mem8*	8A */r*	Move the contents of an 8-bit register or memory operand to an 8-bit destination register.

Mnemonic	Opcode	Description

Page fault, #PF		X	X	A page fault resulted from the execution of the instruction.
Alignment check, #AC		X	X	An unaligned memory reference was performed while alignment checking was enabled.

MOVBE Move Big Endian

Loads or stores a general purpose register while swapping the byte order. Operates on 16-bit, 32-bit, or 64-bit values. Converts big-endian formatted memory data to little-endian format when loading a register and reverses the conversion when storing a GPR to memory.

The load form reads a 16-, 32-, or 64-bit value from memory, swaps the byte order, and places the reordered value in a general-purpose register. When the operand size is 16 bits, the upper word of the destination register remains unchanged. In 64-bit mode, when the operand size is 32 bits, the upper doubleword of the destination register is cleared.

The store form takes a 16-, 32-, or 64-bit value from a general-purpose register, swaps the byte order, and stores the reordered value in the specified memory location. The contents of the source GPR remains unchanged.

In the 16-bit swap, the upper and lower bytes are exchanged. In the doubleword swap operation, bits 7:0 are exchanged with bits 31:24 and bits 15:8 are exchanged with bits 23:16. In the quadword swap operation, bits 7:0 are exchanged with bits 63:56, bits 15:8 with bits 55:48, bits 23:16 with bits 47:40, and bits 31:24 with bits 39:32.

Support for the MOVBE instruction is indicated by CPUID Fn0000_0001_ECX[MOVBE] = 1.

For more information on using the CPUID instruction, see the instruction reference page for the CPUID instruction on page 165. For a description of all feature flags related to instruction subset support, see Appendix D, “Instruction Subsets and CPUID Feature Flags,” on page 587.

MOVD Move Doubleword or Quadword

Moves a 32-bit or 64-bit value in one of the following ways:

- from a 32-bit or 64-bit general-purpose register or memory location to the low-order 32 or 64 bits of an XMM register, with zero-extension to 128 bits
- from the low-order 32 or 64 bits of an XMM to a 32-bit or 64-bit general-purpose register or memory location
- from a 32-bit or 64-bit general-purpose register or memory location to the low-order 32 bits (with zero-extension to 64 bits) or the full 64 bits of an MMX register
- from the low-order 32 or the full 64 bits of an MMX register to a 32-bit or 64-bit general-purpose register or memory location

Figure 3-1 on page 239 illustrates the operation of the MOVD instruction.

The MOVD instruction form that moves data to or from MMX registers is part of the MMX instruction subset. Support for MMX instructions is indicated by CPUID Fn0000_0001_EDX[MMX] or Fn0000_0001_EDX[MMX] = 1.

The MOVD instruction form that moves data to or from XMM registers is part of the SSE2 instruction subset. Support for SSE2 instructions is indicated by CPUID Fn0000_0001_EDX[SSE2] = 1.

For more information on using the CPUID instruction, see the instruction reference page for the CPUID instruction on page 165. For a description of all feature flags related to instruction subset support, see Appendix D, “Instruction Subsets and CPUID Feature Flags,” on page 587.

MOVNTI Move Non-Temporal Doubleword or Quadword

Stores a value in a 32-bit or 64-bit general-purpose register (second operand) in a memory location (first operand). This instruction indicates to the processor that the data is non-temporal and is unlikely to be used again soon. The processor treats the store as a write-combining (WC) memory write, which minimizes cache pollution. The exact method by which cache pollution is minimized depends on the hardware implementation of the instruction. For further information, see “Memory Optimization” in Volume 1.

The MOVNTI instruction is weakly-ordered with respect to other instructions that operate on memory. Software should use an SFENCE instruction to force strong memory ordering of MOVNTI with respect to other stores.

The MOVNTI instruction is an SSE2 instruction. Support for SSE2 instructions is indicated by CPUID Fn0000_0001_EDX[SSE2] = 1.

For more information on using the CPUID instruction, see the instruction reference page for the CPUID instruction on page 165. For a description of all feature flags related to instruction subset support, see Appendix D, “Instruction Subsets and CPUID Feature Flags,” on page 587.

Mnemonic	Opcode	Description
MOVNTI *mem32*, *reg32*	0F C3 */r*	Stores a 32-bit general-purpose register value into a 32-bit memory location, minimizing cache pollution.
MOVNTI *mem64*, *reg64*	0F C3 */r*	Stores a 64-bit general-purpose register value into a 64-bit memory location, minimizing cache pollution.

MOVS
MOVSB
MOVSW
MOVSD
MOVSQ

Move String

Moves a byte, word, doubleword, or quadword from the memory location pointed to by DS:rSI to the memory location pointed to by ES:rDI, and then increments or decrements the rSI and rDI registers according to the state of the DF flag in the rFLAGS register.

If the DF flag is 0, the instruction increments both pointers; otherwise, it decrements them. It increments or decrements the pointers by 1, 2, 4, or 8, depending on the size of the operands.

The forms of the MOVS*x* instruction with explicit operands address the first operand at *seg*:[rSI]. The value of *seg* defaults to the DS segment, but can be overridden by a segment prefix. These instructions always address the second operand at ES:[rDI] (ES may not be overridden). The explicit operands serve only to specify the type (size) of the value being moved.

The no-operands forms of the instruction use the DS:[rSI] and ES:[rDI] registers to point to the value to be moved (they do not allow a segment prefix). The mnemonic determines the size of the operands.

Do not confuse this MOVSD instruction with the same-mnemonic MOVSD (move scalar double-precision floating-point) instruction in the 128-bit media instruction set. Assemblers can distinguish the instructions by the number and type of operands.

The MOVS*x* instructions support the REP prefixes. For details about the REP prefixes, see “Repeat Prefixes” on page 12.

Mnemonic	Opcode	Description
MOVS *mem8*, *mem8*	A4	Move byte at DS:rSI to ES:rDI, and then increment or decrement rSI and rDI.
MOVS *mem16*, *mem16*	A5	Move word at DS:rSI to ES:rDI, and then increment or decrement rSI and rDI.
MOVS *mem32*, *mem32*	A5	Move doubleword at DS:rSI to ES:rDI, and then increment or decrement rSI and rDI.
MOVS *mem64*, *mem64*	A5	Move quadword at DS:rSI to ES:rDI, and then increment or decrement rSI and rDI.
MOVSB	A4	Move byte at DS:rSI to ES:rDI, and then increment or decrement rSI and rDI.
MOVSW	A5	Move word at DS:rSI to ES:rDI, and then increment or decrement rSI and rDI.

Mnemonic	Opcode	Description
MOVSD	A5	Move doubleword at DS:rSI to ES:rDI, and then increment or decrement rSI and rDI.
MOVSQ	A5	Move quadword at DS:rSI to ES:rDI, and then increment or decrement rSI and rDI.

Alignment check, #AC		X	X	An unaligned memory reference was performed while alignment checking was enabled.

MOVSXD Move with Sign-Extend Doubleword

Copies the 32-bit value in a register or memory location (second operand) into a 64-bit register (first operand), extending the most significant bit of the 32-bit value into all higher bits of the 64-bit register.

This instruction requires the REX prefix 64-bit operand size bit (REX.W) to be set to 1 to sign-extend a 32-bit source operand to a 64-bit result. Without the REX operand-size prefix, the operand size will be 32 bits, the default for 64-bit mode, and the source is zero-extended into a 64-bit register. With a 16-bit operand size, only 16 bits are copied, without modifying the upper 48 bits in the destination.

This instruction is available only in 64-bit mode. In legacy or compatibility mode this opcode is interpreted as ARPL.

Mnemonic	Opcode	Description
MOVSXD *reg64*, *reg/mem32*	63 */r*	Move the contents of a 32-bit register or memory operand to a 64-bit register with sign extension.

Alignment check, #AC			X	An unaligned memory reference was performed while alignment checking was enabled.

MOVZX Move with Zero-Extension

Copies the value in a register or memory location (second operand) into a register (first operand), zero-extending the value to fit in the destination register. The operand-size attribute determines the size of the zero-extended value.

Mnemonic	Opcode	Description
MOVZX *reg16*, *reg/mem8*	0F B6 */r*	Move the contents of an 8-bit register or memory operand to a 16-bit register with zero-extension.
MOVZX *reg32*, *reg/mem8*	0F B6 */r*	Move the contents of an 8-bit register or memory operand to a 32-bit register with zero-extension.

MUL Unsigned Multiply

Multiplies the unsigned byte, word, doubleword, or quadword value in the specified register or memory location by the value in AL, AX, EAX, or RAX and stores the result in AX, DX:AX, EDX:EAX, or RDX:RAX (depending on the operand size). It puts the high-order bits of the product in AH, DX, EDX, or RDX.

If the upper half of the product is non-zero, the instruction sets the carry flag (CF) and overflow flag (OF) both to 1. Otherwise, it clears CF and OF to 0. The other arithmetic flags (SF, ZF, AF, PF) are undefined.

Mnemonic	Opcode	Description
MUL *reg/mem8*	F6 /4	Multiplies an 8-bit register or memory operand by the contents of the AL register and stores the result in the AX register.
MUL *reg/mem16*	F7 /4	Multiplies a 16-bit register or memory operand by the contents of the AX register and stores the result in the DX:AX register.
MUL *reg/mem32*	F7 /4	Multiplies a 32-bit register or memory operand by the contents of the EAX register and stores the result in the EDX:EAX register.
MUL *reg/mem64*	F7 /4	Multiplies a 64-bit register or memory operand by the contents of the RAX register and stores the result in the RDX:RAX register.

MULX Multiply Unsigned

Computes the unsigned product of the specified source operand and the implicit source operand rDX. Writes the upper half of the product to the first destination and the lower half to the second. Does not affect the arithmetic flags.

This instruction has three operands:

MULX *dest1*, *dest2*, *src*

In 64-bit mode, the operand size is determined by the value of VEX.W. If VEX.W is 1, the operand size is 64 bits; if VEX.W is 0, the operand size is 32 bits. In 32-bit mode, VEX.W is ignored. 16-bit operands are not supported.

The first and second operands (*dest1* and *dest2*) are general purpose registers. The specified source operand (*src*) is either a general purpose register or a memory operand. If the first and second operands specify the same register, the register receives the upper half of the product.

This instruction is a BMI2 instruction. Support for this instruction is indicated by CPUID Fn0000_0007_EBX_x0[BMI2] = 1.

For more information on using the CPUID instruction, see the instruction reference page for the CPUID instruction on page 165. For a description of all feature flags related to instruction subset support, see Appendix D, “Instruction Subsets and CPUID Feature Flags,” on page 587.

Alignment check, #AC			X	An unaligned memory reference was performed while alignment checking was enabled.

MWAITX Monitor Wait with Timeout

Used in conjunction with the MONITORX instruction to cause a processor to wait until a store occurs to a specific linear address range from another processor or the timer expires. The previously executed MONITORX instruction causes the processor to enter the monitor event pending state. The MWAITX instruction may enter an implementation dependent power state until the monitor event pending state is exited. The MWAITX instruction has the same effect on architectural state as the NOP instruction.

Events that cause an exit from the monitor event pending state include:

- A store from another processor matches the address range established by the MONITORX instruction.
- The timer expires.
- Any unmasked interrupt, including INTR, NMI, SMI, INIT.
- RESET.
- Any far control transfer that occurs between the MONITORX and the MWAITX.

EAX specifies optional hints for the MWAITX instruction. Optimized C-state request is communicated through EAX[7:4]. The processor C-state is EAX[7:4]+1, so to request C0 is to place the value F in EAX[7:4] and to request C1 is to place the value 0 in EAX[7:4]. All other components of EAX should be zero when making the C1 request. Setting a reserved bit in EAX is ignored by the processor. This is implicitly a 32-bit operand.

ECX specifies optional extensions for the MWAITX instruction. The extensions currently defined for ECX are:

- Bit 0: When set, allows interrupts to wake MWAITX, even when eFLAGS.IF = 0. Support for this extension is indicated by a feature flag returned by the CPUID instruction.
- Bit 1: When set, EBX contains the maximum wait time expressed in Software P0 clocks, the same clocks counted by the TSC. Setting bit 1 but passing in a value of zero on EBX is equivalent to setting bit 1 to a zero. The timer will not be an exit condition.
- Bit 31-2: When non-zero, results in a #GP(0) exception.

This is implicitly a 32-bit operand.

CPUID Function 0000_0005h indicates support for extended features of MONITORX/MWAITX as well as MONITOR/MWAIT:

- CPUID Fn0000_0005_ECX[EMX] = 1 indicates support for enumeration of MONITOR/MWAIT/MONITORX/MWAITX extensions.
- CPUID Fn0000_0005_ECX[IBE] = 1 indicates that MWAIT/MWAITX can set ECX[0] to allow interrupts to cause an exit from the monitor event pending state even when eFLAGS.IF = 0.

The MWAITX instruction can be executed at any privilege level and MSR C001_0015h[MonMwaitUserEn] has no effect on MWAITX.

Support for the MWAITX instruction is indicated by CPUID Fn8000_0001_ECX[MONITORX] (bit 29)= 1.

Software must check the CPUID bit once per program or library initialization before using the MWAITX instruction, or inconsistent behavior may result.

The use of the MWAITX instruction is contingent upon the satisfaction of the following coding requirements:

- MONITORX must precede the MWAITX and occur in the same loop.
- MWAITX must be conditionally executed only if the awaited store has not already occurred. (This prevents a race condition between the MONITORX instruction arming the monitoring hardware and the store intended to trigger the monitoring hardware.)

There is no indication after exiting MWAITX of why the processor exited or if the timer expired. It is up to software to check whether the awaiting store has occurred, and if not, determining how much time has elapsed if it wants to re-establish the MONITORX with a new timer value.

Mnemonic	Opcode	Description
MWAITX	0F 01 FB	Causes the processor to stop instruction execution and enter an implementation-dependent optimized state until occurrence of a class of events

General protection, #GP	X	X	X	Unsupported extension bits in ECX

NEG Two's Complement Negation

Performs the two's complement negation of the value in the specified register or memory location by subtracting the value from 0. Use this instruction only on signed integer numbers.

If the value is 0, the instruction clears the CF flag to 0; otherwise, it sets CF to 1. The OF, SF, ZF, AF, and PF flag settings depend on the result of the operation.

The forms of the NEG instruction that write to memory support the LOCK prefix. For details about the LOCK prefix, see "Lock Prefix" on page 11.

Mnemonic	Opcode	Description
NEG *reg/mem8*	F6 /3	Performs a two's complement negation on an 8-bit register or memory operand.
NEG *reg/mem16*	F7 /3	Performs a two's complement negation on a 16-bit register or memory operand.
NEG *reg/mem32*	F7 /3	Performs a two's complement negation on a 32-bit register or memory operand.
NEG *reg/mem64*	F7 /3	Performs a two's complement negation on a 64-bit register or memory operand.

NOT One's Complement Negation

Performs the one's complement negation of the value in the specified register or memory location by inverting each bit of the value.

The memory-operand forms of the NOT instruction support the LOCK prefix. For details about the LOCK prefix, see "Lock Prefix" on page 11.

Mnemonic	Opcode	Description
NOT *reg/mem8*	F6 /2	Complements the bits in an 8-bit register or memory operand.
NOT *reg/mem16*	F7 /2	Complements the bits in a 16-bit register or memory operand.
NOT *reg/mem32*	F7 /2	Complements the bits in a 32-bit register or memory operand.
NOT *reg/mem64*	F7 /2	Compliments the bits in a 64-bit register or memory operand.

			X	The destination operand was in a non-writable segment.
			X	A null data segment was used to reference memory.
Page fault, #PF		X	X	A page fault resulted from the execution of the instruction.
Alignment check, #AC		X	X	An unaligned memory reference is performed while alignment checking was enabled.

OR — Logical OR

Performs a logical or on the bits in a register, memory location, or immediate value (second operand) and a register or memory location (first operand) and stores the result in the first operand location. The two operands cannot both be memory locations.

If both corresponding bits are 0, the corresponding bit of the result is 0; otherwise, the corresponding result bit is 1.

The forms of the OR instruction that write to memory support the LOCK prefix. For details about the LOCK prefix, see “Lock Prefix” on page 11.

Mnemonic	Opcode	Description
OR AL, *imm8*	0C *ib*	or the contents of AL with an immediate 8-bit value.
OR AX, *imm16*	0D *iw*	or the contents of AX with an immediate 16-bit value.
OR EAX, *imm32*	0D *id*	or the contents of EAX with an immediate 32-bit value.
OR RAX, *imm32*	0D *id*	or the contents of RAX with a sign-extended immediate 32-bit value.
OR *reg/mem8*, *imm8*	80 /1 *ib*	or the contents of an 8-bit register or memory operand and an immediate 8-bit value.
OR *reg/mem16*, *imm16*	81 /1 *iw*	or the contents of a 16-bit register or memory operand and an immediate 16-bit value.
OR *reg/mem32*, *imm32*	81 /1 *id*	or the contents of a 32-bit register or memory operand and an immediate 32-bit value.
OR *reg/mem64*, *imm32*	81 /1 *id*	or the contents of a 64-bit register or memory operand and sign-extended immediate 32-bit value.
OR *reg/mem16*, *imm8*	83 /1 *ib*	or the contents of a 16-bit register or memory operand and a sign-extended immediate 8-bit value.
OR *reg/mem32*, *imm8*	83 /1 *ib*	or the contents of a 32-bit register or memory operand and a sign-extended immediate 8-bit value.
OR *reg/mem64*, *imm8*	83 /1 *ib*	or the contents of a 64-bit register or memory operand and a sign-extended immediate 8-bit value.
OR *reg/mem8*, reg8	08 */r*	or the contents of an 8-bit register or memory operand with the contents of an 8-bit register.
OR *reg/mem16*, *reg16*	09 */r*	or the contents of a 16-bit register or memory operand with the contents of a 16-bit register.
OR *reg/mem32*, *reg32*	09 */r*	or the contents of a 32-bit register or memory operand with the contents of a 32-bit register.
OR *reg/mem64*, *reg64*	09 */r*	or the contents of a 64-bit register or memory operand with the contents of a 64-bit register.

Mnemonic	Opcode	Description
OR *reg8*, *reg/mem8*	0A */r*	or the contents of an 8-bit register with the contents of an 8-bit register or memory operand.
OR *reg16*, *reg/mem16*	0B */r*	or the contents of a 16-bit register with the contents of a 16-bit register or memory operand.
OR *reg32*, *reg/mem32*	0B */r*	or the contents of a 32-bit register with the contents of a 32-bit register or memory operand.
OR *reg64*, *reg/mem64*	0B */r*	or the contents of a 64-bit register with the contents of a 64-bit register or memory operand.

The following chart summarizes the effect of this instruction:

OUT Output to Port

Copies the value from the AL, AX, or EAX register (second operand) to an I/O port (first operand). The port address can be a byte-immediate value (00h to FFh) or the value in the DX register (0000h to FFFFh). The source register used determines the size of the port (8, 16, or 32 bits).

If the operand size is 64 bits, OUT only writes to a 32-bit I/O port.

If the CPL is higher than the IOPL or the mode is virtual mode, OUT checks the I/O permission bitmap in the TSS before allowing access to the I/O port. See Volume 2 for details on the TSS I/O permission bitmap.

Mnemonic	Opcode	Description
OUT *imm8*, AL	E6 *ib*	Output the byte in the AL register to the port specified by an 8-bit immediate value.
OUT *imm8*, AX	E7 *ib*	Output the word in the AX register to the port specified by an 8-bit immediate value.
OUT *imm8*, EAX	E7 *ib*	Output the doubleword in the EAX register to the port specified by an 8-bit immediate value.
OUT DX, AL	EE	Output byte in AL to the output port specified in DX.
OUT DX, AX	EF	Output word in AX to the output port specified in DX.
OUT DX, EAX	EF	Output doubleword in EAX to the output port specified in DX.

Page fault (#PF)		X	X	A page fault resulted from the execution of the instruction.

OUTS
OUTSB
OUTSW
OUTSD

Output String

Copies data from the memory location pointed to by DS:rSI to the I/O port address (0000h to FFFFh) specified in the DX register, and then increments or decrements the rSI register according to the setting of the DF flag in the rFLAGS register.

If the DF flag is 0, the instruction increments rSI; otherwise, it decrements rSI. It increments or decrements the pointer by 1, 2, or 4, depending on the size of the value being copied.

The OUTS DX mnemonic uses an explicit memory operand (second operand) to determine the type (size) of the value being copied, but always uses DS:rSI for the location of the value to copy. The explicit register operand (first operand) specifies the I/O port address and must always be DX.

The no-operands forms of the mnemonic use the DS:rSI register pair to point to the memory data to be copied and the contents of the DX register as the destination I/O port address. The mnemonic specifies the size of the I/O port and the type (size) of the value being copied.

The OUTS*x* instruction supports the REP prefix. For details about the REP prefix, see “Repeat Prefixes” on page 12.

If the effective operand size is 64-bits, the instruction behaves as if the operand size were 32 bits.

If the CPL is higher than the IOPL or the mode is virtual mode, OUTS*x* checks the I/O permission bitmap in the TSS before allowing access to the I/O port. See Volume 2 for details on the TSS I/O permission bitmap.

Mnemonic	Opcode	Description
OUTS DX, *mem8*	6E	Output the byte in DS:rSI to the port specified in DX, then increment or decrement rSI.
OUTS DX, *mem16*	6F	Output the word in DS:rSI to the port specified in DX, then increment or decrement rSI.
OUTS DX, *mem32*	6F	Output the doubleword in DS:rSI to the port specified in DX, then increment or decrement rSI.
OUTSB	6E	Output the byte in DS:rSI to the port specified in DX, then increment or decrement rSI.
OUTSW	6F	Output the word in DS:rSI to the port specified in DX, then increment or decrement rSI.
OUTSD	6F	Output the doubleword in DS:rSI to the port specified in DX, then increment or decrement rSI.

PAUSE Pause

Improves the performance of spin loops, by providing a hint to the processor that the current code is in a spin loop. The processor may use this to optimize power consumption while in the spin loop.

Architecturally, this instruction behaves like a NOP instruction.

Processors that do not support PAUSE treat this opcode as a NOP instruction.

Mnemonic	Opcode	Description
PAUSE	F3 90	Provides a hint to processor that a spin loop is being executed.

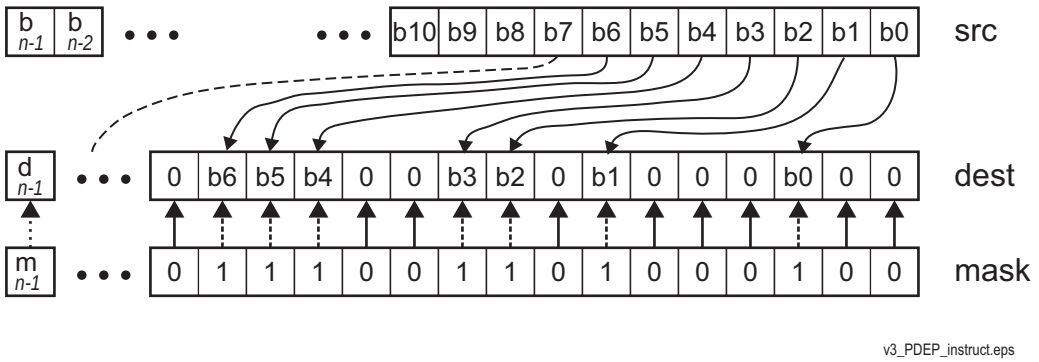
PDEP Parallel Deposit Bits

Scatters consecutive bits of the first source operand, starting at the least significant bit, to bit positions in the destination as specified by 1 bits in the second source operand (*mask*). Bit positions in the destination corresponding to 0 bits in the mask are cleared.

This instruction has three operands:

PDEP *dest*, *src, mask*

The following diagram illustrates the operation of this instruction.



If the mask is all ones, the execution of this instruction effectively copies the source to the destination.

In 64-bit mode, the operand size is determined by the value of VEX.W. If VEX.W is 1, the operand size is 64 bits; if VEX.W is 0, the operand size is 32 bits. In 32-bit mode, VEX.W is ignored. 16-bit operands are not supported.

The destination (*dest*) and the source (*src*) are general-purpose registers. The second source operand (*mask*) is either a general-purpose register or a memory operand.

This instruction is a BMI2 instruction. Support for this instruction is indicated by CPUID Fn0000_0007_EBX_x0[BMI2] = 1.

For more information on using the CPUID instruction, see the instruction reference page for the CPUID instruction on page 165. For a description of all feature flags related to instruction subset support, see Appendix D, “Instruction Subsets and CPUID Feature Flags,” on page 587.

Mnemonic	Encoding

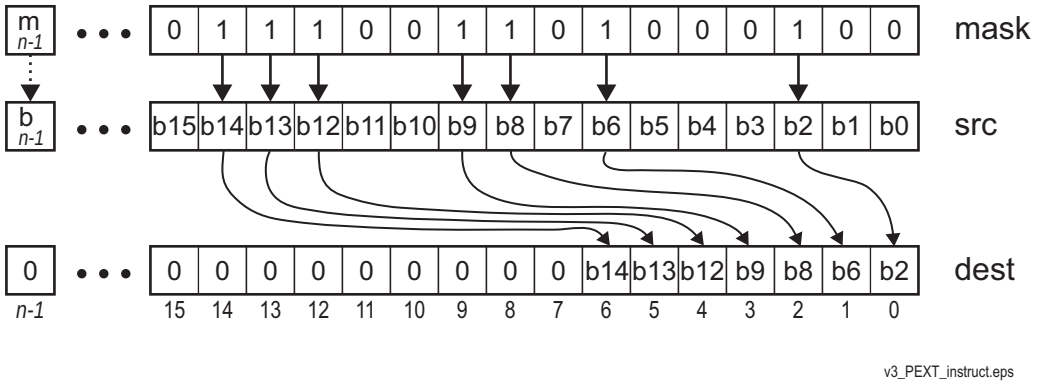
PEXT Parallel Extract Bits

Copies bits from the source operand, based on a mask, and packs them into the low-order bits of the destination. Clears all bits in the destination to the left of the most-significant bit copied.

This instruction has three operands:

PEXT *dest*, *src, mask*

The following diagram illustrates the operation of this instruction.



If the mask is all ones, the execution of this instruction effectively copies the source to the destination.

In 64-bit mode, the operand size is determined by the value of VEX.W. If VEX.W is 1, the operand size is 64 bits; if VEX.W is 0, the operand size is 32 bits. In 32-bit mode, VEX.W is ignored. 16-bit operands are not supported.

The destination (*dest*) and the source (*src*) are general-purpose registers. The second source operand (*mask*) is either a general-purpose register or a memory operand.

This instruction is a BMI2 instruction. Support for this instruction is indicated by CPUID Fn0000_0007_EBX_x0[BMI2] = 1.

For more information on using the CPUID instruction, see the instruction reference page for the CPUID instruction on page 165. For a description of all feature flags related to instruction subset support, see Appendix D, “Instruction Subsets and CPUID Feature Flags,” on page 587.

POP Pop Stack

Copies the value pointed to by the stack pointer (SS:rSP) to the specified register or memory location and then increments the rSP by 2 for a 16-bit pop, 4 for a 32-bit pop, or 8 for a 64-bit pop.

The operand-size attribute determines the amount by which the stack pointer is incremented (2, 4 or 8 bytes). The stack-size attribute determines whether SP, ESP, or RSP is incremented.

For forms of the instruction that load a segment register (POP DS, POP ES, POP FS, POP GS, POP SS), the source operand must be a valid segment selector. When a segment selector is popped into a segment register, the processor also loads all associated descriptor information into the hidden part of the register and validates it.

It is possible to pop a null segment selector value (0000–0003h) into the DS, ES, FS, or GS register. This action does not cause a general protection fault, but a subsequent reference to such a segment *does* cause a #GP exception. For more information about segment selectors, see "Segment Selectors and Registers" in *Volume 2: System Programming*.

In 64-bit mode, the POP operand size defaults to 64 bits and there is no prefix available to encode a 32-bit operand size. Using POP DS, POP ES, or POP SS instruction in 64-bit mode generates an invalid-opcode exception.

This instruction cannot pop a value into the CS register. The RET (Far) instruction performs this function.

Mnemonic	Opcode	Description
POP reg/*mem16*	8F /0	Pop the top of the stack into a 16-bit register or memory location.
POP reg/*mem32*	8F /0	Pop the top of the stack into a 32-bit register or memory location. (No prefix for encoding this in 64-bit mode.)
POP reg/*mem64*	8F /0	Pop the top of the stack into a 64-bit register or memory location.
POP *reg16*	58 +*rw*	Pop the top of the stack into a 16-bit register.
POP *reg32*	58 +*rd*	Pop the top of the stack into a 32-bit register. (No prefix for encoding this in 64-bit mode.)
POP *reg64*	58 +*rq*	Pop the top of the stack into a 64-bit register.
POP DS	1F	Pop the top of the stack into the DS register. (Invalid in 64-bit mode.)
POP ES	07	Pop the top of the stack into the ES register. (Invalid in 64-bit mode.)
POP SS	17	Pop the top of the stack into the SS register. (Invalid in 64-bit mode.)

Mnemonic	Opcode	Description
POP FS	0F A1	Pop the top of the stack into the FS register.
POP GS	0F A9	Pop the top of the stack into the GS register.

Page fault, #PF		X	X	A page fault resulted from the execution of the instruction.
Alignment check, #AC		X	X	An unaligned memory reference was performed while alignment checking was enabled.

POPA POPAD — POP All GPRs

Pops words or doublewords from the stack into the general-purpose registers in the following order: eDI, eSI, eBP, eSP (image is popped and discarded), eBX, eDX, eCX, and eAX. The instruction increments the stack pointer by 16 or 32, depending on the operand size.

Using the POPA or POPAD instructions in 64-bit mode generates an invalid-opcode exception.

Mnemonic	Opcode	Description
POPA	61	Pop the DI, SI, BP, SP, BX, DX, CX, and AX registers. (Invalid in 64-bit mode.)
POPAD	61	Pop the EDI, ESI, EBP, ESP, EBX, EDX, ECX, and EAX registers. (Invalid in 64-bit mode.)

Alignment check, #AC		X	X	An unaligned memory reference was performed while alignment checking was enabled.

POPCNT Bit Population Count

Counts the number of bits having a value of 1 in the source operand and places the result in the destination register. The source operand is a 16-, 32-, or 64-bit general purpose register or memory operand; the destination operand is a general purpose register of the same size as the source operand register.

If the input operand is zero, the ZF flag is set to 1 and zero is written to the destination register. Otherwise, the ZF flag is cleared. The other flags are cleared.

Support for the POPCNT instruction is indicated by CPUID Fn0000_0001_ECX[POPCNT] = 1. Software MUST check the CPUID bit once per program or library initialization before using the POPCNT instruction, or inconsistent behavior may result.

For more information on using the CPUID instruction, see the instruction reference page for the CPUID instruction on page 165. For a description of all feature flags related to instruction subset support, see Appendix D, “Instruction Subsets and CPUID Feature Flags,” on page 587.

Mnemonic		Opcode	Description
POPCNT	*reg16*, r*eg/mem16*	F3 0F B8 /r	Count the 1s in reg/mem16.
POPCNT	*reg32*, *reg/mem32*	F3 0F B8 /r	Count the 1s in reg/mem32.
POPCNT	*reg64*, *reg/mem64*	F3 0F B8 /r	Count the 1s in reg/mem64.

POPF
POPFD
POPFQ

POP to rFLAGS

Pops a word, doubleword, or quadword from the stack into the rFLAGS register and then increments the stack pointer by 2, 4, or 8, depending on the operand size.

In protected or real mode, all the non-reserved flags in the rFLAGS register can be modified, except the VIP, VIF, and VM flags, which are unchanged. In protected mode, at a privilege level greater than 0 the IOPL is also unchanged. The instruction alters the interrupt flag (IF) only when the CPL is less than or equal to the IOPL.

In virtual-8086 mode, if IOPL field is less than 3, attempting to execute a POPF*x* or PUSHF*x* instruction while VME is not enabled, or the operand size is not 16-bit, generates a #GP exception.

In 64-bit mode, this instruction defaults to a 64-bit operand size; there is no prefix available to encode a 32-bit operand size.

Mnemonic	Opcode	Description
POPF	9D	Pop a word from the stack into the FLAGS register.
POPFD	9D	Pop a double word from the stack into the EFLAGS register. (No prefix for encoding this in 64-bit mode.)
POPFQ	9D	Pop a quadword from the stack to the RFLAGS register.

Stack, #SS	X	X	X	A memory address exceeded the stack segment limit or was non-canonical.
General protection, #GP		X		The I/O privilege level was less than 3 and one of the following conditions was true: • CR4.VME was 0. • The effective operand size was 32-bit. • Both the original EFLAGS.VIP and the new EFLAGS.IF bits were set. • The new EFLAGS.TF bit was set.
Page fault, #PF		X	X	A page fault resulted from the execution of the instruction.
Alignment check, #AC		X	X	An unaligned memory reference was performed while alignment checking was enabled.

PREFETCH
PREFETCHW — Prefetch L1 Data-Cache Line

Loads the entire 64-byte aligned memory sequence *containing* the specified memory address into the L1 data cache. The position of the specified memory address within the 64-byte cache line is irrelevant. If a cache hit occurs, or if a memory fault is detected, no bus cycle is initiated and the instruction is treated as a NOP.

The PREFETCHW instruction loads the prefetched line and sets the cache-line state to Modified, in anticipation of subsequent data writes to the line. The PREFETCH instruction, by contrast, typically sets the cache-line state to Exclusive (depending on the hardware implementation).

The opcodes for the PREFETCH/PREFETCHW instructions include the ModRM byte; however, only the memory form of ModRM is valid. The register form of ModRM causes an invalid-opcode exception. Because there is no destination register, the three destination register field bits of the ModRM byte define the type of prefetch to be performed. The bit patterns 000b and 001b define the PREFETCH and PREFETCHW instructions, respectively. All other bit patterns are reserved for future use.

The *reserved* PREFETCH types do not result in an invalid-opcode exception if executed. Instead, for forward compatibility with future processors that may implement additional forms of the PREFETCH instruction, all reserved PREFETCH types are implemented as synonyms of the basic PREFETCH type (the PREFETCH instruction with type 000b).

The operation of these instructions is implementation-dependent. The processor implementation can ignore or change these instructions. The size of the cache line also depends on the implementation, with a minimum size of 32 bytes. For details on the use of this instruction, see the processor data sheets or other software-optimization documentation relating to particular hardware implementations.

When paging is enabled and PREFETCHW performs a prefetch from a writable page, it may set the PTE Dirty bit to 1.

Support for the PREFETCH and PREFETCHW instructions is indicated by CPUID Fn8000_0001_ECX[3DNowPrefetch] OR Fn8000_0001_EDX[LM] OR Fn8000_0001_EDX[3DNow] = 1.

For more information on using the CPUID instruction, see the instruction reference page for the CPUID instruction on page 165. For a description of all feature flags related to instruction subset support, see Appendix D, “Instruction Subsets and CPUID Feature Flags,” on page 587.

Mnemonic	Opcode	Description
PREFETCH *mem8*	0F 0D /0	Prefetch processor cache line into L1 data cache.
PREFETCHW *mem8*	0F 0D /1	Prefetch processor cache line into L1 data cache and mark it modified.

Invalid opcode, #UD	X	X	X	PREFETCH and PREFETCHW instructions are not supported, as indicated by CPUID Fn8000_0001_ECX[3DNowPrefetch] AND Fn8000_0001_EDX[LM] AND Fn8000_0001_EDX[3DNow] = 0.
	X	X	X	The operand was a register.

PREFETCH*level* Prefetch Data to Cache Level *level*

Loads a cache line from the specified memory address into the data-cache level specified by the locality reference bits 5:3 of the ModRM byte. Table 3-3 on page 285 lists the locality reference options for the instruction.

This instruction loads a cache line even if the *mem8* address is not aligned with the start of the line. If the cache line is already contained in a cache level that is lower than the specified locality reference, or if a memory fault is detected, a bus cycle is not initiated and the instruction is treated as a NOP.

The operation of this instruction is implementation-dependent. The processor implementation can ignore or change this instruction. The size of the cache line also depends on the implementation, with a minimum size of 32 bytes. AMD processors alias PREFETCH1 and PREFETCH2 to PREFETCH0. For details on the use of this instruction, see the software-optimization documentation relating to particular hardware implementations.

Mnemonic	Opcode	Description
PREFETCHNTA *mem8*	0F 18 /0	Move data closer to the processor using the NTA reference.
PREFETCHT0 *mem8*	0F 18 /1	Move data closer to the processor using the T0 reference.
PREFETCHT1 *mem8*	0F 18 /2	Move data closer to the processor using the T1 reference.
PREFETCHT2 *mem8*	0F 18 /3	Move data closer to the processor using the T2 reference.

Table 3-3. Locality References for the Prefetch Instructions

Locality Reference	Description
NTA	Non-Temporal Access—Move the specified data into the processor with minimum cache pollution. This is intended for data that will be used only once, rather than repeatedly. The specific technique for minimizing cache pollution is implementation-dependent and may include such techniques as allocating space in a software-invisible buffer, allocating a cache line in only a single way, etc. For details, see the software-optimization documentation for a particular hardware implementation.
T0	All Cache Levels—Move the specified data into all cache levels.
T1	Level 2 and Higher—Move the specified data into all cache levels except 0th level (L1) cache.
T2	Level 3 and Higher—Move the specified data into all cache levels except 0th level (L1) and 1st level (L2) caches.

PUSH Push onto Stack

Decrements the stack pointer and then copies the specified immediate value or the value in the specified register or memory location to the top of the stack (the memory location pointed to by SS:rSP).

The operand-size attribute determines the number of bytes pushed to the stack. The stack-size attribute determines whether SP, ESP, or RSP is the stack pointer. The address-size attribute is used only to locate the memory operand when pushing a memory operand to the stack.

If the instruction pushes the stack pointer (rSP), the resulting value on the stack is that of rSP before execution of the instruction.

There is a PUSH CS instruction but no corresponding POP CS. The RET (Far) instruction pops a value from the top of stack into the CS register as part of its operation.

In 64-bit mode, the operand size of all PUSH instructions defaults to 64 bits, and there is no prefix available to encode a 32-bit operand size. Using the PUSH CS, PUSH DS, PUSH ES, or PUSH SS instructions in 64-bit mode generates an invalid-opcode exception.

Pushing an odd number of 16-bit operands when the stack address-size attribute is 32 results in a misaligned stack pointer.

Mnemonic	Opcode	Description
PUSH reg/*mem16*	FF /6	Push the contents of a 16-bit register or memory operand onto the stack.
PUSH reg/*mem32*	FF /6	Push the contents of a 32-bit register or memory operand onto the stack. (No prefix for encoding this in 64-bit mode.)
PUSH reg/*mem64*	FF /6	Push the contents of a 64-bit register or memory operand onto the stack.
PUSH *reg16*	50 +*rw*	Push the contents of a 16-bit register onto the stack.
PUSH *reg32*	50 +*rd*	Push the contents of a 32-bit register onto the stack. (No prefix for encoding this in 64-bit mode.)
PUSH *reg64*	50 +*rq*	Push the contents of a 64-bit register onto the stack.
PUSH *imm8*	6A *ib*	Push an 8-bit immediate value (sign-extended to 16, 32, or 64 bits) onto the stack.
PUSH *imm16*	68 *iw*	Push a 16-bit immediate value onto the stack.
PUSH *imm32*	68 *id*	Push a 32-bit immediate value onto the stack. (No prefix for encoding this in 64-bit mode.)
PUSH *imm64*	68 *id*	Push a sign-extended 32-bit immediate value onto the stack.
PUSH CS	0E	Push the CS selector onto the stack. (Invalid in 64-bit mode.)

Mnemonic	Opcode	Description
PUSH SS	16	Push the SS selector onto the stack. (Invalid in 64-bit mode.)
PUSH DS	1E	Push the DS selector onto the stack. (Invalid in 64-bit mode.)
PUSH ES	06	Push the ES selector onto the stack. (Invalid in 64-bit mode.)
PUSH FS	0F A0	Push the FS selector onto the stack.
PUSH GS	0F A8	Push the GS selector onto the stack.

PUSHF
PUSHFD
PUSHFQ

Push rFLAGS onto Stack

Decrements the rSP register and copies the rFLAGS register (except for the VM and RF flags) onto the stack. The instruction clears the VM and RF flags in the rFLAGS image before putting it on the stack.

The instruction pushes 2, 4, or 8 bytes, depending on the operand size.

In 64-bit mode, this instruction defaults to a 64-bit operand size and there is no prefix available to encode a 32-bit operand size.

In virtual-8086 mode, if system software has set the IOPL field to a value less than 3, a general-protection exception occurs if application software attempts to execute PUSHF*x* or POPF*x* while VME is not enabled or the operand size is not 16-bit.

Mnemonic	Opcode	Description
PUSHF	9C	Push the FLAGS word onto the stack.
PUSHFD	9C	Push the EFLAGS doubleword onto stack. (No prefix encoding this in 64-bit mode.)
PUSHFQ	9C	Push the RFLAGS quadword onto stack.

Action

```
// See “Pseudocode Definition” on page 57.

PUSHF_START:

RCL Rotate Through Carry Left

Rotates the bits of a register or memory location (first operand) to the left (more significant bit positions) and through the carry flag by the number of bit positions in an unsigned immediate value or the CL register (second operand). The bits rotated through the carry flag are rotated back in at the right end (lsb) of the first operand location.

The processor masks the upper three bits of the count operand, thus restricting the count to a number between 0 and 31. When the destination is 64 bits wide, the processor masks the upper two bits of the count, providing a count in the range of 0 to 63.

For 1-bit rotates, the instruction sets the OF flag to the logical `xor` of the CF bit (after the rotate) and the most significant bit of the result. When the rotate count is greater than 1, the OF flag is undefined. When the rotate count is 0, no flags are affected.

Mnemonic	Opcode	Description
RCL *reg/mem8*,1	D0 /2	Rotate the 9 bits consisting of the carry flag and an 8-bit register or memory location left 1 bit.
RCL *reg/mem8*, CL	D2 /2	Rotate the 9 bits consisting of the carry flag and an 8-bit register or memory location left the number of bits specified in the CL register.

RDFSBASE Read FS.base
RDGSBASE Read GS.base

Copies the base field of the FS or GS segment descriptor to the specified register. When supported and enabled, these instructions can be executed at any processor privilege level. The RDFSBASE and RDGSBASE instructions are only defined in 64-bit mode.

System software must set the FSGSBASE bit (bit 16) of CR4 to enable the RDFSBASE and RDGSBASE instructions.

Support for this instruction is indicated by CPUID Fn0000_0007_EBX_x0[FSGSBASE] = 1.

For more information on using the CPUID instruction, see the instruction reference page for the CPUID instruction on page 165. For a description of all feature flags related to instruction subset support, see Appendix D, “Instruction Subsets and CPUID Feature Flags,” on page 587.

Mnemonic	Opcode	Description
RDFSBASE *reg32*	F3 0F AE /0	Copy the lower 32 bits of FS.base to the specified general-purpose register.
RDFSBASE *reg64*	F3 0F AE /0	Copy the entire 64-bit contents of FS.base to the specified general-purpose register.
RDGSBASE *reg32*	F3 0F AE /1	Copy the lower 32 bits of GS.base to the specified general-purpose register.
RDGSBASE *reg64*	F3 0F AE /1	Copy the entire 64-bit contents of GS.base to the specified general-purpose register.

RDPID Read Processor ID

RDPID reads the value of TSC_AUX MSR used by the RDTSCP instruction into the specified destination register. Normal operand size prefixes do not apply and the update is either 32 bit or 64 bit based on the current mode.

The RDPID instruction can be used to access the TSC_AUX value at CPL > 0 in cases where the operating system has disabled unprivileged execution of the RDTSCP instruction.

The content of the TSC_AUX MSR, including how and even whether it actually indicates a processor ID, is a matter of operating system convention.

The RDPID instruction is supported if the feature flag CPUID Fn0000_0007_X0_ECX[22]=1.

Mnemonic	Opcode	Description
RDPID	F3 0F C7/7	Read TSC_AUX

RDPRU Read Processor Register

RDPRU instruction is used to give access to some processor registers that are typically only accessible when the privilege level is zero. ECX is used as the implicit register to specify which register to read. RDPRU places the specified register's value into EDX:EAX.

The RDPRU instruction normally can be executed at any privilege level. When CR4.TSD=1, RDPRU can only be used when the privilege level is zero. When the CPL>0 with CR4.TSD=1, the RDPRU instruction will generate a #UD fault.

The RDPRU instruction is supported if the feature flag CPUID Fn8000_0008 EBX[4]=1. The 16-bit field in CPUID Fn8000_0008-EDX[31:16] returns the largest ECX value that returns a valid register. Any unsupported ECX values return zero. Registers currently supported by ECX values are:

- ECX Value 0 = Register MPERF
- ECX Value 1 = Register APERF

Mnemonic	Opcode	Description
RDPRU	0F 01 FD	Copy register specified by ECX into EDX:EAX

RDRAND Read Random

Loads the destination register with a hardware-generated random value.

The size of the returned value in bits is determined by the size of the destination register.

Hardware modifies the CF flag to indicate whether the value returned in the destination register is valid. If CF = 1, the value is valid. If CF = 0, the value is invalid. Software must test the state of the CF flag prior to using the value returned in the destination register to determine if the value is valid. If the returned value is invalid, software must execute the instruction again. Software should implement a retry limit to ensure forward progress of code.

The execution of RDRAND clears the OF, SF, ZF, AF, and PF flags.

Support for the RDRAND instruction is optional. On processors that support the instruction, CPUID Fn0000_0001_ECX[RDRAND] = 1.

For more information on using the CPUID instruction, see the instruction reference page for the CPUID instruction on page 165. For a description of all feature flags related to instruction subset support, see Appendix D, “Instruction Subsets and CPUID Feature Flags,” on page 587.

Mnemonic	Opcode	Description
RDRAND *reg16*	0F C7 /6	Load the destination register with a 16-bit random number.

RDSEED Read Random Seed

Loads the destination register with a hardware-generated random "seed" value.

The size of the returned value in bits is determined by the size of the destination register.

Hardware modifies the CF flag to indicate whether the value returned in the destination register is valid. If CF = 1, the value is valid. If CF = 0, the value is invalid and will be returned as zero. Software must test the state of the CF flag prior to using the value returned in the destination register to determine if the value is valid. If the returned value is invalid, software must execute the instruction again. Software should implement a retry limit to ensure forward progress of code.

The execution of RDSEED clears the OF, SF, ZF, AF, and PF flags.

Mnemonic	Opcode	Description
RDSEED *reg16*	0F C7 /7	Read 16-bit random seed
RDSEED *reg32*	0F C7 /7	Read 32-bit random seed
RDSEED *reg64*	0F C7 /7	Read 64-bit random seed

RET (Near) Near Return from Called Procedure

Returns from a procedure previously entered by a CALL near instruction. This form of the RET instruction returns to a calling procedure within the current code segment.

This instruction pops the rIP from the stack, with the size of the pop determined by the operand size. The new rIP is then zero-extended to 64 bits. The RET instruction can accept an immediate value operand that it adds to the rSP after it pops the target rIP. This action skips over any parameters previously passed back to the subroutine that are no longer needed.

In 64-bit mode, the operand size defaults to 64 bits (eight bytes) without the need for a REX prefix. No prefix is available to encode a 32-bit operand size in 64-bit mode.

See RET (Far) for information on far returns—returns to procedures located outside of the current code segment. For details about control-flow instructions, see “Control Transfers” in Volume 1, and “Control-Transfer Privilege Checks” in Volume 2.

Mnemonic	Opcode	Description
RET	C3	Near return to the calling procedure.
RET *imm16*	C2 *iw*	Near return to the calling procedure then pop the specified number of bytes from the stack.

Action

```
RETN_START:

IF (OPCODE == retn imm16)
   temp_IMM = 16 bit immediate from the instruction, zero-extended to 64 bits
ELSE // (OPCODE == retn)
   temp_IMM = 0

RET (Far) Far Return from Called Procedure

Returns from a procedure previously entered by a CALL Far instruction. This form of the RET instruction returns to a calling procedure in a different segment than the current code segment. It can return to the same CPL or to a less privileged CPL.

RET Far pops a target CS and rIP from the stack. If the new code segment is less privileged than the current code segment, the stack pointer is incremented by the number of bytes indicated by the immediate operand, if present; then a new SS and rSP are also popped from the stack.

The final value of rSP is incremented by the number of bytes indicated by the immediate operand, if present. This action skips over the parameters (previously passed to the subroutine) that are no longer needed.

All stack pops are determined by the operand size. If necessary, the target rIP is zero-extended to 64 bits before assuming program control.

If the CPL changes, the data segment selectors are set to NULL for any of the data segments (DS, ES, FS, GS) not accessible at the new CPL.

See RET (Near) for information on near returns—returns to procedures located inside the current code segment. For details about control-flow instructions, see “Control Transfers” in Volume 1, and “Control-Transfer Privilege Checks” in Volume 2.

Mnemonic	Opcode	Description
RETF	CB	Far return to the calling procedure.
RETF *imm16*	CA *iw*	Far return to the calling procedure, then pop the specified number of bytes from the stack.

ROL Rotate Left

Rotates the bits of a register or memory location (first operand) to the left (toward the more significant bit positions) by the number of bit positions in an unsigned immediate value or the CL register (second operand). The bits rotated out left are rotated back in at the right end (lsb) of the first operand location.

The processor masks the upper three bits of the count operand, thus restricting the count to a number between 0 and 31. When the destination is 64 bits wide, it masks the upper two bits of the count, providing a count in the range of 0 to 63.

After completing the rotation, the instruction sets the CF flag to the last bit rotated out (the lsb of the result). For 1-bit rotates, the instruction sets the OF flag to the logical `xor` of the CF bit (after the rotate) and the most significant bit of the result. When the rotate count is greater than 1, the OF flag is undefined. When the rotate count is 0, no flags are affected.

Mnemonic	Opcode	Description
ROL *reg/mem8*, 1	D0 /0	Rotate an 8-bit register or memory operand left 1 bit.
ROL *reg/mem8*, CL	D2 /0	Rotate an 8-bit register or memory operand left the number of bits specified in the CL register.
ROL *reg/mem8*, *imm8*	C0 /0 *ib*	Rotate an 8-bit register or memory operand left the number of bits specified by an 8-bit immediate value.
ROL *reg/mem16*, 1	D1 /0	Rotate a 16-bit register or memory operand left 1 bit.

ROR Rotate Right

Rotates the bits of a register or memory location (first operand) to the right (toward the less significant bit positions) by the number of bit positions in an unsigned immediate value or the CL register (second operand). The bits rotated out right are rotated back in at the left end (the most significant bit) of the first operand location.

The processor masks the upper three bits of the count operand, thus restricting the count to a number between 0 and 31. When the destination is 64 bits wide, the processor masks the upper two bits of the count, providing a count in the range of 0 to 63.

After completing the rotation, the instruction sets the CF flag to the last bit rotated out (the most significant bit of the result). For 1-bit rotates, the instruction sets the OF flag to the logical `xor` of the two most significant bits of the result. When the rotate count is greater than 1, the OF flag is undefined. When the rotate count is 0, no flags are affected.

RORX Rotate Right Extended

Rotates the bits of the source operand right (toward the least-significant bit) by the number of bit positions specified in an immediate operand and writes the result to the destination. Does not affect the arithmetic flags.

This instruction has three operands:

RORX *dest*, *src, rot_cnt*

On each right-shift, the bit shifted out of the least-significant bit position is copied to the most-significant bit. This instruction performs a non-destructive operation; that is, the contents of the source operand are unaffected by the operation, unless the destination and source are the same general-purpose register.

In 64-bit mode, the operand size is determined by the value of VEX.W. If VEX.W is 1, the operand size is 64 bits; if VEX.W is 0, the operand size is 32 bits. In 32-bit mode, VEX.W is ignored. 16-bit operands are not supported.

The destination (*dest*) is a general-purpose register and the source (*src*) is either a general-purpose register or a memory operand. The rotate count *rot_cnt* is encoded in an immediate byte. When the operand size is 32, bits [7:5] of the immediate byte are ignored; when the operand size is 64, bits [7:6] of the immediate byte are ignored.

This instruction is a BMI2 instruction. Support for this instruction is indicated by CPUID Fn0000_0007_EBX_x0[BMI2] = 1.

For more information on using the CPUID instruction, see the instruction reference page for the CPUID instruction on page 165. For a description of all feature flags related to instruction subset support, see Appendix D, “Instruction Subsets and CPUID Feature Flags,” on page 587.

SAHF Store AH into Flags

Loads the SF, ZF, AF, PF, and CF flags of the EFLAGS register with values from the corresponding bits in the AH register (bits 7, 6, 4, 2, and 0, respectively). The instruction ignores bits 1, 3, and 5 of register AH; it sets those bits in the EFLAGS register to 1, 0, and 0, respectively.

The SAHF instruction is available in 64-bit mode if CPUID Fn8000_0001_ECX[LahfSahf] = 1. It is always available in the other operating modes (including compatibility mode)

For more information on using the CPUID instruction, see the instruction reference page for the CPUID instruction on page 165. For a description of all feature flags related to instruction subset support, see Appendix D, “Instruction Subsets and CPUID Feature Flags,” on page 587.

Mnemonic	Opcode	Description
SAHF	9E	Loads the sign flag, the zero flag, the auxiliary flag, the parity flag, and the carry flag from the AH register into the lower 8 bits of the EFLAGS register.

SAL
SHL — Shift Left

Shifts the bits of a register or memory location (first operand) to the left through the CF bit by the number of bit positions in an unsigned immediate value or the CL register (second operand). The instruction discards bits shifted out of the CF flag. For each bit shift, the SAL instruction clears the least-significant bit to 0. At the end of the shift operation, the CF flag contains the last bit shifted out of the first operand.

The processor masks the upper three bits of the count operand, thus restricting the count to a number between 0 and 31. When the destination is 64 bits wide, the processor masks the upper two bits of the count, providing a count in the range of 0 to 63.

The effect of this instruction is multiplication by powers of two.

For 1-bit shifts, the instruction sets the OF flag to the logical `xor` of the CF bit (after the shift) and the most significant bit of the result. When the shift count is greater than 1, the OF flag is undefined.

If the shift count is 0, no flags are modified.

SHL is an alias to the SAL instruction.

Mnemonic	Opcode	Description
SAL *reg/mem8*, 1	D0 /4	Shift an 8-bit register or memory location left 1 bit.
SAL *reg/mem8*, CL	D2 /4	Shift an 8-bit register or memory location left the number of bits specified in the CL register.

SAR Shift Arithmetic Right

Shifts the bits of a register or memory location (first operand) to the right through the CF bit by the number of bit positions in an unsigned immediate value or the CL register (second operand). The instruction discards bits shifted out of the CF flag. At the end of the shift operation, the CF flag contains the last bit shifted out of the first operand.

The SAR instruction does not change the sign bit of the target operand. For each bit shift, it copies the sign bit to the next bit, preserving the sign of the result.

The processor masks the upper three bits of the count operand, thus restricting the count to a number between 0 and 31. When the destination is 64 bits wide, the processor masks the upper two bits of the count, providing a count in the range of 0 to 63.

For 1-bit shifts, the instruction clears the OF flag to 0. When the shift count is greater than 1, the OF flag is undefined.

If the shift count is 0, no flags are modified.

Although the SAR instruction effectively divides the operand by a power of 2, the behavior is different from the IDIV instruction. For example, shifting –11 (FFFFFFF5h) by two bits to the right (that is, divide –11 by 4), gives a result of FFFFFFFDh, or –3, whereas the IDIV instruction for dividing –11 by 4 gives a result of –2. This is because the IDIV instruction rounds off the quotient to zero, whereas the SAR instruction rounds off the remainder to zero for positive dividends and to negative infinity for negative dividends. So, for positive operands, SAR behaves like the corresponding IDIV instruction. For negative operands, it gives the same result if and only if all the shifted-out bits are zeroes; otherwise, the result is smaller by 1.

Mnemonic	Opcode	Description

SARX Shift Right Arithmetic Extended

Shifts the bits of the first source operand right (toward the least-significant bit) arithmetically by the number of bit positions specified in the second source operand and writes the result to the destination. Does not affect the arithmetic flags.

This instruction has three operands:

SARX *dest*, *src, shft_cnt*

On each right-shift, the most-significant bit (the sign bit) is replicated. This instruction performs a non-destructive operation; that is, the contents of the source operand are unaffected by the operation, unless the destination and source are the same general-purpose register.

In 64-bit mode, the operand size is determined by the value of VEX.W. If VEX.W is 1, the operand size is 64 bits; if VEX.W is 0, the operand size is 32 bits. In 32-bit mode, VEX.W is ignored. 16-bit operands are not supported.

The destination (*dest*) is a general-purpose register and the first source (*src*) is either a general-purpose register or a memory operand. The second source operand *shft_cnt* is a general-purpose register. When the operand size is 32, bits [31:5] of *shft_cnt* are ignored; when the operand size is 64, bits [63:6] of *shft_cnt* are ignored.

This instruction is a BMI2 instruction. Support for this instruction is indicated by CPUID Fn0000_0007_EBX_x0[BMI2] = 1.

For more information on using the CPUID instruction, see the instruction reference page for the CPUID instruction on page 165. For a description of all feature flags related to instruction subset support, see Appendix D, “Instruction Subsets and CPUID Feature Flags,” on page 587.

SBB Subtract with Borrow

Subtracts an immediate value or the value in a register or a memory location (second operand) from a register or a memory location (first operand), and stores the result in the first operand location. If the carry flag (CF) is 1, the instruction subtracts 1 from the result. Otherwise, it operates like SUB.

The SBB instruction sign-extends immediate value operands to the length of the first operand size.

This instruction evaluates the result for both signed and unsigned data types and sets the OF and CF flags to indicate a borrow in a signed or unsigned result, respectively. It sets the SF flag to indicate the sign of a signed result.

This instruction is useful for multibyte (multiword) numbers because it takes into account the borrow from a previous SUB instruction.

The forms of the SBB instruction that write to memory support the LOCK prefix. For details about the LOCK prefix, see “Lock Prefix” on page 11.

Mnemonic	Opcode	Description
SBB AL, *imm8*	1C *ib*	Subtract an immediate 8-bit value from the AL register with borrow.
SBB AX, *imm16*	1D *iw*	Subtract an immediate 16-bit value from the AX register with borrow.

SCAS
SCASB
SCASW
SCASD
SCASQ

Scan String

Compares the AL, AX, EAX, or RAX register with the byte, word, doubleword, or quadword pointed to by ES:rDI, sets the status flags in the rFLAGS register according to the results, and then increments or decrements the rDI register according to the state of the DF flag in the rFLAGS register.

If the DF flag is 0, the instruction increments the rDI register; otherwise, it decrements it. The instruction increments or decrements the rDI register by 1, 2, 4, or 8, depending on the size of the operands.

The forms of the SCASx instruction with an explicit operand address the operand at ES:rDI. The explicit operand serves only to specify the size of the values being compared.

The no-operands forms of the instruction use the ES:rDI registers to point to the value to be compared. The mnemonic determines the size of the operands and the specific register containing the other comparison value.

For block comparisons, the SCASx instructions support the REPE or REPZ prefixes (they are synonyms) and the REPNE or REPNZ prefixes (they are synonyms). For details about the REP prefixes, see “Repeat Prefixes” on page 12. A SCAS*x* instruction can also operate inside a loop controlled by the LOOP*cc* instruction.

Mnemonic	Opcode	Description
SCAS *mem8*	AE	Compare the contents of the AL register with the byte at ES:rDI, and then increment or decrement rDI.
SCAS *mem16*	AF	Compare the contents of the AX register with the word at ES:rDI, and then increment or decrement rDI.

SET*cc* Set Byte on Condition

Checks the status flags in the rFLAGS register and, if the flags meet the condition specified in the mnemonic (*cc*), sets the value in the specified 8-bit memory location or register to 1. If the flags do not meet the specified condition, SET*cc* clears the memory location or register to 0.

Mnemonics with the A (above) and B (below) tags are intended for use when performing unsigned integer comparisons; those with G (greater) and L (less) tags are intended for use with signed integer comparisons.

Software typically uses the SET*cc* instructions to set logical indicators. Like the CMOV*cc* instructions (page 152), the SET*cc* instructions can replace two instructions—a conditional jump and a move. Replacing conditional jumps with conditional sets can help avoid branch-prediction penalties that may result from conditional jumps.

If the logical value “true” (logical one) is represented in a high-level language as an integer with all bits set to 1, software can accomplish such representation by first executing the opposite SET*cc* instruction—for example, the opposite of SETZ is SETNZ—and then decrementing the result.

A ModR/M byte is used to identify the operand. The *reg* field in the ModR/M byte is unused.

Mnemonic	Opcode	Description

SFENCE Store Fence

Acts as a barrier to force strong memory ordering (serialization) between store instructions preceding the SFENCE and store instructions that follow the SFENCE. Stores to differing memory types, or within the WC memory type, may become visible out of program order; the SFENCE instruction ensures that the system completes all previous stores in such a way that they are globally visible before executing subsequent stores. This includes emptying the store buffer and all write-combining buffers.

The SFENCE instruction is weakly-ordered with respect to load instructions, data and instruction prefetches, and the LFENCE instruction. Speculative loads initiated by the processor, or specified explicitly using cache-prefetch instructions, can be reordered around an SFENCE.

In addition to store instructions, SFENCE is strongly ordered with respect to other SFENCE instructions, MFENCE instructions, and serializing instructions. Further details on the use of MFENCE to order accesses among differing memory types may be found in *AMD64 Architecture Programmer's Manual Volume 2: System Programming*, section 7.4 "Memory Types" on page 172.

The SFENCE instruction is an SSE1 instruction. Support for SSE1 instructions is indicated by CPUID Fn0000_0001_EDX[SSE] = 1.

For more information on using the CPUID instruction, see the instruction reference page for the CPUID instruction on page 165. For a description of all feature flags related to instruction subset support, see Appendix D, "Instruction Subsets and CPUID Feature Flags," on page 587.

SHL Shift Left

This instruction is synonymous with the SAL instruction. For information, see “SAL SHL” on page 315.

SHLD Shift Left Double

Shifts the bits of a register or memory location (first operand) to the left by the number of bit positions in an unsigned immediate value or the CL register (third operand), and shifts in a bit pattern (second operand) from the right. At the end of the shift operation, the CF flag contains the last bit shifted out of the first operand.

The processor masks the upper three bits of the count operand, thus restricting the count to a number between 0 and 31. When the destination is 64 bits wide, the processor masks the upper two bits of the count, providing a count in the range of 0 to 63. If the masked count is greater than the operand size, the result in the destination register is undefined.

If the shift count is 0, no flags are modified.

If the count is 1 and the sign of the operand being shifted changes, the instruction sets the OF flag to 1. If the count is greater than 1, OF is undefined.

Mnemonic	Opcode	Description
SHLD *reg/mem16*, *reg16*, *imm8*	0F A4 */r ib*	Shift bits of a 16-bit destination register or memory operand to the left the number of bits specified in an 8-bit immediate value, while shifting in bits from the second operand.

SHLX Shift Left Logical Extended

Shifts the bits of the first source operand left (toward the most-significant bit) by the number of bit positions specified in the second source operand and writes the result to the destination. Does not affect the arithmetic flags.

This instruction has three operands:

SHLX *dest*, *src, shft_cnt*

On each left-shift, a zero is shifted into the least-significant bit position. This instruction performs a non-destructive operation; that is, the contents of the source operand are unaffected by the operation, unless the destination and source are the same general-purpose register.

In 64-bit mode, the operand size is determined by the value of VEX.W. If VEX.W is 1, the operand size is 64 bits; if VEX.W is 0, the operand size is 32 bits. In 32-bit mode, VEX.W is ignored. 16-bit operands are not supported.

The destination (*dest*) is a general-purpose register and the first source (*src*) is either a general-purpose register or a memory operand. The second source operand *shft_cnt* is a general-purpose register. When the operand size is 32, bits [31:5] of *shft_cnt* are ignored; when the operand size is 64, bits [63:6] of *shft_cnt* are ignored.

This instruction is a BMI2 instruction. Support for this instruction is indicated by CPUID Fn0000_0007_EBX_x0[BMI2] = 1.

For more information on using the CPUID instruction, see the instruction reference page for the CPUID instruction on page 165. For a description of all feature flags related to instruction subset support, see Appendix D, “Instruction Subsets and CPUID Feature Flags,” on page 587.

SHR Shift Right

Shifts the bits of a register or memory location (first operand) to the right through the CF bit by the number of bit positions in an unsigned immediate value or the CL register (second operand). The instruction discards bits shifted out of the CF flag. At the end of the shift operation, the CF flag contains the last bit shifted out of the first operand.

For each bit shift, the instruction clears the most-significant bit to 0.

The effect of this instruction is unsigned division by powers of two.

The processor masks the upper three bits of the count operand, thus restricting the count to a number between 0 and 31. When the destination is 64 bits wide, the processor masks the upper two bits of the count, providing a count in the range of 0 to 63.

For 1-bit shifts, the instruction sets the OF flag to the most-significant bit of the original value. If the count is greater than 1, the OF flag is undefined.

If the shift count is 0, no flags are modified.

Mnemonic	Opcode	Description

SHRD Shift Right Double

Shifts the bits of a register or memory location (first operand) to the right by the number of bit positions in an unsigned immediate value or the CL register (third operand), and shifts in a bit pattern (second operand) from the left. At the end of the shift operation, the CF flag contains the last bit shifted out of the first operand.

The processor masks the upper three bits of the count operand, thus restricting the count to a number between 0 and 31. When the destination is 64 bits wide, the processor masks the upper two bits of the count, providing a count in the range of 0 to 63. If the masked count is greater than the operand size, the result in the destination register is undefined.

If the shift count is 0, no flags are modified.

If the count is 1 and the sign of the value being shifted changes, the instruction sets the OF flag to 1. If the count is greater than 1, the OF flag is undefined.

Mnemonic	Opcode	Description
SHRD *reg/mem16*, *reg16*, *imm8*	0F AC */r ib*	Shift bits of a 16-bit destination register or memory operand to the right the number of bits specified in an 8-bit immediate value, while shifting in bits from the second operand.

SHRX Shift Right Logical Extended

Shifts the bits of the first source operand right (toward the least-significant bit) by the number of bit positions specified in the second source operand and writes the result to the destination. Does not affect the arithmetic flags.

This instruction has three operands:

SHRX *dest*, *src, shft_cnt*

On each right-shift, a zero is shifted into the most-significant bit position. This instruction performs a non-destructive operation; that is, the contents of the source operand are unaffected by the operation, unless the destination and source are the same general-purpose register.

In 64-bit mode, the operand size is determined by the value of VEX.W. If VEX.W is 1, the operand size is 64 bits; if VEX.W is 0, the operand size is 32 bits. In 32-bit mode, VEX.W is ignored. 16-bit operands are not supported.

The destination (*dest*) is a general-purpose register and the first source (*src*) is either a general-purpose register or a memory operand. The second source operand *shft_cnt* is a general-purpose register. When the operand size is 32, bits [31:5] of *shft_cnt* are ignored; when the operand size is 64, bits [63:6] of *shft_cnt* are ignored.

This instruction is a BMI2 instruction. Support for this instruction is indicated by CPUID Fn0000_0007_EBX_x0[BMI2] = 1.

For more information on using the CPUID instruction, see the instruction reference page for the CPUID instruction on page 165. For a description of all feature flags related to instruction subset support, see Appendix D, “Instruction Subsets and CPUID Feature Flags,” on page 587.

SLWPCB Store Lightweight Profiling Control Block Address

Flushes Lightweight Profiling (LWP) state to memory and returns the current effective address of the Lightweight Profiling Control Block (LWPCB) in the specified register. The LWPCB address returned is truncated to 32 bits if the operand size is 32.

If LWP is not currently enabled, SLWPCB sets the specified register to zero.

The flush operation stores the internal event counters for active events and the current ring buffer head pointer into the LWPCB. If there is an unwritten event record pending, it is written to the event ring buffer.

The LWP_CBADDR MSR holds the linear address of the current LWPCB. If the contents of LWP_CBADDR is not zero, the value returned in the specified register is an effective address that is calculated by subtracting the current DS.Base address from the linear address kept in LWP_CBADDR. Note that if DS has changed between the time LLWPCB was executed and the time SLWPCB is executed, this might result in an address that is not currently accessible by the application.

SLWPCB generates an invalid opcode exception (#UD) if the machine is not in protected mode or if LWP is not available.

It is possible to execute SLWPCB when the CPL != 3 or when SMM is active, but if the LWPCB pointer is not zero, system software must ensure that the LWPCB and the entire ring buffer are properly mapped into writable memory in order to avoid a #PF fault. Using SLWPCB in these situations is not recommended.

See the discussion of lightweight profiling in Volume 2, Chapter 13 for more information on the use of the LLWPCB, SLWPCB, LWPINS, and LWPVAL instructions.

The SLWPCB instruction is implemented if LWP is supported on a processor. Support for LWP is indicated by CPUID Fn8000_0001_ECX[LWP] = 1.

For more information on using the CPUID instruction, see the instruction reference page for the CPUID instruction on page 165. For a description of all feature flags related to instruction subset support, see Appendix D, “Instruction Subsets and CPUID Feature Flags,” on page 587.

Instruction Encoding

Store String

Copies a byte, word, doubleword, or quadword from the AL, AX, EAX, or RAX registers to the memory location pointed to by ES:rDI and increments or decrements the rDI register according to the state of the DF flag in the rFLAGS register.

If the DF flag is 0, the instruction increments the pointer; otherwise, it decrements the pointer. It increments or decrements the pointer by 1, 2, 4, or 8, depending on the size of the value being copied.

The forms of the STOS*x* instruction with an explicit operand use the operand only to specify the type (size) of the value being copied.

The no-operands forms specify the type (size) of the value being copied with the mnemonic.

The STOS*x* instructions support the REP prefixes. For details about the REP prefixes, see “Repeat Prefixes” on page 12. The STOS*x* instructions can also operate inside a LOOP*cc* instruction.

Mnemonic	Opcode	Description
STOS *mem8*	AA	Store the contents of the AL register to ES:rDI, and then increment or decrement rDI.
STOS *mem16*	AB	Store the contents of the AX register to ES:rDI, and then increment or decrement rDI.
STOS *mem32*	AB	Store the contents of the EAX register to ES:rDI, and then increment or decrement rDI.
STOS *mem64*	AB	Store the contents of the RAX register to ES:rDI, and then increment or decrement rDI.
STOSB	AA	Store the contents of the AL register to ES:rDI, and then increment or decrement rDI.
STOSW	AB	Store the contents of the AX register to ES:rDI, and then increment or decrement rDI.
STOSD	AB	Store the contents of the EAX register to ES:rDI, and then increment or decrement rDI.

Alignment check, #AC		X	X	An unaligned memory reference was performed while alignment checking was enabled.

SUB Subtract

Subtracts an immediate value or the value in a register or memory location (second operand) from a register or a memory location (first operand) and stores the result in the first operand location. An immediate value is sign-extended to the length of the first operand.

This instruction evaluates the result for both signed and unsigned data types and sets the OF and CF flags to indicate a borrow in a signed or unsigned result, respectively. It sets the SF flag to indicate the sign of a signed result.

The forms of the SUB instruction that write to memory support the LOCK prefix. For details about the LOCK prefix, see “Lock Prefix” on page 11.

Mnemonic	Opcode	Description
SUB AL, *imm8*	2C *ib*	Subtract an immediate 8-bit value from the AL register and store the result in AL.
SUB AX, *imm16*	2D *iw*	Subtract an immediate 16-bit value from the AX register and store the result in AX.
SUB EAX, *imm32*	2D *id*	Subtract an immediate 32-bit value from the EAX register and store the result in EAX.
SUB RAX, *imm32*	2D *id*	Subtract a sign-extended immediate 32-bit value from the RAX register and store the result in RAX.
SUB *reg/mem8*, *imm8*	80 /5 *ib*	Subtract an immediate 8-bit value from an 8-bit destination register or memory location.

T1MSKC Inverse Mask From Trailing Ones

Finds the least significant zero bit in the source operand, clears all bits below that bit to 0, sets all other bits to 1 (including the found bit) and writes the result to the destination. If the least significant bit of the source operand is 0, the destination is written with all ones.

This instruction has two operands:

T1MSKC *dest*, *src*

In 64-bit mode, the operand size is determined by the value of XOP.W. If XOP.W is 1, the operand size is 64-bit; if XOP.W is 0, the operand size is 32-bit. In 32-bit mode, XOP.W is ignored. 16-bit operands are not supported.

The destination (*dest*) is a general purpose register.

The source operand (*src*) is a general purpose register or a memory operand.

The T1MSKC instruction effectively performs a bit-wise logical `or` of the inverse of the source operand and the result of incrementing the source operand by 1 and stores the result to the destination register:

```
add tmp1, src, 1
not tmp2, src
or  dest, tmp1, tmp2
```

The value of the carry flag of rFLAGs is generated by the `add` pseudo-instruction and the remaining arithmetic flags are generated by the `or` pseudo-instruction.

The T1MSKC instruction is a TBM instruction. Support for this instruction is indicated by CPUID Fn8000_0001_ECX[TBM] = 1.

For more information on using the CPUID instruction, see the instruction reference page for the CPUID instruction on page 165. For a description of all feature flags related to instruction subset support, see Appendix D, “Instruction Subsets and CPUID Feature Flags,” on page 587.

Invalid opcode, #UD	X	X		TBM instructions are only recognized in protected mode.
			X	TBM instructions are not supported, as indicated by CPUID Fn8000_0001_ECX[TBM] = 0.
			X	XOP.L is 1.
Stack, #SS			X	A memory address exceeded the stack segment limit or was non-canonical.
General protection, #GP			X	A memory address exceeded a data segment limit or was non-canonical.
			X	A null data segment was used to reference memory.
Page fault, #PF			X	A page fault resulted from the execution of the instruction.
Alignment check, #AC			X	An unaligned memory reference was performed while alignment checking was enabled.

TEST Test Bits

Performs a bit-wise logical and on the value in a register or memory location (first operand) with an immediate value or the value in a register (second operand) and sets the flags in the rFLAGS register based on the result.

This instruction has two operands:

TEST *dest*, *src*

While the AND instruction changes the contents of the destination and the flag bits, the TEST instruction changes only the flag bits.

Mnemonic	Opcode	Description
TEST AL, *imm8*	A8 *ib*	and an immediate 8-bit value with the contents of the AL register and set rFLAGS to reflect the result.
TEST AX, *imm16*	A9 *iw*	and an immediate 16-bit value with the contents of the AX register and set rFLAGS to reflect the result.
TEST EAX, *imm32*	A9 *id*	and an immediate 32-bit value with the contents of the EAX register and set rFLAGS to reflect the result.
TEST RAX, *imm32*	A9 *id*	and a sign-extended immediate 32-bit value with the contents of the RAX register and set rFLAGS to reflect the result.
TEST *reg/mem8*, *imm8*	F6 /0 *ib*	and an immediate 8-bit value with the contents of an 8-bit register or memory operand and set rFLAGS to reflect the result.
TEST *reg/mem16*, *imm16*	F7 /0 *iw*	and an immediate 16-bit value with the contents of a 16-bit register or memory operand and set rFLAGS to reflect the result.
TEST *reg/mem32*, *imm32*	F7 /0 *id*	and an immediate 32-bit value with the contents of a 32-bit register or memory operand and set rFLAGS to reflect the result.
TEST *reg/mem64*, *imm32*	F7 /0 *id*	and a sign-extended immediate32-bit value with the contents of a 64-bit register or memory operand and set rFLAGS to reflect the result.
TEST *reg/mem8*, *reg8*	84 */r*	and the contents of an 8-bit register with the contents of an 8-bit register or memory operand and set rFLAGS to reflect the result.
TEST *reg/mem16*, *reg16*	85 */r*	and the contents of a 16-bit register with the contents of a 16-bit register or memory operand and set rFLAGS to reflect the result.
TEST *reg/mem32*, *reg32*	85 */r*	and the contents of a 32-bit register with the contents of a 32-bit register or memory operand and set rFLAGS to reflect the result.
TEST *reg/mem64*, *reg64*	85 */r*	and the contents of a 64-bit register with the contents of a 64-bit register or memory operand and set rFLAGS to reflect the result.

TZCNT Count Trailing Zeros

Counts the number of trailing zero bits in the 16-, 32-, or 64-bit general purpose register or memory source operand. Counting starts upward from the least significant bit and stops when the lowest bit having a value of 1 is encountered or when the most significant bit is encountered. The count is written to the destination register.

If the input operand is zero, CF is set to 1 and the size (in bits) of the input operand is written to the destination register. Otherwise, CF is cleared.

If the least significant bit is a one, the ZF flag is set to 1 and zero is written to the destination register. Otherwise, ZF is cleared.

TZCNT is a BMI instruction. Support for BMI instructions is indicated by CPUID Fn0000_0007_EBX_x0[BMI] = 1. If the TZCNT instruction is not available, the encoding is treated as the BSF instruction. Software *must* check the CPUID bit once per program or library initialization before using the TZCNT instruction or inconsistent behavior may result.

For more information on using the CPUID instruction, see the instruction reference page for the CPUID instruction on page 165. For a description of all feature flags related to instruction subset support, see Appendix D, “Instruction Subsets and CPUID Feature Flags,” on page 587.

Mnemonic		Opcode	Description
TZCNT	*reg16*, *reg/mem16*	F3 0F BC /r	Count the number of trailing zeros in reg/mem16.
TZCNT	*reg32*, *reg/mem32*	F3 0F BC /r	Count the number of trailing zeros in reg/mem32.
TZCNT	*reg64*, *reg/mem64*	F3 0F BC /r	Count the number of trailing zeros in reg/mem64.

TZMSK Mask From Trailing Zeros

Finds the least significant one bit in the source operand, sets all bits below that bit to 1, clears all other bits to 0 (including the found bit) and writes the result to the destination. If the least significant bit of the source operand is 1, the destination is written with all zeros.

This instruction has two operands:

TZMSK *dest*, *src*

In 64-bit mode, the operand size is determined by the value of XOP.W. If XOP.W is 1, the operand size is 64-bit; if XOP.W is 0, the operand size is 32-bit. In 32-bit mode, XOP.W is ignored. 16-bit operands are not supported.

The destination (*dest*) is a general purpose register.

The source operand (*src*) is a general purpose register or a memory operand.

The TZMSK instruction effectively performs a bit-wise logical `and` of the negation of the source operand and the result of subtracting 1 from the source operand, and stores the result to the destination register:

```
sub tmp1, src, 1
not tmp2, src
and dest, tmp1, tmp2
```

The value of the carry flag of rFLAGs is generated by the `sub` pseudo-instruction and the remaining arithmetic flags are generated by the `and` pseudo-instruction.

The TZMSK instruction is a TBM instruction. Support for this instruction is indicated by CPUID Fn8000_0001_ECX[TBM] = 1.

For more information on using the CPUID instruction, see the instruction reference page for the CPUID instruction on page 165. For a description of all feature flags related to instruction subset support, see Appendix D, “Instruction Subsets and CPUID Feature Flags,” on page 587.

UD0, UD1, UD2 Undefined Operation

These opcodes generate an invalid opcode exception. Unlike other undefined opcodes that may be defined as legal instructions in the future, these opcodes are intended to stay undefined. On some AMD64 processor implementations, UD1 may report an invalid opcode exception regardless of whether fetching the ModRM byte could trigger a paging or segmentation exception.

Mnemonic	Opcode	Description
UD0	0F FF	Raise an invalid opcode exception
UD1	0F B9 /r	Raise an invalid opcode exception
UD2	0F 0B	Raise an invalid opcode exception.

Invalid opcode, #UD	X	X	X	This instruction is not recognized.

WRFSBASE Write FS.base
WRGSBASE Write GS.base

Writes the base field of the FS or GS segment descriptor with the value contained in the register operand. When supported and enabled, these instructions can be executed at any processor privilege level. Instructions are only defined in 64-bit mode. The address written to the base field must be in canonical form or a #GP fault will occur.

System software must set the FSGSBASE bit (bit 16) of CR4 to enable the WRFSBASE and WRGSBASE instructions.

Support for this instruction is indicated by CPUID Fn0000_0007_EBX_x0[FSGSBASE] = 1.

For more information on using the CPUID instruction, see the instruction reference page for the CPUID instruction on page 165. For a description of all feature flags related to instruction subset support, see Appendix D, “Instruction Subsets and CPUID Feature Flags,” on page 587.

Mnemonic	Opcode	Description
WRFSBASE *reg32*	F3 0F AE /2	Copy the contents of the specified 32-bit general-purpose register to the lower 32 bits of FS.base.
WRFSBASE *reg64*	F3 0F AE /2	Copy the contents of the specified 64-bit general-purpose register to FS.base.
WRGSBASE *reg32*	F3 0F AE /3	Copy the contents of the specified 32-bit general-purpose register to the lower 32 bits of GS.base.
WRGSBASE *reg64*	F3 0F AE /3	Copy the contents of the specified 64-bit general-purpose register to GS.base.

#UD	X	X		Instruction is not valid in compatibility or legacy modes.
			X	Instruction not supported as indicated by CPUID Fn0000_0007_EBX_x0[FSGSBASE] = 0 or, if supported, not enabled in CR4.
#GP			X	Attempt to write non-canonical address to segment base address.

XADD Exchange and Add

Exchanges the contents of a register (second operand) with the contents of a register or memory location (first operand), computes the sum of the two values, and stores the result in the first operand location.

The forms of the XADD instruction that write to memory support the LOCK prefix. For details about the LOCK prefix, see “Lock Prefix” on page 11.

Mnemonic	Opcode	Description
XADD *reg/mem8*, *reg8*	0F C0 */r*	Exchange the contents of an 8-bit register with the contents of an 8-bit destination register or memory operand and load their sum into the destination.
XADD *reg/mem16*, *reg16*	0F C1 */r*	Exchange the contents of a 16-bit register with the contents of a 16-bit destination register or memory operand and load their sum into the destination.
XADD *reg/mem32*, *reg32*	0F C1 */r*	Exchange the contents of a 32-bit register with the contents of a 32-bit destination register or memory operand and load their sum into the destination.
XADD *reg/mem64*, *reg64*	0F C1 */r*	Exchange the contents of a 64-bit register with the contents of a 64-bit destination register or memory operand and load their sum into the destination.

Page fault, #PF		X	X	A page fault resulted from the execution of the instruction.
Alignment check, #AC		X	X	An unaligned memory reference was performed while alignment checking was enabled.

XCHG Exchange

Exchanges the contents of the two operands. The operands can be two general-purpose registers or a register and a memory location. If either operand references memory, the processor locks automatically, whether or not the LOCK prefix is used and independently of the value of IOPL. For details about the LOCK prefix, see “Lock Prefix” on page 11.

The x86 architecture commonly uses the XCHG EAX, EAX instruction (opcode 90h) as a one-byte NOP. In 64-bit mode, the processor treats opcode 90h as a true NOP only if it would exchange rAX with itself. Without this special handling, the instruction would zero-extend the upper 32 bits of RAX, and thus it would not be a true no-operation. Opcode 90h can still be used to exchange rAX and r8 if the appropriate REX prefix is used.

This special handling does not apply to the two-byte ModRM form of the XCHG instruction.

Mnemonic	Opcode	Description
XCHG AX, *reg16*	90 +*rw*	Exchange the contents of the AX register with the contents of a 16-bit register.
XCHG *reg16*, AX	90 +*rw*	Exchange the contents of a 16-bit register with the contents of the AX register.
XCHG EAX, *reg32*	90 +*rd*	Exchange the contents of the EAX register with the contents of a 32-bit register.
XCHG *reg32*, EAX	90 +*rd*	Exchange the contents of a 32-bit register with the contents of the EAX register.
XCHG RAX, *reg64*	90 +*rq*	Exchange the contents of the RAX register with the contents of a 64-bit register.
XCHG *reg64*, RAX	90 +*rq*	Exchange the contents of a 64-bit register with the contents of the RAX register.
XCHG *reg/mem8*, *reg8*	86 */r*	Exchange the contents of an 8-bit register with the contents of an 8-bit register or memory operand.
XCHG *reg8*, *reg/mem8*	86 */r*	Exchange the contents of an 8-bit register or memory operand with the contents of an 8-bit register.
XCHG *reg/mem16*, *reg16*	87 */r*	Exchange the contents of a 16-bit register with the contents of a 16-bit register or memory operand.
XCHG *reg16*, *reg/mem16*	87 */r*	Exchange the contents of a 16-bit register or memory operand with the contents of a 16-bit register.
XCHG *reg/mem32*, *reg32*	87 */r*	Exchange the contents of a 32-bit register with the contents of a 32-bit register or memory operand.
XCHG *reg32*, *reg/mem32*	87 */r*	Exchange the contents of a 32-bit register or memory operand with the contents of a 32-bit register.
XCHG *reg/mem64*, *reg64*	87 */r*	Exchange the contents of a 64-bit register with the contents of a 64-bit register or memory operand.
XCHG *reg64*, *reg/mem64*	87 */r*	Exchange the contents of a 64-bit register or memory operand with the contents of a 64-bit register.

Alignment check, #AC		X	X	An unaligned memory reference was performed while alignment checking was enabled.

XLAT
XLATB
Translate Table Index

Uses the unsigned integer in the AL register as an offset into a table and copies the contents of the table entry at that location to the AL register.

The instruction uses *seg*:[rBX] as the base address of the table. The value of *seg* defaults to the DS segment, but may be overridden by a segment prefix.

This instruction writes AL without changing RAX[63:8]. This instruction ignores operand size.

The single-operand form of the XLAT instruction uses the operand to document the segment and address size attribute, but it uses the base address specified by the rBX register.

This instruction is often used to translate data from one format (such as ASCII) to another (such as EBCDIC).

Mnemonic	Opcode	Description
XLAT *mem8*	D7	Set AL to the contents of DS:[rBX + unsigned AL].
XLATB	D7	Set AL to the contents of DS:[rBX + unsigned AL].

			X	A null data segment was used to reference memory.
Page fault, #PF		X	X	A page fault resulted from the execution of the instruction.

XOR Logical Exclusive OR

Performs a bit-wise logical xor operation on both operands and stores the result in the first operand location. The first operand can be a register or memory location. The second operand can be an immediate value, a register, or a memory location. XOR-ing a register with itself clears the register.

The forms of the XOR instruction that write to memory support the LOCK prefix. For details about the LOCK prefix, see “Lock Prefix” on page 11.

The instruction performs the following operation for each bit:

X	Y	X xor Y
0	0	0
0	1	1
1	0	1
1	1	0

Mnemonic	Opcode	Description
XOR AL, *imm8*	34 *ib*	xor the contents of AL with an immediate 8-bit operand and store the result in AL.
XOR AX, *imm16*	35 *iw*	xor the contents of AX with an immediate 16-bit operand and store the result in AX.
XOR EAX, *imm32*	35 *id*	xor the contents of EAX with an immediate 32-bit operand and store the result in EAX.
XOR RAX, *imm32*	35 *id*	xor the contents of RAX with a sign-extended immediate 32-bit operand and store the result in RAX.
XOR *reg/mem8*, *imm8*	80 /6 *ib*	xor the contents of an 8-bit destination register or memory operand with an 8-bit immediate value and store the result in the destination.
XOR *reg/mem16*, *imm16*	81 /6 *iw*	xor the contents of a 16-bit destination register or memory operand with a 16-bit immediate value and store the result in the destination.
XOR *reg/mem32*, *imm32*	81 /6 *id*	xor the contents of a 32-bit destination register or memory operand with a 32-bit immediate value and store the result in the destination.
XOR *reg/mem64*, *imm32*	81 /6 *id*	xor the contents of a 64-bit destination register or memory operand with a sign-extended 32-bit immediate value and store the result in the destination.
XOR *reg/mem16*, *imm8*	83 /6 *ib*	xor the contents of a 16-bit destination register or memory operand with a sign-extended 8-bit immediate value and store the result in the destination.

Mnemonic	Opcode	Description
XOR *reg/mem32*, *imm8*	83 /6 *ib*	xor the contents of a 32-bit destination register or memory operand with a sign-extended 8-bit immediate value and store the result in the destination.
XOR *reg/mem64*, *imm8*	83 /6 *ib*	xor the contents of a 64-bit destination register or memory operand with a sign-extended 8-bit immediate value and store the result in the destination.
XOR *reg/mem8*, *reg8*	30 */r*	xor the contents of an 8-bit destination register or memory operand with the contents of an 8-bit register and store the result in the destination.
XOR *reg/mem16*, *reg16*	31 */r*	xor the contents of a 16-bit destination register or memory operand with the contents of a 16-bit register and store the result in the destination.
XOR *reg/mem32*, *reg32*	31 */r*	xor the contents of a 32-bit destination register or memory operand with the contents of a 32-bit register and store the result in the destination.
XOR *reg/mem64*, *reg64*	31 */r*	xor the contents of a 64-bit destination register or memory operand with the contents of a 64-bit register and store the result in the destination.
XOR *reg8*, *reg/mem8*	32 */r*	xor the contents of an 8-bit destination register with the contents of an 8-bit register or memory operand and store the results in the destination.
XOR *reg16*, *reg/mem16*	33 */r*	xor the contents of a 16-bit destination register with the contents of a 16-bit register or memory operand and store the results in the destination.
XOR *reg32*, *reg/mem32*	33 */r*	xor the contents of a 32-bit destination register with the contents of a 32-bit register or memory operand and store the results in the destination.

4 System Instruction Reference

This chapter describes the function, mnemonic syntax, opcodes, affected flags, and possible exceptions generated by the system instructions. System instructions are used to establish the processor operating mode, access processor resources, handle program and system errors, manage memory, and instantiate a virtual machine. Most of these instructions can only be executed by privileged software, such as the operating system or a Virtual Machine Monitor (VMM), also known as a hypervisor. Only system instructions can access certain processor resources, such as the control registers, model-specific registers, and debug registers.

Most system instructions are supported in all hardware implementations of the AMD64 architecture. The table below lists instructions that may not be supported on a given processor implementation. System software must execute the CPUID instruction using the function number listed to determine support prior to using these instructions.

Table 4-1. System Instruction Support Indicated by CPUID Feature Bits

Instruction	CPUID Feature Bit	Register[Bit]
CET_SS	0000_0007_0	ECX[7]
CLAC, STAC	0000_0007_0	EBX[20]
Long Mode and Long Mode instructions	8000_0001_EDX[LM]	EDX[29]
INVPCID	0000_0007_0	EBX[10]

There are also several other CPUID feature bits that indicate support for certain paging functions, virtual-mode extensions, machine-check exceptions, advanced programmable interrupt control (APIC), memory-type range registers (MTRRs), etc.

For more information on using the CPUID instruction, see the reference page for the CPUID instruction on page 165. For a comprehensive list of all instruction support feature flags, see Appendix D, “Instruction Subsets and CPUID Feature Flags,” on page 587. For a comprehensive list of all defined CPUID feature numbers and return values, see Appendix E, “Obtaining Processor Information Via the CPUID Instruction,” on page 593.

For further information about the system instructions and register resources, see:

- “System Instructions” in Volume 2.
- “Summary of Registers and Data Types” on page 38.
- “Notation” on page 53.
- “Instruction Prefixes” on page 5.

ARPL Adjust Requestor Privilege Level

Compares the requestor privilege level (RPL) fields of two segment selectors in the source and destination operands of the instruction. If the RPL field of the destination operand is less than the RPL field of the segment selector in the source register, then the zero flag is set and the RPL field of the destination operand is increased to match that of the source operand. Otherwise, the destination operand remains unchanged and the zero flag is cleared.

The destination operand can be either a 16-bit register or memory location; the source operand must be a 16-bit register.

The ARPL instruction is intended for use by operating-system procedures to adjust the RPL of a segment selector that has been passed to the operating system by an application program to match the privilege level of the application program. The segment selector passed to the operating system is placed in the destination operand and the segment selector for the code segment of the application program is placed in the source operand. The RPL field in the source operand represents the privilege level of the application program. The ARPL instruction then insures that the RPL of the segment selector received by the operating system is no lower than the privilege level of the application program.

See “Adjusting Access Rights” in Volume 2, for more information on access rights.

In 64-bit mode, this opcode (63H) is used for the MOVSXD instruction.

Mnemonic	Opcode	Description
ARPL *reg/mem16*, *reg16*	63 */r*	Adjust the RPL of a destination segment selector to a level not less than the RPL of the segment selector specified in the 16-bit source register. (Invalid in 64-bit mode.)

		X	X	Instruction is not supported in virtual mode
	X		X	Lock prefix (F0h) preceding opcode.
			X	CPL was not 0

CLGI Clear Global Interrupt Flag

Clears the global interrupt flag (GIF). While GIF is zero, all external interrupts are disabled.

This is a Secure Virtual Machine instruction. Support for the SVM architecture and the SVM instructions is indicated by CPUID Fn8000_0001_ECX[SVM] = 1. For more information on using the CPUID instruction, see the reference page for the CPUID instruction on page 165.

This instruction generates a #UD exception if SVM is not enabled. See “Enabling SVM” in *AMD64 Architecture Programmer’s Manual Volume-2: System Instructions*, order# 24593.

Mnemonic	Opcode	Description
CLGI	0F 01 DD	Clears the global interrupt flag (GIF).

Related Instructions

STGI

rFLAGS Affected

None.

Exceptions

Exception	Real	Virtual 8086	Protected	Cause of Exception
Invalid opcode, #UD	X	X	X	The SVM instructions are not supported as indicated by CPUID Fn8000_0001_ECX[SVM] = 0.
			X	Secure Virtual Machine was not enabled (EFER.SVME=0).
	X	X		Instruction is only recognized in protected mode.
General protection, #GP			X	CPL was not 0.

CLI Clear Interrupt Flag

Clears the interrupt flag (IF) in the rFLAGS register to zero, thereby masking external interrupts received on the INTR input. Interrupts received on the non-maskable interrupt (NMI) input are not affected by this instruction.

In real mode, this instruction clears IF to 0.

In protected mode and virtual-8086-mode, this instruction is IOPL-sensitive. If the CPL is less than or equal to the rFLAGS.IOPL field, the instruction clears IF to 0.

In protected mode, if IOPL < 3, CPL = 3, and protected mode virtual interrupts are enabled (CR4.PVI = 1), then the instruction instead clears rFLAGS.VIF to 0. If none of these conditions apply, the processor raises a general-purpose exception (#GP). For more information, see “Protected Mode Virtual Interrupts” in Volume 2.

In virtual-8086 mode, if IOPL < 3 and the virtual-8086-mode extensions are enabled (CR4.VME = 1), the CLI instruction clears the virtual interrupt flag (rFLAGS.VIF) to 0 instead.

See “Virtual-8086 Mode Extensions” in Volume 2 for more information about IOPL-sensitive instructions.

Mnemonic	Opcode	Description
CLI	FA	Clear the interrupt flag (IF) to zero.

Action

```
IF (CPL <= IOPL)
      RFLAGS.IF = 0

ELSEIF (((VIRTUAL_MODE) && (CR4.VME == 1))
        || ((PROTECTED_MODE) && (CR4.PVI == 1) && (CPL == 3)))
      RFLAGS.VIF = 0;

ELSE
      EXCEPTION[#GP(0)]
```

CLTS Clear Task-Switched Flag in CR0

Clears the task-switched (TS) flag in the CR0 register to 0. The processor sets the TS flag on each task switch. The CLTS instruction is intended to facilitate the synchronization of FPU context saves during multitasking operations.

This instruction can only be used if the current privilege level is 0.

See “System-Control Registers” in Volume 2 for more information on FPU synchronization and the TS flag.

Mnemonic	Opcode	Description
CLTS	0F 06	Clear the task-switched (TS) flag in CR0 to 0.

CLRSSBSY Clear Shadow Stack Busy

Validates the busy (in use) shadow stack token pointed to by the memory operand and clears the tokens busy bit. If the token validation checks pass, CF is cleared to 0 and SSP is cleared to 0. If the token validation checks fail, CF is set to 1 and the token and SSP are not modified.

CLRSSBY is a privileged instruction and must be executed with CPL=0, otherwise a #GP exception is generated. If shadow stacks are not enabled at the supervisor level, a #UD exception is generated.

Mnemonic	Opcode	Description
CLRSSBSY *mem64*	F3 0F AE /6	Validate shadow stack token and clear busy bit.

			X	A null data segment was used to reference memory.
			X	A non-writable data segment was used.
			X	An execute-only code segment was used to reference memory.
Page fault, #PF			X	The linear address is not a supervisor shadow stack page in the OS page tables.
			X	A page fault resulted from the execution of the instruction.

HLT Halt

Causes the microprocessor to halt instruction execution and enter the HALT state. Entering the HALT state puts the processor in low-power mode. Execution resumes when an unmasked hardware interrupt (INTR), non-maskable interrupt (NMI), system management interrupt (SMI), RESET, or INIT occurs.

If an INTR, NMI, or SMI is used to resume execution after a HLT instruction, the saved instruction pointer points to the instruction following the HLT instruction.

Before executing a HLT instruction, hardware interrupts should be enabled. If rFLAGS.IF = 0, the system will remain in a HALT state until an NMI, SMI, RESET, or INIT occurs.

If an SMI brings the processor out of the HALT state, the SMI handler can decide whether to return to the HALT state or not. See *Volume 2: System Programming*, for information on SMIs.

Current privilege level must be 0 to execute this instruction.

Mnemonic	Opcode	Description
HLT	F4	Halt instruction execution.

INT 3 Interrupt to Debug Vector

Calls the debug exception handler. This instruction maps to a 1-byte opcode (CC) that raises a #BP exception. The INT 3 instruction is normally used by debug software to set instruction breakpoints by replacing the first byte of the instruction opcode bytes with the INT 3 opcode.

This one-byte INT 3 instruction behaves differently from the two-byte INT 3 instruction (opcode CD 03) (see “INT” in Chapter 3 “General Purpose Instructions” for further information) in two ways:

The #BP exception is handled without any IOPL checking in virtual x86 mode. (IOPL mismatches will not trigger an exception.)

- In VME mode, the #BP exception is not redirected via the interrupt redirection table. (Instead, it is handled by a protected mode handler.)

Mnemonic	Opcode	Description
INT 3	CC	Trap to debugger at Interrupt 3.

For complete descriptions of the steps performed by INT instructions, see the following:

- *Legacy-Mode Interrupts:* “Legacy Protected-Mode Interrupt Control Transfers” in Volume 2.
- *Long-Mode Interrupts:* “Long-Mode Interrupt Control Transfers” in Volume 2.

Action

```
// Refer to INT instruction’s Action section for the details on INT_N_REAL,
// INT_N_PROTECTED, and INT_N_VIRTUAL_TO_PROTECTED.
INT3_START:

If (REAL_MODE)
    INT_N_REAL                  //N = 3

Page fault, #PF		X	X	A page fault resulted from the execution of the instruction.
Alignment check, #AC		X	X	An unaligned memory reference was performed while alignment checking was enabled.

INVD Invalidate Caches

Invalidates all levels of cache associated with this processor. This may or may not include lower level caches associated with another processor that shares any level of this processor's cache hierarchy.

No data is written back to main memory from invalidating the caches.

CPUID Fn8000_001D_EDX[WBINVD]_x*N* indicates the behavior of the processor at various levels of the cache hierarchy. If the feature bit is 0, the instruction causes the invalidation of all lower level caches of other processors sharing the designated level of cache. If the feature bit is 1, the instruction does not necessarily cause the invalidation of all lower level caches of other processors sharing the designated level of cache. See Appendix E, “Obtaining Processor Information Via the CPUID Instruction,” on page 593 for more information on using the CPUID function.

This is a privileged instruction. The current privilege level (CPL) of a procedure invalidating the processor’s internal caches must be 0.

To insure that data is written back to memory prior to invalidating caches, use the WBINVD instruction.

This instruction does not invalidate TLB caches.

INVD is a serializing instruction.

Mnemonic	Opcode	Description
INVD	0F 08	Invalidate internal caches and trigger external cache invalidations.

Exceptions

Exception	Real	Virtual 8086	Protected	Cause of Exception
General protection, #GP		X	X	CPL was not 0.

INVLPG Invalidate TLB Entry

Invalidates the TLB entry that would be used for the 1-byte memory operand.

This instruction invalidates the TLB entry, regardless of the G (Global) bit setting in the associated PDE or PTE entry and regardless of the page size (4 Kbytes, 2 Mbytes, 4 Mbytes, or 1 Gbyte). It may invalidate any number of additional TLB entries, in addition to the targeted entry. INVLPG only invalidates TLB entries tagged with the current PCID and also global pages regardless of PCIDs. If PCIDs are disabled (CR4.PCID=0) then the current PCID is zero.

INVLPG is a serializing instruction and a privileged instruction. The current privilege level must be 0 to execute this instruction.

See “Page Translation and Protection” in Volume 2 for more information on page translation.

Mnemonic	Opcode	Description
INVLPG *mem8*	0F 01 /7	Invalidate the TLB entry for the page containing a specified memory location.

Exceptions

Exception	Real	Virtual 8086	Protected	Cause of Exception
General protection, #GP		X	X	CPL was not 0.

INVLPGA Invalidate TLB Entry in a Specified ASID

Invalidates the TLB mapping for a given virtual page and a given ASID. The virtual (linear) address is specified in the implicit register operand rAX. The portion of rAX used to form the address is determined by the effective address size (current execution mode and optional address size prefix). The ASID is taken from ECX.

The INVLPGA instruction may invalidate any number of additional TLB entries, in addition to the targeted entry.

The INVLPGA instruction is a serializing instruction and a privileged instruction. The current privilege level must be 0 to execute this instruction.

This is a Secure Virtual Machine (SVM) instruction. Support for the SVM architecture and the SVM instructions is indicated by CPUID Fn8000_0001_ECX[SVM] = 1. For more information on using the CPUID instruction, see the reference page for the CPUID instruction on page 165.

This instruction generates a #UD exception if SVM is not enabled. See “Enabling SVM” in *AMD64 Architecture Programmer’s Manual Volume-2: System Instructions*, order# 24593.

Mnemonic	Opcode	Description
INVLPGA rAX, ECX	0F 01 DF	Invalidates the TLB mapping for the virtual page specified in rAX and the ASID specified in ECX.

Related Instructions

INVLPG, INVLPGB, INVPCID

rFLAGS Affected

None.

Exceptions

Exception	Real	Virtual 8086	Protected	Cause of Exception
Invalid opcode, #UD	X	X	X	The SVM instructions are not supported as indicated by CPUID Fn8000_0001_ECX[SVM] = 0.
			X	Secure Virtual Machine was not enabled (EFER.SVME=0).
	X	X		Instruction is only recognized in protected mode.
General protection, #GP			X	CPL was not 0.

INVLPGB Invalidate TLB Entry(s) with Broadcast

Invalidates the TLB entry or entries specified by the descriptor in the rAX:EDX register pair. Invalidations are done both in the local TLB and broadcast to all processors to perform the same invalidations. The virtual (linear) address is specified in the implicit register operand rAX. The portion of rAX used to form the address is determined by the effective address size.

The TLB control field is specified in rAX[5:0]. It determines which components of the address (VA, PCID, ASID) are valid for comparison in the TLB and whether to include global entries in the invalidation process. If rAX[4] is set, only the final translation is invalidated and not the cached upper level TLB entries that lead to the final page. This ability may not be possible with all processors in which case the bit is ignored. If rAX[5] is set, all nested translations that could be used for guest translation selected in rAX[4:0] are flushed. rAX[5] can only be set if CPUID Fn8000_0008_EBX[21 =1. ECX provides a count of the number of pages to include in invalidation with the specified address and the page size at which to increment the specified address.

The descriptor in rAX has the following format:

rAX	Attributes
0	Valid VA
1	Valid PCID
2	Valid ASID
3	Include Global
4	Final Translation Only
5	Include Nested Translations
11:6	Reserved, MBZ
63:12 or 31:12	VA

rAX[3:0] provides for various types of invalidations. A few examples are listed in the following table, but all values are legal.

rAX [3:0]	Action
0xF	Invalidate all TLB entries that match {ASID, PCID, VA} including Global
0xC	Invalidate all TLB entries that match {ASID} including Global
0xD	Invalidate all TLB entries that match {ASID, VA} including Global
0x4	Invalidate all TLB entries that match {ASID} excluding Global

rAX [3:0]	Action
0xE	Invalidate all TLB entries that match {ASID, PCID} including Global
0x6	Invalidate all TLB entries that match {ASID, PCID} excluding Global

The descriptor in EDX has the following format:

EDX	Attributes
15:0	ASID
27:16	PCID
31:28	Reserved, MBZ

ECX[15:0] contains a count of the number of sequential pages to invalidate in addition to the original virtual address, starting from the virtual address specified in rAX. A count of 0 invalidates a single page. ECX[31]=0 indicates to increment the virtual address at the 4K boundary. ECX[31]=1 indicates to increment the virtual address at the 2M boundary. The maximum count supported is reported in CPUID function 8000_0008h, EDX[15:0].

This instruction invalidates the TLB entry or entries, regardless of the page size (4 Kbytes, 2 Mbytes, 4 Mbytes, or 1 Gbyte). It may invalidate any number of additional TLB entries in addition to the targeted entry or entries to accomplish the specified function. INVLPGB follows the same rules for cached upper TLB entries as INVLPG which is controlled by EFER.TCE. However, since this is a broadcast, the invalidation is controlled by the EFER.TCE value on the processor executing the INVLPGB instruction. (See Section 3, “Translation Cache Extension” in AMD64 Architecture Programmer’s Manual Volume 2 for more information on EFER.TCE.)

Under the following circumstances, execution of INVLPGB will result in a General Protection fault (#GP):

- If SVM is disabled, requesting the ASID field with any value but zero, even if the ASID is not necessary for the flush.
- If PCID is disabled, requesting the PCID field with any value but zero, even if the PCID is not necessary for the flush.
- If the request exceeds the number of valid ASIDs for the processor, even if the ASID is not valid.
- Attempts to request a count larger than the maximum count supported, even if the VA is not valid
- Attempts to execute an INVLPGB while in 4M paging mode.

Guest Usage of INVLPGB. Guest usage of INVLPGB is supported only when the instruction has been explicitly enabled by the hypervisor in the VMCB (see APM Volume 2 Appendix B, Table B-1: VMCB Layout, Control Area). Support for INVLPGB/TLBSYNC hypervisor enable in VMCB is indicated by CPUID Fn8000_000A_EDX[24] = 1.

A guest that executes a legal INVLPGB that is not intercepted will have the requested ASID field replaced by the current ASID and the valid ASID bit set before doing the broadcast invalidation. Because of its broadcast nature, the ASID field must be global and all processors must allocate the same ASID to the same Guest for proper operation. Hypervisors that do not support a global ASID must intercept the Guest usage of INVLPGB, if enabled, for proper behavior.

Two forms of INVLPGB intercepts, conditional and unconditional, are available to the hypervisor. The unconditional intercept traps all guest usage of INVLPGB. The conditional intercept traps only illegally-specified INVLPGB instructions. An illegally specified INVLPGB is one that would, if not intercepted, cause a #GP for any reason other than not being executed at CPL 0.

INVLPGB is a privileged instruction but not a serializing instruction. It must be executed at CPL 0, but will broadcast the invalidate to the rest of the processors which may be running at any privilege level.

INVLPGB is weakly ordered as it broadcasts the invalidation types throughout the system to all processors, so that a batch of invalidations can be done in a parallel fashion. For software to guarantee that all processors have seen and done the TLB invalidations, a TLBSYNC must be executed on the initiating processor.

Mnemonic	Opcode	Description
INVLPGB	0F 01 FE	Invalidates TLB entry(s) with Broadcast.

Invalid opcode, #UD	X	X		This instruction is only recognized in protected mode.
	X	X	X	This instruction is not supported as indicated by CPUID Fn8000_0008_EBX[INVLPGB] = 0.
			X	The hypervisor has not enabled Guest usage of this instruction.

Exception	Real	Virtual 8086	Protected	Cause of Exception
General protection, #GP			X	CPL was not 0.
			X	EAX[11:6] is not zero or EAX[5] not zero if not supported.
				EDX[31:28] is not zero.
			X	CR4.PCID =0 and EDX[PCID] is not zero.
			X	EFER.SVME =0 and EDX[ASID] is not zero.
			X	EDX[ASID] > number of supported ASIDs.
			X	ECX[15:0] > maximum page count supported.
			X	4M paging is active.

INVPCID Invalidate TLB Entry(s) in a Specified PCID

Invalidates the TLB entry or entries on the logical processor for a given PCID in the local TLB based on the operation type specified in the register operand and the PCID and virtual (linear) address specified by the descriptor in the memory operand. (See “Process Context Identifier” in Chapter 5 of the AMD64 Architecture Programmer’s Manual Volume 2 for more information on PCIDs.)

The register operand is always 64 bits in 64-bit mode and 32 bits outside 64-bit mode regardless of value of CS.D.

The operation type is specified in the register operand bits [1:0]. The operation type determines which components of the address (VA, PCID) are valid for comparison in the TLB and whether to include global valid bits in the invalidation process.

The operation types are:

reg32/64 [1:0]	Action
0	Invalidate TLB entries that match {PCID, VA} excluding Global
1	Invalidate all TLB entries that match {PCID} excluding Global
2	Invalidate all TLB entries including Global
3	Invalidate all TLB entries excluding Global

The descriptor in the memory operand is formatted as follows:

127:64	63:12	11:0
VA	Reserved, MBZ	PCID

This instruction invalidates the TLB entry or entries, regardless of the page size (4 Kbytes, 2 Mbytes, 4 Mbytes, or 1 Gbyte). It may invalidate any number of additional TLB entries, in addition to the targeted entry or entries to accomplish the specified function. INVPCID follows the same rules for cached upper TLB entries as INVLPG which is controlled by EFER.TCE. (See Section 3, “Translation Cache Extension” in AMD64 Architecture Programmer’s Manual Volume 2 for more information on EFER.TCE.)

If PCID is disabled (CR4.PCID = 0), all TLB entries are being cached with PCID = 0. When CR4.PCID = 0, executing INVPCID with type 0 and 1 is only allowed if the PCID specified in the descriptor is zero. Furthermore, when CR4.PCID = 0, executing INVPCID with type 2 or 3 invalidate mappings only for PCID = 0.

INVPCID is a serializing instruction and a privileged instruction. The current privilege level must be 0 to execute this instruction.

Mnemonic	Opcode	Description
INVPCID reg32, mem128	66 0F 38 82 /r	Invalidates the TLB entry(s) by PCID in r32 and descriptor in mem28.
INVPCID reg64, mem128	66 0F 38 82 /r	Invalidates the TLB entry(s) by PCID in r64 and descriptor in mem28.

			X	A null data segment was used to reference memory.
Stack, #SS			X	A memory address exceeded the stack segment limit or was non-canonical.
Page Fault, #PF			X	A page fault resulted from the execution of the instruction.

IRET
IRETD
IRETQ
Return from Interrupt

Returns program control from an exception or interrupt handler to a program or procedure previously interrupted by an exception, an external interrupt, or a software-generated interrupt. These instructions also perform a return from a nested task. All flags, CS, and rIP are restored to the values they had before the interrupt so that execution may continue at the next instruction following the interrupt or exception. In 64-bit mode or if the CPL changes, SS and RSP are also restored.

IRET, IRETD, and IRETQ are synonyms mapping to the same opcode. They are intended to provide semantically distinct forms for various opcode sizes. The IRET instruction is used for 16-bit operand size; IRETD is used for 32-bit operand sizes; IRETQ is used for 64-bit operands. The latter form is only meaningful in 64-bit mode.

IRET, IRETD, or IRETQ must be used to terminate the exception or interrupt handler associated with the exception, external interrupt, or software-generated interrupt.

IRET*x* is a serializing instruction.

For detailed descriptions of the steps performed by IRET*x* instructions, see the following:

- *Legacy-Mode Interrupts:* “Legacy Protected-Mode Interrupt Control Transfers” in Volume 2.
- *Long-Mode Interrupts:* “Long-Mode Interrupt Control Transfers” in Volume 2.

Mnemonic	Opcode	Description
IRET	CF	Return from interrupt (16-bit operand size).
IRETD	CF	Return from interrupt (32-bit operand size).
IRETQ	CF	Return from interrupt (64-bit operand size).

Exceptions

Exception	Real	Virtual 8086	Protected	Cause of Exception
Segment not present, #NP (selector)			X	The return code segment was marked not present.
Stack, #SS	X	X	X	A memory address exceeded the stack segment limit or was non-canonical.
Stack, #SS (selector)			X	The SS register was loaded with a non-null segment selector and the segment was marked not present.
General protection, #GP	X	X	X	The target offset exceeded the code segment limit or was non-canonical.
		X		IOPL was less than 3 and one of the following conditions was true: • CR4.VME was 0. • The effective operand size was 32-bit. • Both the original EFLAGS.VIP and the new EFLAGS.IF were set. • The new EFLAGS.TF was set.
			X	IRET*x* was executed in long mode while EFLAGS.NT=1.

Exception	Real	Virtual 8086	Protected	Cause of Exception
General protection, #GP (selector)			X	The return code selector was a null selector.
			X	The return stack selector was a null selector and the return mode was non-64-bit mode or CPL was 3.
			X	The return code or stack descriptor exceeded the descriptor table limit.
			X	The return code or stack selector's TI bit was set but the LDT selector was a null selector.
			X	The segment descriptor for the return code was not a code segment.
			X	The RPL of the return code segment selector was less than the CPL.
			X	The return code segment was non-conforming and the segment selector's DPL was not equal to the RPL of the code segment's segment selector.
			X	The return code segment was conforming and the segment selector's DPL was greater than the RPL of the code segment's segment selector.
			X	The segment descriptor for the return stack was not a writable data segment.
			X	The stack segment descriptor DPL was not equal to the RPL of the return code segment selector.
			X	The stack segment selector RPL was not equal to the RPL of the return code segment selector.
Page fault, #PF		X	X	A page fault resulted from the execution of the instruction.
Alignment check, #AC		X	X	An unaligned memory reference was performed while alignment checking was enabled.
Control-protection, #CP			X	The return address on the program stack did not match the address on the shadow stack, or the previous SSP is not 4 byte aligned, or the previous SSP was not <4GB when returning to 32-bit mode or compatibility mode.

LAR Load Access Rights Byte

Loads the access rights from the segment descriptor specified by a 16-bit source register or memory operand into a specified 16-bit, 32-bit, or 64-bit general-purpose register and sets the zero (ZF) flag in the rFLAGS register if successful. LAR clears the zero flag if the descriptor is invalid for any reason.

The LAR instruction checks that:

- the segment selector is not a null selector.
- the descriptor is within the GDT or LDT limit.
- the descriptor DPL is greater than or equal to both the CPL and RPL, or the segment is a conforming code segment.
- the descriptor type is valid for the LAR instruction. Valid descriptor types are shown in the following table. LDT and TSS descriptors in 64-bit mode, and call-gate descriptors in long mode, are only valid if bits 12:8 of doubleword +12 are zero.

See Volume 2, Section 6.4 for more information on checking access rights using LAR.

Valid Descriptor Type		Description
Legacy Mode	**Long Mode**	
All	All	All code and data descriptors
1	—	Available 16-bit TSS
2	2	LDT
3	—	Busy 16-bit TSS
4	—	16-bit call gate
5	—	Task gate
9	9	Available 32-bit or 64-bit TSS
B	B	Busy 32-bit or 64-bit TSS
C	C	32-bit or 64-bit call gate

If the segment descriptor passes these checks, the attributes are loaded into the destination general-purpose register. If it does not, then the zero flag is cleared and the destination register is not modified.

When the operand size is 16 bits, access rights include the DPL and Type fields located in bytes 4 and 5 of the descriptor table entry. Before loading the access rights into the destination operand, the low order word is masked with FF00H.

When the operand size is 32 or 64 bits, access rights include the DPL and type as well as the descriptor type (S field), segment present (P flag), available to system (AVL flag), default operation size (D/B

flag), and granularity flags located in bytes 4–7 of the descriptor. Before being loaded into the destination operand, the doubleword is masked with 00FF_FF00H.

In 64-bit mode, for both 32-bit and 64-bit operand sizes, 32-bit register results are zero-extended to 64 bits.

This instruction can only be executed in protected mode.

Mnemonic	Opcode	Description
LAR *reg16*, *reg/mem16*	0F 02 */r*	Reads the GDT/LDT descriptor referenced by the 16-bit source operand, masks the attributes with FF00h and saves the result in the 16-bit destination register.
LAR *reg32*, *reg/mem16*	0F 02 */r*	Reads the GDT/LDT descriptor referenced by the 16-bit source operand, masks the attributes with 00FFFF00h and saves the result in the 32-bit destination register.
LAR *reg64*, *reg/mem16*	0F 02 */r*	Reads the GDT/LDT descriptor referenced by the 16-bit source operand, masks the attributes with 00FFFF00h and saves the result in the 64-bit destination register.

Alignment check, #AC			X	An unaligned memory reference was performed while alignment checking was enabled.

LGDT Load Global Descriptor Table Register

Loads the pseudo-descriptor specified by the source operand into the global descriptor table register (GDTR). The pseudo-descriptor is a memory location containing the GDTR base and limit. In legacy and compatibility mode, the pseudo-descriptor is 6 bytes; in 64-bit mode, it is 10 bytes.

If the operand size is 16 bits, the high-order byte of the 6-byte pseudo-descriptor is not used. The lower two bytes specify the 16-bit limit and the third, fourth, and fifth bytes specify the 24-bit base address. The high-order byte of the GDTR is filled with zeros.

If the operand size is 32 bits, the lower two bytes specify the 16-bit limit and the upper four bytes specify a 32-bit base address.

In 64-bit mode, the lower two bytes specify the 16-bit limit and the upper eight bytes specify a 64-bit base address. In 64-bit mode, operand-size prefixes are ignored and the operand size is forced to 64-bits; therefore, the pseudo-descriptor is always 10 bytes.

This instruction is only used in operating system software and must be executed at CPL 0. It is typically executed once in real mode to initialize the processor before switching to protected mode.

LGDT is a serializing instruction.

Mnemonic	Opcode	Description
LGDT *mem16:32*	0F 01 /2	Loads *mem16:32* into the global descriptor table register.
LGDT *mem16:64*	0F 01 /2	Loads *mem16:64* into the global descriptor table register.

Page fault, #PF			X	A page fault resulted from the execution of the instruction.

LIDT Load Interrupt Descriptor Table Register

Loads the pseudo-descriptor specified by the source operand into the interrupt descriptor table register (IDTR). The pseudo-descriptor is a memory location containing the IDTR base and limit. In legacy and compatibility mode, the pseudo-descriptor is six bytes; in 64-bit mode, it is 10 bytes.

If the operand size is 16 bits, the high-order byte of the 6-byte pseudo-descriptor is not used. The lower two bytes specify the 16-bit limit and the third, fourth, and fifth bytes specify the 24-bit base address. The high-order byte of the IDTR is filled with zeros.

If the operand size is 32 bits, the lower two bytes specify the 16-bit limit and the upper four bytes specify a 32-bit base address.

In 64-bit mode, the lower two bytes specify the 16-bit limit, and the upper eight bytes specify a 64-bit base address. In 64-bit mode, operand-size prefixes are ignored and the operand size is forced to 64-bits; therefore, the pseudo-descriptor is always 10 bytes.

This instruction is only used in operating system software and must be executed at CPL 0. It is normally executed once in real mode to initialize the processor before switching to protected mode.

LIDT is a serializing instruction.

Mnemonic	Opcode	Description
LIDT *mem16:32*	0F 01 /3	Loads *mem16:32* into the interrupt descriptor table register.
LIDT *mem16:64*	0F 01 /3	Loads *mem16:64* into the interrupt descriptor table register.

Page fault, #PF			X	A page fault resulted from the execution of the instruction.

LLDT Load Local Descriptor Table Register

Loads the specified segment selector into the visible portion of the local descriptor table (LDT). The processor uses the selector to locate the descriptor for the LDT in the global descriptor table. It then loads this descriptor into the hidden portion of the LDTR.

If the source operand is a null selector, the LDTR is marked invalid and all references to descriptors in the LDT will generate a general protection exception (#GP), except for the LAR, VERR, VERW or LSL instructions.

In legacy and compatibility modes, the LDT descriptor is 8 bytes long and contains a 32-bit base address.

In 64-bit mode, the LDT descriptor is 16-bytes long and contains a 64-bit base address. The LDT descriptor type (02h) is redefined in 64-bit mode for use as the 16-byte LDT descriptor.

This instruction must be executed in protected mode. It is only provided for use by operating system software at CPL 0.

LLDT is a serializing instruction.

Mnemonic	Opcode	Description
LLDT *reg/mem16*	0F 00 /2	Load the 16-bit segment selector into the local descriptor table register and load the LDT descriptor from the GDT.

			X	The new LDT base address was non-canonical.
Page fault, #PF			X	A page fault resulted from the execution of the instruction.

LMSW Load Machine Status Word

Loads the lower four bits of the 16-bit register or memory operand into bits 3:0 of the machine status word in register CR0. Only the protection enabled (PE), monitor coprocessor (MP), emulation (EM), and task switched (TS) bits of CR0 are modified. Additionally, LMSW can set CR0.PE, but cannot clear it.

The LMSW instruction can be used only when the current privilege level is 0. It is only provided for compatibility with early processors.

Use the MOV CR0 instruction to load all 32 or 64 bits of CR0.

Mnemonic	Opcode	Description
LMSW *reg/mem16*	0F 01 /6	Load the lower 4 bits of the source into the lower 4 bits of CR0.

Related Instructions

MOV CR*n*, SMSW

Page fault, #PF			X	A page fault resulted from the execution of the instruction.

LSL Load Segment Limit

Loads the segment limit from the segment descriptor specified by a 16-bit source register or memory operand into a specified 16-bit, 32-bit, or 64-bit general-purpose register and sets the zero (ZF) flag in the rFLAGS register if successful. LSL clears the zero flag if the descriptor is invalid for any reason.

In 64-bit mode, for both 32-bit and 64-bit operand sizes, 32-bit register results are zero-extended to 64 bits.

The LSL instruction checks that:

- the segment selector is not a null selector.
- the descriptor is within the GDT or LDT limit.
- the descriptor DPL is greater than or equal to both the CPL and RPL, or the segment is a conforming code segment.
- the descriptor type is valid for the LAR instruction. Valid descriptor types are shown in the following table. LDT and TSS descriptors in 64-bit mode are only valid if bits 12:8 of doubleword +12 are zero, as described in “System Descriptors” in Volume 2.

Valid Descriptor Type		Description
Legacy Mode	**Long Mode**	
—	—	All code and data descriptors
1	—	Available 16-bit TSS
2	2	LDT
3	—	Busy 16-bit TSS
9	9	Available 32-bit or 64-bit TSS
B	B	Busy 32-bit or 64-bit TSS

If the segment selector passes these checks and the segment limit is loaded into the destination general-purpose register, the instruction sets the zero flag of the rFLAGS register to 1. If the selector does not pass the checks, then LSL clears the zero flag to 0 and does not modify the destination.

The instruction calculates the segment limit to 32 bits, taking the 20-bit limit and the granularity bit into account. When the operand size is 16 bits, it truncates the upper 16 bits of the 32-bit adjusted segment limit and loads the lower 16-bits into the target register.

Mnemonic	Opcode	Description
LSL *reg16*, *reg/mem16*	0F 03 */r*	Loads a 16-bit general-purpose register with the segment limit for a selector specified in a 16-bit memory or register operand.

LSL *reg32*, *reg/mem16*	0F 03 */r*	Loads a 32-bit general-purpose register with the segment limit for a selector specified in a 16-bit memory or register operand.
LSL *reg64*, *reg/mem16*	0F 03 */r*	Loads a 64-bit general-purpose register with the segment limit for a selector specified in a 16-bit memory or register operand.

			X	A null data segment was used to reference memory.
Page fault, #PF			X	A page fault resulted from the execution of the instruction.
Alignment check, #AC			X	An unaligned memory reference was performed while alignment checking was enabled.

LTR Load Task Register

Loads the specified segment selector into the visible portion of the task register (TR). The processor uses the selector to locate the descriptor for the TSS in the global descriptor table. It then loads this descriptor into the hidden portion of TR. The TSS descriptor in the GDT is marked busy, but no task switch is made.

If the source operand is null, a general protection exception (#GP) is generated.

In legacy and compatibility modes, the TSS descriptor is 8 bytes long and contains a 32-bit base address.

In 64-bit mode, the instruction references a 64-bit descriptor to load a 64-bit base address. The TSS type (09H) is redefined in 64-bit mode for use as the 16-byte TSS descriptor.

This instruction must be executed in protected mode when the current privilege level is 0. It is only provided for use by operating system software.

The operand size attribute has no effect on this instruction.

LTR is a serializing instruction.

Mnemonic	Opcode	Description
LTR *reg/mem16*	0F 00 /3	Load the 16-bit segment selector into the task register and load the TSS descriptor from the GDT.

MONITOR Setup Monitor Address

Establishes a linear address range of memory for hardware to monitor and puts the processor in the monitor event pending state. When in the monitor event pending state, the monitoring hardware detects stores to the specified linear address range and causes the processor to exit the monitor event pending state. The MWAIT instruction uses the state of the monitor hardware.

The address range should be a write-back memory type. Executing MONITOR on an address range for a non-write-back memory type is not guaranteed to cause the processor to enter the monitor event pending state. The size of the linear address range that is established by the MONITOR instruction can be determined by CPUID function 0000_0005h.

The [rAX] register provides the effective address. The DS segment is the default segment used to create the linear address. Segment overrides may be used with the MONITOR instruction.

The ECX register specifies optional extensions for the MONITOR instruction. There are currently no extensions defined and setting any bits in ECX will result in a #GP exception. The ECX register operand is implicitly 32-bits.

The EDX register specifies optional hints for the MONITOR instruction. There are currently no hints defined and EDX is ignored by the processor. The EDX register operand is implicitly 32-bits.

The MONITOR instruction can be executed at CPL 0 and is allowed at CPL > 0 only if MSR C001_0015h[MonMwaitUserEn] = 1. When MSR C001_0015h[MonMwaitUserEn] = 0, MONITOR generates #UD at CPL > 0. (See the *BIOS and Kernel Developer's Guide* applicable to your product for specific details on MSR C001_0015h.)

MONITOR performs the same segmentation and paging checks as a 1-byte read.

Support for the MONITOR instruction is indicated by CPUID Fn0000_0001_ECX[MONITOR] = 1. Software must check the CPUID bit once per program or library initialization before using the MONITOR instruction, or inconsistent behavior may result. Software designed to run at CPL greater than 0 must also check for availability by testing whether executing MONITOR causes a #UD exception.

The following pseudo-code shows typical usage of a MONITOR/MWAIT pair:

```
EAX = Linear_Address_to_Monitor;
ECX = 0;  // Extensions
EDX = 0;  // Hints

while (!matching_store_done){
      MONITOR EAX, ECX, EDX
      IF (!matching_store_done) {
           MWAIT EAX, ECX
  }
}
```

Mnemonic	Opcode	Description
MONITOR	0F 01 C8	Establishes a linear address range to be monitored by hardware and activates the monitor hardware.

MOV CR*n* Move to/from Control Registers

Moves the contents of a 32-bit or 64-bit general-purpose register to a control register or vice versa.

In 64-bit mode, the operand size is fixed at 64 bits without the need for a REX prefix. In non-64-bit mode, the operand size is fixed at 32 bits and the upper 32 bits of the destination are forced to 0.

CR0 maintains the state of various control bits. CR2 and CR3 are used for page translation. CR4 holds various feature enable bits. CR8 is used to prioritize external interrupts. CR1, CR5, CR6, CR7, and CR9 through CR15 are all reserved and raise an undefined opcode exception (#UD) if referenced.

CR8 can be read and written in 64-bit mode, using a REX prefix. CR8 can be read and written in all modes using a LOCK prefix instead of a REX prefix to specify the additional opcode bit. To verify whether the LOCK prefix can be used in this way, check for support of this feature. CPUID Fn8000_0001_ECX[AltMovCr8] = 1, indicates that this feature is supported.

For more information on using the CPUID instruction, see the description of the CPUID instruction on page 165.

CR8 can also be read and modified using the task priority register described in “System-Control Registers” in Volume 2.

This instruction is always treated as a register-to-register (MOD = 11) instruction, regardless of the encoding of the MOD field in the MODR/M byte.

MOV CR*n* is a privileged instruction and must always be executed at CPL = 0.

MOV CR*n* is a serializing instruction.

Mnemonic	Opcode	Description
MOV CR*n*, *reg32*	0F 22 /r	Move the contents of a 32-bit register to CR*n*
MOV CR*n*, *reg64*	0F 22 /r	Move the contents of a 64-bit register to CR*n*
MOV *reg32*, CR*n*	0F 20 /r	Move the contents of CR*n* to a 32-bit register.
MOV *reg64*, CR*n*	0F 20 /r	Move the contents of CR*n* to a 64-bit register.
MOV CR8, *reg32*	F0 0F 22/r	Move the contents of a 32-bit register to CR8.
MOV CR8, *reg64*	F0 0F 22/r	Move the contents of a 64-bit register to CR8.
MOV reg32, CR8	F0 0F 20/r	Move the contents of CR8 into a 32-bit register.
MOV reg64, CR8	F0 0F 20/r	Move the contents of CR8 into a 64-bit register.

			X	An attempt was made to set CR0.PG=0 when CR4.PCIDE=1.

MOV DR*n* Move to/from Debug Registers

Moves the contents of a debug register into a 32-bit or 64-bit general-purpose register or vice versa.

In 64-bit mode, the operand size is fixed at 64 bits without the need for a REX prefix. In non-64-bit mode, the operand size is fixed at 32-bits and the upper 32 bits of the destination are forced to 0.

DR0 through DR3 are linear breakpoint address registers. DR6 is the debug status register and DR7 is the debug control register. DR4 and DR5 are aliased to DR6 and DR7 if CR4.DE = 0, and are reserved if CR4.DE = 1.

DR8 through DR15 are reserved and generate an undefined opcode exception if referenced.

These instructions are privileged and must be executed at CPL 0.

The `MOV DRn,reg32` and `MOV DRn,reg64` instructions are serializing instructions.

The MOV(DR) instruction is always treated as a register-to-register (MOD = 11) instruction, regardless of the encoding of the MOD field in the MODR/M byte.

See “Debug and Performance Resources” in Volume 2 for details.

Mnemonic	Opcode	Description
MOV *reg32*, DR*n*	0F 21 /r	Move the contents of DR*n* to a 32-bit register.
MOV *reg64*, DR*n*	0F 21 /r	Move the contents of DR*n* to a 64-bit register.
MOV DR*n*, *reg32*	0F 23 /r	Move the contents of a 32-bit register to DR*n*.
MOV DR*n*, *reg64*	0F 23 /r	Move the contents of a 64-bit register to DR*n*.

MWAIT Monitor Wait

Used in conjunction with the MONITOR instruction to cause a processor to wait until a store occurs to a specific linear address range from another processor. The previously executed MONITOR instruction causes the processor to enter the monitor event pending state. The MWAIT instruction may enter an implementation dependent power state until the monitor event pending state is exited. The MWAIT instruction has the same effect on architectural state as the NOP instruction.

Events that cause an exit from the monitor event pending state include:

- A store from another processor matches the address range established by the MONITOR instruction.
- Any unmasked interrupt, including INTR, NMI, SMI, INIT.
- RESET.
- Any far control transfer that occurs between the MONITOR and the MWAIT.

EAX specifies optional hints for the MWAIT instruction. Optimized C-state request is communicated through EAX[7:4]. The processor C-state is EAX[7:4]+1, so to request C0 is to place the value F in EAX[7:4] and to request C1 is to place the value 0 in EAX[7:4]. All other components of EAX should be zero when making the C1 request. Setting a reserved bit in EAX is ignored by the processor. This is implicitly a 32-bit operand.

ECX specifies optional extensions for the MWAIT instruction. The only extension currently defined is ECX bit 0, which allows interrupts to wake MWAIT, even when eFLAGS.IF = 0. Support for this extension is indicated by a feature flage returned by the CPUID instruction. Setting any unsupported bit in ECX results in a #GP exception. This is implicitly a 32-bit operand.

CPUID Function 0000_0005h indicates support for extended features of MONITOR/MWAIT:

- CPUID Fn0000_0005_ECX[EMX] = 1 indicates support for enumeration of MONITOR/MWAIT extensions.
- CPUID Fn0000_0005_ECX[IBE] = 1 indicates that MWAIT can set ECX[0] to allow interrupts to cause an exit from the monitor event pending state even when eFLAGS.IF = 0.

The MWAIT instruction can be executed at CPL 0 and is allowed at CPL > 0 only if MSR C001_0015h[MonMwaitUserEn] =1. When MSR C001_0015h[MonMwaitUserEn] is 0, MWAIT generates #UD at CPL > 0. (See the *BIOS and Kernel Developer's Guide* applicable to your product for specific details on MSR C001_0015h.)

Support for the MWAIT instruction is indicated by CPUID Fn0000_0001_ECX[MONITOR] = 1. Software MUST check the CPUID bit once per program or library initialization before using the MWAIT instruction, or inconsistent behavior may result. Software designed to run at CPL greater than 0 must also check for availability by testing whether executing MWAIT causes a #UD exception.

The use of the MWAIT instruction is contingent upon the satisfaction of the following coding requirements:

- MONITOR must precede the MWAIT and occur in the same loop.
- MWAIT must be conditionally executed only if the awaited store has not already occurred. (This prevents a race condition between the MONITOR instruction arming the monitoring hardware and the store intended to trigger the monitoring hardware.)

The following pseudo-code shows typical usage of a MONITOR/MWAIT pair:

```
EAX = Linear_Address_to_Monitor;
ECX = 0;  // Extensions
EDX = 0;  // Hints

WHILE (!matching_store_done ){
     MONITOR EAX, ECX, EDX
     IF ( !matching_store_done ) {
          MWAIT EAX, ECX
     }
}
```

Mnemonic	Opcode	Description
MWAIT	0F 01 C9	Causes the processor to stop instruction execution and enter an implementation-dependent optimized state until occurrence of a class of events.

PSMASH Page Smash

Expands a 2MB-page RMP entry into a corresponding set of contiguous 4KB-page RMP entries. The 2MB page's system physical address is specified in the RAX register.

The new entries inherit the attributes of the original entry. Upon completion, a return code is stored in EAX. rFLAGS bits OF, ZF, AF, PF and SF are set based on this return code.

The PSMASH instruction invalidates all TLB entries in the system that translate to the 2MB page being expanded.

This instruction is intended for hypervisor use. Attempted execution at an ASID other than 0 will result in a FAIL_PERMISSION return code.

This is a privileged instruction. Attempted execution at a privilege level other than CPL0 will result in a #GP(0) exception. In addition, this instruction is only valid in 64-bit mode with SNP enabled; in all other modes a #UD exception will be generated.

Support for this instruction is indicated by CPUID Fn8000_001F_EAX[SNP]=1.

Mnemonic	Opcode	Description
PSMASH	F3 0F 01 FF	Creates 512 4KB RMP entries from a 2MB RMP entry

Action

```
SYSTEM_PA = RAX & ~0x1FFFFF

IF (!64BIT_MODE)                // Instruction only valid in 64-bit mode
   EXCEPTION [#UD]

IF (!SYSCFG.SNP_EN)             // Instruction only valid when SNP is enabled
   EXCEPTION [#UD]

IF (CPL != 0)                   // Instruction only allowed at CPL 0
   EXCEPTION [#GP(0)]

IF (CURRENT_ASID != 0)          // Instruction only allowed at ASID 0
   EAX = FAIL_PERMISSION
   EXIT

RMP_ENTRY_PA = RMP_BASE + 0x4000 + (SYSTEM_PA / 0x1000) * 16

IF (RMP_ENTRY_PA > RMP_END)     // System address must have an RMP entry
   EAX = FAIL_INPUT
   EXIT

temp_RMP = READ_MEM_PA.o [RMP_ENTRY_PA]

IF (temp_RMP.IMMUTABLE || !temp_RMP.ASSIGNED || (temp_RMP.PAGE_SIZE != 2MB))
```

```
  EAX = FAIL_BADADDR
  EXIT

temp_RMP.PAGE_ SIZE = 4KB
WRITE_MEM_PA.o [RMP_ENTRY_PA] = temp_RMP

FOR (I = 1; I < 512, I++)
{
   temp_RMP.GUEST_PA = temp_RMP.GUEST_PA + 0x1000;
   WRITE_MEM_PA.o [RMP_ENTRY_PA + I * 16] = temp_RMP;
}

EAX = SUCCESS
EXIT
```

Return Codes

Value	Name	Description
0	SUCCESS	Successful completion
1	FAIL_INPUT	Illegal input parameters
2	FAIL_PERMISSION	Current ASID not 0
3	FAIL_INUSE	Another processor is modifying the same RMP entry
4	FAIL_BADADDR	The page did not meet smashing criteria

PVALIDATE Page Validate

Validates or rescinds validation of a guest page's RMP entry. The guest virtual address is specified in the register operand rAX. The portion of RAX used to form the address is determined by the effective address size (current execution mode and optional address size prefix). The page size is specified in ECX[0]. The new RMP Validated bit is specified in EDX[0].

The PVALIDATE instruction is used by an SNP-active guest to modify the validation status of a page. The PVALIDATE instruction will attempt to access the provided page and will take a #VMEXIT(NPF) if a nested translation error occurs or the translated address is outside the range of memory covered by the RMP. Assuming no error is detected, the PVALIDATE instruction will store EDX[0] to the Validated bit in the page's RMP entry.

Upon completion, a return code is stored in EAX. rFLAGS bits OF, ZF, AF, PF and SF are set based on this return code. If the instruction completed successfully, the rFLAGS bit CF indicates if the contents of the RMP entry were changed or not.

While this instruction is intended for use in SNP-active guest system software, it is recognized in any operating mode at CPL0. If the PVALIDATE instruction is executed by an SNP-active guest and changes the Validated bit in the RMP entry, upon completion it sets rFLAGS.CF to 0. If the PVALIDATE instruction is executed in a non-SNP-active environment or does not change the Validated bit in the RMP entry, it sets rFLAGS.CF to 1 and otherwise behaves as a NOP instruction.

This is a privileged instruction. Attempted execution at a privilege level other than CPL0 will result in a #GP(0) exception.

PVALIDATE performs the same segmentation and paging checks as a 1-byte read. PVALIDATE does not invalidate TLB caches.

Support for this instruction is indicated by CPUID Fn8000_001F_EAX[SNP]=1.

Mnemonic	Opcode	Description
PVALIDATE	F2 0F 01 FF	Performs guest page validation

Action

```
GUEST_VA = rAX & ~0xFFF
PAGE_SIZE = ECX[0]
VALIDATE_PAGE = EDX[0]

RDMSR Read Model-Specific Register

Loads the contents of a 64-bit model-specific register (MSR) specified in the ECX register into registers EDX:EAX. The EDX register receives the high-order 32 bits and the EAX register receives the low order bits. The RDMSR instruction ignores operand size; ECX always holds the MSR number, and EDX:EAX holds the data. If a model-specific register has fewer than 64 bits, the unimplemented bit positions loaded into the destination registers are undefined.

This instruction must be executed at a privilege level of 0 or a general protection exception (#GP) will be raised. This exception is also generated if a reserved or unimplemented model-specific register is specified in ECX.

Support for the RDMSR instruction is indicated by CPUID Fn0000_0001_EDX[MSR] = 1 OR CPUID Fn8000_0001_EDX[MSR] = 1. For more information on using the CPUID instruction, see the description of the CPUID instruction on page 165.

For more information about model-specific registers, see the documentation for various hardware implementations and “Model-Specific Registers (MSRs)” in *Volume 2: System Programming*.

Mnemonic	Opcode	Description
RDMSR	0F 32	Copy MSR specified by ECX into EDX:EAX.

General protection, #GP		X	X	CPL was not 0.
	X		X	The value in ECX specifies a reserved or unimplemented MSR address.

RDPKRU Read Protection Key Rights

Loads the contents of the 32-bit Protection Key Rights (PKRU) register into RAX[31:0] and clears the upper 32 bits of RAX. RDX is also cleared to 0. The RDPKRU instruction ignores operand size.

This instruction must be executed with ECX=0, otherwise a general protection fault (#GP) is generated. The upper 32 bits of RCX are ignored. Memory protection keys must be enabled (CR4.PKE=1), otherwise executing this instruction generates an invalid opcode fault (#UD).

Software can check that the operating system has enabled memory protection keys (CR4.PKE=1) by testing CPUID Function 0000_0007h_ECX[OSPKE]. (See Section 5, “Protection Key Rights for User Pages” in AMD64 Architecture Programmer’s Manual Volume 2 for more information on memory protection keys.)

RDPKRU can be executed at any privilege level.

Mnemonic	Opcode	Description
RDPKRU	0F 01 EE	Read the PKRU MSR into EAX and clear RDX

RDPMC Read Performance-Monitoring Counter

Reads the contents of a 64-bit performance counter and returns it in the registers EDX:EAX. The ECX register is used to specify the index of the performance counter to be read. The EDX register receives the high-order 32 bits and the EAX register receives the low order 32 bits of the counter. The RDPMC instruction ignores operand size; the index and the return values are all 32 bits.

The base architecture supports four core performance counters: PerfCtr0–3. An extension to the architecture increases the number of core performance counters to 6 (PerfCtr0–5). Other extensions add four northbridge performance counters NB_PerfCtr0–3 and four L2 cache performance counters L2I_PerfCtr0–3.

To select the core performance counter to be read, specify the counter index, rather than the performance counter MSR address. To access the northbridge performance counters, specify the index of the counter plus 6. To access the L2 cache performance counters, specify the index of the counter plus 10.

Programs running at any privilege level can read performance monitor counters if the PCE flag in CR4 is set to 1; otherwise this instruction must be executed at a privilege level of 0.

This instruction is not serializing. Therefore, there is no guarantee that all instructions have completed at the time the performance counter is read.

For more information about performance-counter registers, see the documentation for various hardware implementations and “Performance Counters” in Volume 2.

Support for performance counters beyond PerfCtr0–3 is indicated as follows:

- CPUID Fn8000_0001_ECX[PerfCtrExtCore] = 1 indicates support for core performance counters PerfCtr4-5
- CPUID Fn8000_0001_ECX[PerfCtrExtNB] = 1 indicates support for the 4 architecturally defined Northbridge performance counters .
- CPUID Fn8000_0022_EBX[NumDfPmc] > 4 indicates support for additional Northbridge performance counters.
- CPUID Fn8000_0001_ECX[PerfCtrExtLLC] = 1 indicates support for the six L3 performance counters.

For more information on using the CPUID instruction, see the description of the CPUID instruction on page 165.

RDSSP Read Shawdow Stack Pointer

Reads the current Shadow Stack Pointer (SSP) to the specified GPR. The operand size is 64 bits in 64-bit mode when REX.W=1 and is 32 bits in all other cases. RDSSP is treated as a NOP if CR4.CET = 0, or if shadow stacks are not enabled at the current privilege level.

Mnemonic	Opcode	Description
RDSSPD *reg32*	F3 0F 1E /1	Read SSP[31:0] to reg32
RDSSPQ *reg64*	F3 0F 1E /1	Read SSP[63:0] to reg64

Action

```
IF (((CPL==3) && SSTK_USER_ENABLED) || ((CPL!=3) && SSTK_SUPV_ENABLED))

   IF (OPERAND_SIZE == 64)
      reg64 = SSP
   ELSE
      reg32 = SSP[31:0]
EXIT
```

Exceptions

None.

RDTSC Read Time-Stamp Counter

Loads the value of the processor's 64-bit time-stamp counter into registers EDX:EAX.

The time-stamp counter (TSC) is contained in a 64-bit model-specific register (MSR). The processor sets the counter to 0 upon reset and increments the counter every clock cycle. INIT does not modify the TSC.

The high-order 32 bits are loaded into EDX, and the low-order 32 bits are loaded into the EAX register. This instruction ignores operand size.

When the time-stamp disable flag (TSD) in CR4 is set to 1, the RDTSC instruction can only be used at privilege level 0. If the TSD flag is 0, this instruction can be used at any privilege level.

This instruction is not serializing. Therefore, there is no guarantee that all instructions have completed at the time the time-stamp counter is read.

The behavior of the RDTSC instruction is implementation dependent. The TSC counts at a constant rate, but may be affected by power management events (such as frequency changes), depending on the processor implementation. If CPUID Fn8000_0007_EDX[TscInvariant] = 1, then the TSC rate is ensured to be invariant across all P-States, C-States, and stop-grant transitions (such as STPCLK Throttling); therefore, the TSC is suitable for use as a source of time. Consult the *BIOS and Kernel Developer's Guide* applicable to your product for information concerning the effect of power management on the TSC.

Support for the RDTSC instruction is indicated by CPUID Fn0000_0001_EDX[TSC] = 1 OR CPUID Fn8000_0001_EDX[TSC] = 1. For more information on using the CPUID instruction, see the description of the CPUID instruction on page 165.

Instruction Encoding

Mnemonic	Opcode	Description
RDTSC	0F 31	Copy the time-stamp counter into EDX:EAX.

General protection, #GP		X	X	CPL was not 0 and CR4.TSD = 1.

RDTSCP Read Time-Stamp Counter and Processor ID

Loads the value of the processor's 64-bit time-stamp counter into registers EDX:EAX, and loads the value of TSC_AUX into ECX. This instruction ignores operand size.

The time-stamp counter is contained in a 64-bit model-specific register (MSR). The processor sets the counter to 0 upon reset and increments the counter every clock cycle. INIT does not modify the TSC.

The high-order 32 bits are loaded into EDX, and the low-order 32 bits are loaded into the EAX register.

The TSC_AUX value is contained in the low-order 32 bits of the TSC_AUX register (MSR address C000_0103h). This MSR is initialized by privileged software to any meaningful value, such as a processor ID, that software wants to associate with the returned TSC value.

When the time-stamp disable flag (TSD) in CR4 is set to 1, the RDTSCP instruction can only be used at privilege level 0. If the TSD flag is 0, this instruction can be used at any privilege level.

Unlike the RDTSC instruction, RDTSCP forces all older instructions to retire before reading the time-stamp counter.

The behavior of the RDTSCP instruction is implementation dependent. The TSC counts at a constant rate, but may be affected by power management events (such as frequency changes), depending on the processor implementation. If CPUID Fn8000_0007_EDX[TscInvariant] = 1, then the TSC rate is ensured to be invariant across all P-States, C-States, and stop-grant transitions (such as STPCLK Throttling); therefore, the TSC is suitable for use as a source of time. Consult the *BIOS and Kernel Developer's Guide* applicable to your product for information concerning the effect of power management on the TSC.

Support for the RDTSCP instruction is indicated by CPUID Fn8000_0001_EDX[RDTSCP] = 1. For more information on using the CPUID instruction, see the description of the CPUID instruction on page 165.

General protection, #GP		X	X	CPL was not 0 and CR4.TSD = 1.

RMPADJUST Adjust RMP Permissions

Modifies RMP permissions for a guest page. The guest virtual address is specified in the RAX register. The page size is specified in RCX[0]. The target VMPL and its permissions are specified in the RDX register as follows:

RDX bits	Field	Description
[63:17]	RESERVED	
[16]	VMSA	Indicates if the page may be used as a VM Save Area page. This bit is ignored whenever the current VMPL is not 0
[15:8]	TARGET_PERM_MASK	Desired permission mask settings
[7:0]	TARGET_VMPL	Target VMPL

The RMPADJUST instruction is used by an SNP-active guest to modify RMP permissions of a lesser-privileged VMPL. The RMPADJUST instruction will attempt to access the specified page and will take a #VMEXIT(NPF) if a nested translation error occurs or the translated address is outside the range of memory covered by the RMP. Assuming no such error is detected, the target VMPL is numerically higher than the current VMPL, and the specified permissions for the target VMPL are not greater than the permissions of the current VMPL, the RMPADJUST instruction will modify the target permission mask in the RMP entry.

Upon completion, a return code is stored in EAX. rFLAGS bits OF, ZF, AF, PF and SF are set based on this return code.

RMPADJUST performs the same segmentation and paging checks as a 1-byte read. RMPADJUST does not invalidate TLB caches.

This is a privileged instruction. Attempted execution at a privilege level other than CPL0 will result in a #GP(0) exception. In addition, this instruction is only valid in 64-bit mode in an SNP-active guest; in all other modes a #UD exception will be generated.

Support for this instruction is indicated by CPUID Fn8000_001F_EAX[SNP]=1.

RMPUPDATE Write RMP Entry

Writes a new RMP entry. The system physical address of a page whose RMP entry is modified is specified in the RAX register. The RCX register provides the effective address of a 16-byte data structure which contains the new RMP state. The DS segment is the default segment used to create the linear address, but may be overridden by a segment prefix. The layout of the data structure with the new RMP state is as follows:

Byte Offset	Length (bytes)	Name	Description
00h	8	GUEST_PA	Guest physical address
08h	1	ASSIGNED	Assigned flag (bit 0)
09h	1	PAGE_SIZE	Page size (0 = 4KB, 1 = 2MB) (bit 0)
0Ah	1	IMMUTABLE	Immutable flag (bit 0)
0Bh	1	-	Reserved (SBZ)
0Ch	4	ASID	ASID of intended page owner

The RMPUPDATE instruction checks that new RMP state is legal before it updates the RMP table.

Upon completion, a return code is stored in EAX. rFLAGS bits OF, ZF, AF, PF and SF are set based on this return code.

The RMPUPDATE instruction invalidates all TLB entries in the system that translate to the page being modified.

This instruction is intended for hypervisor use. Attempted execution at an ASID other than 0 will result in a FAIL_PERMISSION return code.

This is a privileged instruction. Attempted execution at a privilege level other than CPL0 will result in a #GP(0) exception. In addition, this instruction is only valid in 64-bit mode with SNP enabled; in all other modes a #UD exception will be generated.

Support for this instruction is indicated by the feature flag CPUID Fn8000_001F_EAX[SNP]=1.

RSM Resume from System Management Mode

Resumes an operating system or application procedure previously interrupted by a system management interrupt (SMI). The processor state is restored from the information saved when the SMI was taken. The processor goes into a shutdown state if it detects invalid state information in the system management mode (SMM) save area during RSM.

RSM will shut down if any of the following conditions are found in the save map (SSM):

- An illegal combination of flags in CR0 (CR0.PG = 1 and CR0.PE = 0, or CR0.NW = 1 and CR0.CD = 0).
- A reserved bit in CR3, CR4, or the extended feature enable register (EFER) is set to 1.
- A reserved bit in the range 63:32 of CR0, DR6, or DR7 is set to 1.
- The following bit combination occurs: EFER.LME = 1, CR0.PG = 1, CR4.PAE = 0.
- The following bit combination occurs: EFER.LME = 1, CR0.PG = 1, CR4.PAE = 1, CS.D = 1, CS.L = 1.
- SMM revision field has been modified.
- The following bit combination occurs: CR4.PCIDE=1 and EFER.LMA=0.

RSM cannot modify EFER.SVME. Attempts to do so are ignored.

When EFER.SVME is 1, RSM reloads the four PDPEs (through the incoming CR3) when returning to a mode that has legacy PAE mode paging enabled.

When EFER.SVME is 1, the RSM instruction is permitted to return to paged real mode (i.e., CR0.PE=0 and CR0.PG=1).

The AMD64 architecture uses a new 64-bit SMM state-save memory image. This 64-bit save-state map is used in all modes, regardless of mode. See “System-Management Mode” in Volume 2 for details.

Mnemonic	Opcode	Description
RSM	0F AA	Resume operation of an interrupted program.

RSTORSSP Restore Saved Shadow Stack Pointer

Restores SSP using the shadow stack restore token pointed to by the memory operand. If the token validation checks pass, SSP is set to the linear address of the memory operand and the restore token is replaced with a previous SSP token.

If a return to the previous shadow stack is required, the SAVEPREVSSP instruction can be used to save the previous SSP token to the previous stack. Otherwise, the INCSSP instruction can be used to pop the unneeded previous SSP token from the shadow stack.

If the restored SSP is 4-byte aligned and not 8-byte aligned, CF is set to 1 indicating an alignment hole. The INCSSP instruction can be used to increment SSP past the alignment hole.

Mnemonic	Opcode	Description
RSTORSSP *mem64*	F3 0F 01 /5	Restore SSP and create previous SSP token.

SGDT Store Global Descriptor Table Register

Stores the global descriptor table register (GDTR) into the destination operand. In legacy and compatibility mode, the destination operand is 6 bytes; in 64-bit mode, it is 10 bytes. In all modes, operand-size prefixes are ignored.

In non-64-bit mode, the lower two bytes of the operand specify the 16-bit limit and the upper 4 bytes specify the 32-bit base address.

In 64-bit mode, the lower two bytes of the operand specify the 16-bit limit and the upper 8 bytes specify the 64-bit base address.

This instruction is intended for use in operating system software, but it can be used at any privilege level.

Mnemonic	Opcode	Description
SGDT *mem16:32*	0F 01 /0	Store global descriptor table register to memory.
SGDT *mem16:64*	0F 01 /0	Store global descriptor table register to memory.

SKINIT Secure Init and Jump with Attestation

Securely reinitializes the cpu, allowing for the startup of trusted software (such as a VMM). The code to be executed after reinitialization can be verified based on a secure hash comparison. SKINIT takes the physical base address of the SLB as its only input operand, in EAX. The SLB must be structured as described in “Secure Loader Block” on page 499 of the *AMD64 Architecture Programmer’s Manual Volume 2: System Programming*, order# 24593, and is assumed to contain the code for a Secure Loader (SL).

This is a Secure Virtual Machine (SVM) instruction. Support for the SVM architecture and the SVM instructions is indicated by CPUID Fn8000_0001_ECX[SVM] = 1. For more information on using the CPUID instruction, see the reference page for the CPUID instruction on page 165.

This instruction generates a #UD exception if SVM is not enabled. See “Enabling SVM” in *AMD64 Architecture Programmer’s Manual Volume 2: System Instructions*, order# 24593.

Mnemonic	Opcode	Description
SKINIT EAX	0F 01 DE	Secure initialization and jump, with attestation.

Action

```

General protection, #GP			X	CPL was not 0.

SLDT Store Local Descriptor Table Register

Stores the local descriptor table (LDT) selector to a register or memory destination operand.

If the destination is a register, the selector is zero-extended into a 16-, 32-, or 64-bit general purpose register, depending on operand size.

If the destination operand is a memory location, the segment selector is written to memory as a 16-bit value, regardless of operand size.

This SLDT instruction can only be used in protected mode, but it can be executed at any privilege level.

Mnemonic	Opcode	Description
SLDT *reg16*	0F 00 /0	Store the segment selector from the local descriptor table register to a 16-bit register.
SLDT *reg32*	0F 00 /0	Store the segment selector from the local descriptor table register to a 32-bit register.
SLDT *reg64*	0F 00 /0	Store the segment selector from the local descriptor table register to a 64-bit register.
SLDT *mem16*	0F 00 /0	Store the segment selector from the local descriptor table register to a 16-bit memory location.

SMSW Store Machine Status Word

Stores the lower bits of the machine status word (CR0). The target can be a 16-, 32-, or 64-bit register or a 16-bit memory operand.

This instruction is provided for compatibility with early processors.

This instruction can be used at any privilege level (CPL).

Mnemonic	Opcode	Description
SMSW *reg16*	0F 01 /4	Store the low 16 bits of CR0 to a 16-bit register.
SMSW *reg32*	0F 01 /4	Store the low 32 bits of CR0 to a 32-bit register.
SMSW *reg64*	0F 01 /4	Store the entire 64-bit CR0 to a 64-bit register.
SMSW *mem16*	0F 01 /4	Store the low 16 bits of CR0 to memory.

STI Set Interrupt Flag

Sets the interrupt flag (IF) in the rFLAGS register to 1, thereby allowing external interrupts received on the INTR input. Interrupts received on the non-maskable interrupt (NMI) input are not affected by this instruction.

In real mode, this instruction sets IF to 1.

In protected mode and virtual-8086-mode, this instruction is IOPL-sensitive. If the CPL is less than or equal to the rFLAGS.IOPL field, the instruction sets IF to 1.

In protected mode, if IOPL < 3, CPL = 3, and protected mode virtual interrupts are enabled (CR4.PVI = 1), then the instruction instead sets rFLAGS.VIF to 1. If none of these conditions apply, the processor raises a general protection exception (#GP). For more information, see “Protected Mode Virtual Interrupts” in Volume 2.

In virtual-8086 mode, if IOPL < 3 and the virtual-8086-mode extensions are enabled (CR4.VME = 1), the STI instruction instead sets the virtual interrupt flag (rFLAGS.VIF) to 1.

If STI sets the IF flag and IF was initially clear, then interrupts are not enabled until after the instruction following STI. Thus, if IF is 0, this code will not allow an INTR to happen:

```
STI
CLI
```

In the following sequence, INTR will be allowed to happen only after the NOP.

```
STI
NOP
CLI
```

If STI sets the VIF flag and VIP is already set, a #GP fault will be generated.

See “Virtual-8086 Mode Extensions” in Volume 2 for more information about IOPL-sensitive instructions.

Mnemonic	Opcode	Description
STI	FB	Set interrupt flag (IF) to 1.

Action

```
IF (CPL <= IOPL)
      RFLAGS.IF = 1

ELSIF (((VIRTUAL_MODE) && (CR4.VME == 1))
        || ((PROTECTED_MODE) && (CR4.PVI == 1) && (CPL == 3)))
       {
         IF (RFLAGS.VIP == 1)
             EXCEPTION[#GP(0)]
         RFLAGS.VIF = 1
       }
ELSE
       EXCEPTION[#GP(0)]
```

Exceptions

Exception	Real	Virtual 8086	Protected	Cause of Exception
General protection, #GP		X		The CPL was greater than the IOPL and virtual-mode extensions were not enabled (CR4.VME = 0).
			X	The CPL was greater than the IOPL and either the CPL was not 3 or protected-mode virtual interrupts were not enabled (CR4.PVI = 0).
		X	X	This instruction would set RFLAGS.VIF to 1 and RFLAGS.VIP was already 1.

STGI Set Global Interrupt Flag

Sets the global interrupt flag (GIF) to 1. While GIF is zero, all external interrupts are disabled.

This is a Secure Virtual Machine (SVM) instruction.

Attempted execution of this instruction causes a #UD exception if SVM is not enabled and neither SVM Lock nor the device exclusion vector (DEV) are supported. Support for SVM Lock is indicated by CPUID Fn8000_000A_EDX[SVML] = 1. Support for DEV is part of the SKINIT architecture and is indicated by CPUID Fn8000_0001_ECX[SKINIT] = 1. For more information on using the CPUID instruction, see the description of the CPUID instruction on page 165.

For information on enabling SVM, see “Enabling SVM” in *AMD64 Architecture Programmer’s Manual Volume-2: System Instructions*, order# 24593.

Mnemonic	Opcode	Description
STGI	0F 01 DC	Sets the global interrupt flag (GIF).

SWAPGS Swap GS Register with KernelGSbase MSR

Provides a fast method for system software to load a pointer to system data structures. SWAPGS can be used upon entering system-software routines as a result of a SYSCALL instruction, an interrupt or an exception. Prior to returning to application software, SWAPGS can be used to restore the application data pointer that was replaced by the system data-structure pointer.

This instruction can only be executed in 64-bit mode. Executing SWAPGS in any other mode generates an undefined opcode exception.

The SWAPGS instruction only exchanges the base-address value located in the KernelGSbase model-specific register (MSR address C000_0102h) with the base-address value located in the hidden-portion of the GS selector register (GS.base). This allows the system-kernel software to access kernel data structures by using the GS segment-override prefix during memory references.

The address stored in the KernelGSbase MSR must be in canonical form. The WRMSR instruction used to load the KernelGSbase MSR causes a general-protection exception if the address loaded is not in canonical form. The SWAPGS instruction itself does not perform a canonical check.

This instruction is only valid in 64-bit mode at CPL 0. A general protection exception (#GP) is generated if this instruction is executed at any other privilege level.

For additional information about this instruction, refer to “System Instructions” in Volume 2.

Examples

At a kernel entry point, the OS uses SwapGS to obtain a pointer to kernel data structures and simultaneously save the user's GS base. Upon exit, it uses SwapGS to restore the user's GS base:

```
SystemCallEntryPoint:
SwapGS                          ; get kernel pointer, save user GSbase
mov gs:[SavedUserRSP], rsp     ; save user's stack pointer
mov rsp, gs:[KernelStackPtr]   ; set up kernel stack
push rax                        ; now save user GPRs on kernel stack
               .                ; perform system service
               .
SwapGS                          ; restore user GS, save kernel pointer
```

Mnemonic	Opcode	Description
SWAPGS	0F 01 F8	Exchange GS base with KernelGSBase MSR. (Invalid in legacy and compatibility modes.)

SYSCALL Fast System Call

Transfers control to a fixed entry point in an operating system. It is designed for use by system and application software implementing a flat-segment memory model.

The SYSCALL and SYSRET instructions are low-latency system call and return control-transfer instructions, which assume that the operating system implements a flat-segment memory model. By eliminating unneeded checks, and by loading pre-determined values into the CS and SS segment registers (both visible and hidden portions), calls to and returns from the operating system are greatly simplified. These instructions can be used in protected mode and are particularly well-suited for use in 64-bit mode, which requires implementation of a paged, flat-segment memory model.

This instruction has been optimized by reducing the number of checks and memory references that are normally made so that a call or return takes considerably fewer clock cycles than the CALL FAR /RET FAR instruction method.

It is assumed that the base, limit, and attributes of the Code Segment will remain flat for all processes and for the operating system, and that only the current privilege level for the selector of the calling process should be changed from a current privilege level of 3 to a new privilege level of 0. It is also assumed (but not checked) that the RPL of the SYSCALL and SYSRET target selectors are set to 0 and 3, respectively.

SYSCALL sets the CPL to 0, regardless of the values of bits 33:32 of the STAR register. There are no permission checks based on the CPL, real mode, or virtual-8086 mode. SYSCALL and SYSRET must be enabled by setting EFER.SCE to 1.

It is the responsibility of the operating system to keep the descriptors in memory that correspond to the CS and SS selectors loaded by the SYSCALL and SYSRET instructions consistent with the segment base, limit, and attribute values forced by these instructions.

Legacy x86 Mode. In legacy x86 mode, when SYSCALL is executed, the EIP of the instruction following the SYSCALL is copied into the ECX register. Bits 31:0 of the SYSCALL/SYSRET target address register (STAR) are copied into the EIP register. (The STAR register is model-specific register C000_0081h.)

New selectors are loaded, without permission checking (see above), as follows:

- Bits 47:32 of the STAR register specify the selector that is copied into the CS register.
- Bits 47:32 of the STAR register + 8 specify the selector that is copied into the SS register.
- The CS_base and the SS_base are both forced to zero.
- The CS_limit and the SS_limit are both forced to 4 Gbyte.
- The CS segment attributes are set to execute/read 32-bit code with a CPL of zero.
- The SS segment attributes are set to read/write and expand-up with a 32-bit stack referenced by ESP.

Long Mode. When long mode is activated, the behavior of the SYSCALL instruction depends on whether the calling software is in 64-bit mode or compatibility mode. In 64-bit mode, SYSCALL saves the RIP of the instruction following the SYSCALL into RCX and loads the new RIP from LSTAR bits 63:0. (The LSTAR register is model-specific register C000_0082h.) In compatibility mode, SYSCALL saves the RIP of the instruction following the SYSCALL into RCX and loads the new RIP from CSTAR bits 63:0. (The CSTAR register is model-specific register C000_0083h.)

New selectors are loaded, without permission checking (see above), as follows:

- Bits 47:32 of the STAR register specify the selector that is copied into the CS register.
- Bits 47:32 of the STAR register + 8 specify the selector that is copied into the SS register.
- The CS_base and the SS_base are both forced to zero.
- The CS_limit and the SS_limit are both forced to 4 Gbyte.
- The CS segment attributes are set to execute/read 64-bit code with a CPL of zero.
- The SS segment attributes are set to read/write and expand-up with a 64-bit stack referenced by RSP.

The WRMSR instruction loads the target RIP into the LSTAR and CSTAR registers. If an RIP written by WRMSR is not in canonical form, a general-protection exception (#GP) occurs.

How SYSCALL and SYSRET handle rFLAGS, depends on the processor's operating mode.

In legacy mode, SYSCALL treats EFLAGS as follows:

- EFLAGS.IF is cleared to 0.
- EFLAGS.RF is cleared to 0.
- EFLAGS.VM is cleared to 0.

In long mode, SYSCALL treats RFLAGS as follows:

- The current value of RFLAGS is saved in R11.
- RFLAGS is masked using the value stored in SYSCALL_FLAG_MASK.
- RFLAGS.RF is cleared to 0.

For further details on the SYSCALL and SYSRET instructions and their associated MSR registers (STAR, LSTAR, CSTAR, and SYSCALL_FLAG_MASK), see "Fast System Call and Return" in Volume 2.

Support for the SYSCALL instruction is indicated by CPUID Fn8000_0001_EDX[SysCallSysRet] = 1. For more information on using the CPUID instruction, see the description of the CPUID instruction on page 165.

Note: *Bits 31:22, 15, 5, 3, and 1 are reserved. A flag set to one or cleared to zero is M (modified). Unaffected flags are blank. Undefined flags are U.*

Exceptions

Exception	Real	Virtual 8086	Protected	Cause of Exception
Invalid opcode, #UD	X	X	X	The SYSCALL and SYSRET instructions are not supported, as indicated by CPUID Fn8000_0001_EDX[SysCallSysRet] = 0.
	X	X	X	The system call extension bit (SCE) of the extended feature enable register (EFER) is set to 0. (The EFER register is MSR C000_0080h.)

SYSENTER System Call

Transfers control to a fixed entry point in an operating system. It is designed for use by system and application software implementing a flat-segment memory model. This instruction is valid only in legacy mode.

Three model-specific registers (MSRs) are used to specify the target address and stack pointers for the SYSENTER instruction, as well as the CS and SS selectors of the called and returned procedures:

- MSR_SYSENTER_CS: Contains the CS selector of the called procedure. The SS selector is set to MSR_SYSENTER_CS + 8.
- MSR_SYSENTER_ESP: Contains the called procedure’s stack pointer.
- MSR_SYSENTER_EIP: Contains the offset into the CS of the called procedure.

The hidden portions of the CS and SS segment registers are not loaded from the descriptor table as they would be using a legacy x86 CALL instruction. Instead, the hidden portions are forced by the processor to the following values:

- The CS and SS base values are forced to 0.
- The CS and SS limit values are forced to 4 Gbytes.
- The CS segment attributes are set to execute/read 32-bit code with a CPL of zero.
- The SS segment attributes are set to read/write and expand-up with a 32-bit stack referenced by ESP.

System software must create corresponding descriptor-table entries referenced by the new CS and SS selectors that match the values described above.

The return EIP and application stack are not saved by this instruction. System software must explicitly save that information.

An invalid-opcode exception occurs if this instruction is used in long mode. Software should use the SYSCALL (and SYSRET) instructions in long mode. If SYSENTER is used in real mode, a #GP is raised.

For additional information on this instruction, see “SYSENTER and SYSEXIT (Legacy Mode Only)” in Volume 2.

Support for the SYSENTER instruction is indicated by CPUID Fn0000_0001_EDX[SysEnterSysExit] = 1. For more information on using the CPUID instruction, see the description of the CPUID instruction on page 165.

Instruction Encoding

Mnemonic	Opcode	Description
SYSENTER	0F 34	Call operating system.

Note: *Bits 31:22, 15, 5, 3, and 1 are reserved. A flag set to one or zero is M (modified). Unaffected flags are blank. Undefined flags are U.*

Exceptions

Exception	Real	Virtual 8086	Protected	Cause of Exception
Invalid opcode, #UD	X	X	X	The SYSENTER and SYSEXIT instructions are not supported, as indicated by CPUID Fn0000_0001_EDX[SysEnterSysExit] = 0.
			X	This instruction is not recognized in long mode.
General protection, #GP	X			This instruction is not recognized in real mode.
		X	X	MSR_SYSENTER_CS was a null selector.

SYSEXIT System Return

Returns from the operating system to an application. It is a low-latency system return instruction designed for use by system and application software implementing a flat-segment memory model.

This is a privileged instruction. The current privilege level must be zero to execute this instruction. An invalid-opcode exception occurs if this instruction is used in long mode. Software should use the SYSRET (and SYSCALL) instructions when running in long mode.

When a system procedure performs a SYSEXIT back to application software, the CS selector is updated to point to the second descriptor entry after the SYSENTER CS value (MSR SYSENTER_CS+16). The SS selector is updated to point to the third descriptor entry after the SYSENTER CS value (MSR SYSENTER_CS+24). The CPL is forced to 3, as are the descriptor privilege levels.

The hidden portions of the CS and SS segment registers are not loaded from the descriptor table as they would be using a legacy x86 RET instruction. Instead, the hidden portions are forced by the processor to the following values:

- The CS and SS base values are forced to 0.
- The CS and SS limit values are forced to 4 Gbytes.
- The CS segment attributes are set to 32-bit read/execute at CPL 3.
- The SS segment attributes are set to read/write and expand-up with a 32-bit stack referenced by ESP.

System software must create corresponding descriptor-table entries referenced by the new CS and SS selectors that match the values described above.

The following additional actions result from executing SYSEXIT:

- EIP is loaded from EDX.
- ESP is loaded from ECX.

System software must explicitly load the return address and application software-stack pointer into the EDX and ECX registers prior to executing SYSEXIT.

For additional information on this instruction, see “SYSENTER and SYSEXIT (Legacy Mode Only)” in Volume 2.

Support for the SYSEXIT instruction is indicated by CPUID Fn0000_0001_EDX[SysEnterSysExit] = 1. For more information on using the CPUID instruction, see the description of the CPUID instruction on page 165.

SYSRET Fast System Return

Returns from the operating system to an application. It is a low-latency system return instruction designed for use by system and application software implementing a flat segmentation memory model.

The SYSCALL and SYSRET instructions are low-latency system call and return control-transfer instructions that assume that the operating system implements a flat-segment memory model. By eliminating unneeded checks, and by loading pre-determined values into the CS and SS segment registers (both visible and hidden portions), calls to and returns from the operating system are greatly simplified. These instructions can be used in protected mode and are particularly well-suited for use in 64-bit mode, which requires implementation of a paged, flat-segment memory model.

This instruction has been optimized by reducing the number of checks and memory references that are normally made so that a call or return takes substantially fewer internal clock cycles when compared to the CALL/RET instruction method.

It is assumed that the base, limit, and attributes of the Code Segment will remain flat for all processes and for the operating system, and that only the current privilege level for the selector of the calling process should be changed from a current privilege level of 0 to a new privilege level of 3. It is also assumed (but not checked) that the RPL of the SYSCALL and SYSRET target selectors are set to 0 and 3, respectively.

SYSRET sets the CPL to 3, regardless of the values of bits 49:48 of the star register. SYSRET can only be executed in protected mode at CPL 0. SYSCALL and SYSRET must be enabled by setting EFER.SCE to 1.

It is the responsibility of the operating system to keep the descriptors in memory that correspond to the CS and SS selectors loaded by the SYSCALL and SYSRET instructions consistent with the segment base, limit, and attribute values forced by these instructions.

When a system procedure performs a SYSRET back to application software, the CS selector is updated from bits 63:50 of the STAR register (STAR.SYSRET_CS) as follows:

- If the return is to 32-bit mode (legacy or compatibility), CS is updated with the value of STAR.SYSRET_CS.
- If the return is to 64-bit mode, CS is updated with the value of STAR.SYSRET_CS + 16.

In both cases, the CPL is forced to 3, effectively ignoring STAR bits 49:48. The SS selector is updated to point to the next descriptor-table entry after the CS descriptor (STAR.SYSRET_CS + 8), and its RPL is not forced to 3.

The hidden portions of the CS and SS segment registers are not loaded from the descriptor table as they would be using a legacy x86 RET instruction. Instead, the hidden portions are forced by the processor to the following values:

- The CS base value is forced to 0.
- The CS limit value is forced to 4 Gbytes.

- The CS segment attributes are set to execute-read 32 bits or 64 bits (see below).
- The SS segment base, limit, and attributes are not modified.

When SYSCALLed system software is running in 64-bit mode, it has been entered from either 64-bit mode or compatibility mode. The corresponding SYSRET needs to know the mode to which it must return. Executing SYSRET in non-64-bit mode or with a 16- or 32-bit operand size returns to 32-bit mode with a 32-bit stack pointer. Executing SYSRET in 64-bit mode with a 64-bit operand size returns to 64-bit mode with a 64-bit stack pointer.

The instruction pointer is updated with the return address based on the operating mode in which SYSRET is executed:

- If returning to 64-bit mode, SYSRET loads RIP with the value of RCX.
- If returning to 32-bit mode, SYSRET loads EIP with the value of ECX.

How SYSRET handles RFLAGS depends on the processor's operating mode:

- If executed in 64-bit mode, SYSRET loads the lower-32 RFLAGS bits from R11[31:0] and clears the upper 32 RFLAGS bits.
- If executed in legacy mode or compatibility mode, SYSRET sets EFLAGS.IF.

For further details on the SYSCALL and SYSRET instructions and their associated MSR registers (STAR, LSTAR, and CSTAR), see "Fast System Call and Return" in Volume 2.

Support for the SYSRET instruction is indicated by CPUID Fn8000_0001_EDX[SysCallSysRet] = 1. For more information on using the CPUID instruction, see the description of the CPUID instruction on page 165.

	X	X	X	The system call extension bit (SCE) of the extended feature enable register (EFER) is set to 0. (The EFER register is MSR C000_0080h.)
General protection, #GP	X	X		This instruction is only recognized in protected mode.
			X	CPL was not 0.

TLBSYNC Synchronize TLB Invalidations

TLBSYNC acts as a synchronizing instruction to ensure that all logical processors in a system have responded to an INVLPGB previously executed by the current logical processor. Upon execution of an INVLPGB, the processor does not wait for confirmation that the other processors have performed the specified TLB invalidation. A TLBSYNC is therefore required before software can move forward with the knowledge that all requested invalidations have been completed in the system. A TLBSYNC also ensures that memory instructions using the translations invalidated by those prior INVLPGB instructions have retired and writes using the translations have drained from the write combining buffers.

The TLBSYNC instruction is weakly ordered with respect to data and instruction prefetches.

The TLBSYNC instruction is strongly ordered with respect to surrounding loads and stores.

TLBSYNC is a serializing instruction and is privileged. It can only be executed at CPL 0. TLBSYNC is only supported in guests if enabled by hypervisor in the VMCB.

Mnemonic	Opcode	Description
TLBSYNC	0F 01 FF	Synchronize broadcasted TLB Invalidations

VERR Verify Segment for Reads

Verifies whether a code or data segment specified by the segment selector in the 16-bit register or memory operand is readable from the current privilege level. The zero flag (ZF) is set to 1 if the specified segment is readable. Otherwise, ZF is cleared.

A segment is readable if all of the following apply:

- the selector is not a null selector.
- the descriptor is within the GDT or LDT limit.
- the segment is a data segment or readable code segment.
- the descriptor DPL is greater than or equal to both the CPL and RPL, or the segment is a conforming code segment.

The processor does not recognize the VERR instruction in real or virtual-8086 mode.

Mnemonic	Opcode	Description
VERR *reg/mem16*	0F 00 /4	Set the zero flag (ZF) to 1 if the segment selected can be read.

VMLOAD Load State from VMCB

Loads a subset of processor state from the VMCB specified by the system-physical address in the rAX register. The portion of RAX used to form the address is determined by the effective address size.

The VMSAVE and VMLOAD instructions complement the state save/restore abilities of VMRUN and #VMEXIT, providing access to hidden state that software is otherwise unable to access, plus some additional commonly-used state.

This is a Secure Virtual Machine (SVM) instruction. Support for the SVM architecture and the SVM instructions is indicated by CPUID Fn8000_0001_ECX[SVM] = 1. For more information on using the CPUID instruction, see the reference page for the CPUID instruction on page 165.

This instruction generates a #UD exception if SVM is not enabled. See “Enabling SVM” in *AMD64 Architecture Programmer’s Manual Volume 2: System Instructions*, order# 24593.

Mnemonic	Opcode	Description
VMLOAD rAX	0F 01 DA	Load additional state from VMCB.

Action

```
IF ((MSR_EFER.SVME == 0) || (!PROTECTED_MODE))
    EXCEPTION [#UD]       //  This instruction can only be executed in protected
                            //  mode with SVM enabled

IF (CPL != 0)               //  This instruction is only allowed at CPL 0
    EXCEPTION [#GP]

IF (rAX contains an unsupported system-physical address)
    EXCEPTION [#GP]

Load from a VMCB at system-physical address rAX:
      FS, GS, TR, LDTR (including all hidden state)

VMMCALL Call VMM
VMGEXIT SEV-ES Exit to VMM

VMMCALL and VMGEXIT provide a mechanism for a non-SEV-ES and an SEV-ES guest, respectively, to explicitly communicate with the VMM by generating a #VMEXIT.

A non-intercepted VMMCALL unconditionally raises a #UD exception. VMGEXIT is always intercepted and unconditionally causes a #VMEXIT.

VMMCALL and VMGEXIT instructions are allowed in all modes and at all privilege levels. These instructions generate a #UD exception if SVM is not enabled. See “Enabling SVM” in AMD64 Architecture Programmer’s Manual Volume 2: System Instructions, order# 24593.

VMMCALL and VMGEXIT are Secure Virtual Machine (SVM) instructions. Support for the SVM architecture and the SVM instructions is indicated by CPUID Fn8000_0001_ECX[SVM] = 1. Support for VMGEXIT instruction is indicated by CPUID Fn8000_001F_EAX[SEV-ES] = 1. The VMGEXIT encoding is interpreted as VMMCALL on processors that do not explicitly support VMGEXIT, including legacy processors, or if VMGEXIT instruction is not executed by an SEV-ES guest. For more information on using the CPUID instruction, see the reference page for the CPUID instruction on page 165.

Mnemonic	Opcode	Description

VMRUN Run Virtual Machine

Starts execution of a guest instruction stream. The physical address of the *virtual machine control block* (VMCB) describing the guest is taken from the rAX register (the portion of RAX used to form the address is determined by the effective address size). The physical address of the VMCB must be aligned on a 4KB boundary.

VMRUN saves a subset of host processor state to the host state-save area specified by the physical address in the VM_HSAVE_PA MSR. VMRUN then loads guest processor state (and control information) from the VMCB at the physical address specified in rAX. The processor then executes guest instructions until one of several *intercept* events (specified in the VMCB) is triggered. When an intercept event occurs, the processor stores a snapshot of the guest state back into the VMCB, reloads the host state, and continues execution of host code at the instruction following the VMRUN instruction.

This is a Secure Virtual Machine (SVM) instruction. Support for the SVM architecture and the SVM instructions is indicated by CPUID Fn8000_0001_ECX[SVM] = 1. For more information on using the CPUID instruction, see the reference page for the CPUID instruction on page 165.

This instruction generates a #UD exception if SVM is not enabled. See “Enabling SVM” in *AMD64 Architecture Programmer’s Manual Volume 2: System Instructions*, order# 24593.

The VMRUN instruction is not supported in System Management Mode. Processor behavior resulting from an attempt to execute this instruction from within the SMM handler is undefined.

WBINVD Writeback and Invalidate Caches
WBNOINVD Writeback With No Invalidate

WBINVD writes all modified lines in all levels of cache associated with this processor to main memory and invalidates the caches. This may or may not include lower level caches associated with another processor that shares any level of this processor's cache hierarchy. WBNOINVD does not invalidate the caches, instead leaving all (or most) cache lines in the cache hierarchy in non-modified state, but in all other respects it behaves the same as WBINVD.

CPUID Fn8000_001D_EDX[WBINVD]_x*N* indicates the behavior of the operation at various levels of the cache hierarchy, for both WBINVD and WBNOINVD, with respect to lower branches in the cache hierarchy. If the feature bit is 0, the instruction causes the write back and (for WBINVD) invalidation of all lower level caches of other processors sharing the designated level of cache. If the feature bit is 1, the instruction does not necessarily cause the write back and invalidation of all lower level caches of other processors sharing the designated level of cache. See Appendix E, “Obtaining Processor Information Via the CPUID Instruction,” on page 593 for more information on using the CPUID function.

The INVD instruction can be used when cache coherence with memory is not important.

These instructions do not invalidate TLB caches.

These are privileged instructions. The current privilege level of a procedure invalidating the processor’s internal caches must be zero.

WBINVD and WBNOINVD are serializing instructions

Support for WBNOINVD is indicated by CPUID Fn8000_0008_EBX[WBNOINVD] = 1. However, the encoding of WBNOINVD results in it being interpreted as WBINVD on processors that do not explicitly support WBNOINVD, including legacy processors. For more information on using the CPUID instruction, see the description of the CPUID instruction on page 165.

On some processor implementations, WBINVD and WBNOINVD can be made interruptible by setting EFER.INTWB to 1. When this bit is set, the processor periodically checks for all types of interrupts (SMI, INTR, NMI, etc.) while flushing the caches. If an interrupt is observed, the processor stops flushing the caches, saves the instruction pointer and transfers control to the interrupt handler. Upon returning (via an IRET), the processor restarts the flush process from the beginning as lines will have been modified and cached while executing the interrupt handler. Support for setting EFER.INTWB is indicated by CPUID Fn8008_0008_EBX[INT_WBINVD] (bit 13) = 1.

Mnemonic	Opcode	Description
WBINVD	0F 09	Write modified cache lines to main memory, invalidate internal caches, and trigger external cache flushes.
WBNOINVD	F3 0F 09	Write modified cache lines to main memory and trigger external cache flushes.

WRMSR Write to Model-Specific Register

Writes data to 64-bit model-specific registers (MSRs). These registers are widely used in performance-monitoring and debugging applications, as well as testability and program execution tracing.

This instruction writes the contents of the EDX:EAX register pair into a 64-bit model-specific register specified in the ECX register. The 32 bits in the EDX register are mapped into the high-order bits of the model-specific register and the 32 bits in EAX form the low-order 32 bits.

This instruction must be executed at a privilege level of 0 or a general protection fault #GP(0) will be raised. This exception is also generated if an attempt is made to specify a reserved or unimplemented model-specific register in ECX.

WRMSR is a serializing instruction for most MSRs, however some x2APIC and AVIC MSRs may have relaxed serialization semantics. See the APIC and AVIC sections in volume 2 for details.

Support for the WRMSR instruction is indicated by CPUID Fn0000_0001_EDX[MSR] = 1 OR CPUID Fn8000_0001_EDX[MSR] = 1. For more information on using the CPUID instruction, see the description of the CPUID instruction on page 165.

The CPUID instruction can provide model information useful in determining the existence of a particular MSR.

See “Model-Specific Registers (MSRs)” in *Volume 2: System Programming*, for more information about model-specific registers, machine check architecture, performance monitoring and debug registers.

Mnemonic	Opcode	Description
WRMSR	0F 30	Write EDX:EAX to the MSR specified by ECX.

Exceptions

Exception	Real	Virtual 8086	Protected	Cause of Exception
Invalid opcode, #UD	X	X	X	The WRMSR instruction is not supported, as indicated by CPUID Fn0000_0001_EDX[MSR] = 0 OR CPUID Fn8000_0001_EDX[MSR] = 0.
General protection, #GP		X	X	CPL was not 0.
	X		X	The value in ECX specifies a reserved or unimplemented MSR address.
	X		X	Writing 1 to any bit that must be zero (MBZ) in the MSR.
	X		X	Writing a non-canonical value to a MSR that can only be written with canonical values.

WRPKRU Write Protection Key Rights

Writes the contents of the 32-bit Protection Key Rights (PKRU) register with the value in EAX. This instruction forces strong memory ordering between load and store instructions preceding the WRPKRU, and load and store instructions that follow the WRPKRU.

This instruction must be executed with ECX=0 and EDX=0, otherwise a general protection fault (#GP) is generated. The upper 32 bits of RCX and RDX are ignored. The WRPKRU instruction ignores operand size overrides.

Memory protection keys must be enabled (CR4.PKE=1), otherwise executing this instruction generates an invalid opcode fault (#UD).

Software can check that system software has enabled memory protection keys (CR4.PKE=1) by testing CPUID Function 0000_0007h_ECX[OSPKE]. (See Section 5, “Protection Key Rights for User Pages” in AMD64 Architecture Programmer’s Manual Volume 2 for more information on memory protection keys.)

WRPKRU can be executed at any privilege level.

Mnemonic	Opcode	Description
WRPKRU	0F 01 EF	Write the value in EAX to the PKRU MSR

WRSS Write to Shadow Stack

Writes 4 or 8 bytes from the source register operand to the specified address in a shadow stack page. The operand size is 8 bytes in 64-bit mode (when REX.W set to 1) and 4 bytes in all other cases.

If shadow stacks are not enabled at the current privilege level, or if WRSS is not enabled at the current privilege level a #UD exception is generated.

Mnemonic	Opcode	Description
WRSS *mem32*, *reg32*	66 0F 38 F6	Write 4 bytes to shadow stack at mem32
WRSSQ *mem64*, *reg64*	66 0F 38 F6	Write 8 bytes to shadow stack at mem64

Action

```
// see "Pseudocode Definition" on page 57

IF (CPL == 3)
   {
   IF ((CR4.CET && U_CET.SH_STK_EN) == 0)
         EXCEPTION [#UD]
   IF (U_CET.WR_SSTK_EN == 0)
         EXCEPTION [#UD]        // WRSS not enabled in U_CET
   }
ELSE  // CPL <3
   {
   IF ((CR4.CET && S_CET.SH_STK_EN) == 0)
         EXCEPTION [#UD]
   IF (S_CET.WR_SSTK_EN == 0)
         EXCEPTION [#UD]        // WRSS not enabled in S_CET
   }

IF (OPERAND_SIZE == 64)
   {
   temp_LinAdr = Linear_Address(mem64)
   IF (temp_LinAdr is 8-byte aligned)
      SSTK_WRITE_MEM.q[temp_LinAdr] = reg64[63:0] // write reg64
                                                  // to shadow stack
   ELSE
      EXCEPTION [#GP(0)]
   }
ELSE
   {
   temp_LinAdr = Linear_Address(mem32)
   IF (tmp_LinAdr is 4-byte aligned)
      SSTK_WRITE_MEM.d[temp_LinAdr] = reg32[31:0] // write reg32
                                                  // to shadow stack

Appendix A Opcode and Operand Encodings

This appendix specifies the opcode and operand encodings for each instruction in the AMD64 instruction set. As discussed in Chapter 1, “Instruction Encoding,” the basic operation and implied operand type(s) of an instruction are encoded by the binary value of the opcode byte. The correspondence between an opcode binary value and its meaning is provided by the *opcode map*.

Each opcode map has 256 entries and can encode up to 256 different operations. Since the AMD64 instruction set comprises more than 256 instructions, multiple opcode maps are utilized to encode the instruction set. A particular opcode map is selected using the instruction encoding syntax diagrammed in Figure 1-1 on page 2. For each opcode map, values may be reserved or utilized for purposes other than encoding an instruction operation.

To preserve compatibility with future instruction architectural extensions, reserved opcodes should not be used. If a means to reliably cause an invalid-opcode exception (#UD) is required, software should use one of the UD*x* opcodes. These opcodes are set aside for this purpose and will not be used for future instructions. The UD opcodes are located on the secondary opcode map at code points B9h, 0Bh, and FFh.

The following section provides a key to the notation used in the opcode maps to specify the implied operand types.

Opcode-Syntax Notation

In the opcode maps which follow, each table entry represents a specific form of an instruction, identifying the instruction by its mnemonic and listing the operand or operands peculiar to that opcode. If a register-based operand is specified by the opcode itself, the operand is represented directly using the register mnemonic as defined in “Summary of Registers and Data Types” on page 38. If the operand is encoded in one or more bytes following the opcode byte, the following special notation is used to represent the operand and its encoding in more generic terms.

This special notation, used exclusively in the opcode maps, is composed of three parts:

- an initial capital letter that represents the operand source / destination (register-based, memory-based, or immediate) and how it is encoded in the instruction (either as an immediate, or via the ModRM.reg, ModRM.{mod,r/m}, or VEX/XOP.vvvv fields). For register-based operands, the inital letter also specifies the register type (General-purpose, MMX, YMM/XMM, debug, or control register).
- one, two, or three letter modifier (in lowercase) that represents the data type (for example, byte, word, quadword, packed single-precision floating-point vector).
- *x*, which indicates for an SSE instruction that the instruction supports both vector sizes (128 bits and 256 bits). The specific vector size is encoded in the VEX/XOP.L field. L=0 indicates 128 bits and L=1 indicates 256 bits.

The following list describes the meaning of each letter that is used in the first position of the operand notation:

A A far pointer encoded in the instruction. No ModRM byte in the instruction encoding.

B General-purpose register specified by the VEX or XOP vvvv field.

C Control register specified by the ModRM.reg field.

D Debug register specified by the ModRM.reg field.

E General purpose register or memory operand specified by the r/m field of the ModRM byte. For memory operands, the ModRM byte may be followed by a SIB byte to specify one of the indexed register-indirect addressing forms.

F rFLAGS register.

G General purpose register specified by the ModRM.reg field.

H YMM or XMM register specified by the VEX/XOP.vvvv field.

I Immediate value encoded in the instruction immediate field.

J The instruction encoding includes a relative offset that is added to the rIP.

L YMM or XMM register specified using the most-significant 4 bits of an 8-bit immediate value. In legacy or compatibility mode the most significant bit is ignored.

M A memory operand specified by the {mod, r/m} field of the ModRM byte. ModRM.mod ≠ 11b.

*M** A sparse array of memory operands addressed using the VSIB addressing mode. See “VSIB Addressing” in Volume 4.

N 64-bit MMX register specified by the ModRM.r/m field. The ModRM.mod field must be 11b.

O The offset of an operand is encoded in the instruction. There is no ModRM byte in the instruction encoding. Indexed register-indirect addressing using the SIB byte is not supported.

P 64-bit MMX register specified by the ModRM.reg field.

Q 64-bit MMX-register or memory operand specified by the {mod, r/m} field of the ModRM byte. For memory operands, the ModRM byte may be followed by a SIB byte to specify one of the indexed register-indirect addressing forms.

R General purpose register specified by the ModRM.r/m field. The ModRM.mod field must be 11b.

S Segment register specified by the ModRM.reg field.

U YMM/XMM register specified by the ModRM.r/m field. The ModRM.mod field must be 11b.

V YMM/XMM register specified by the ModRM.reg field.

W YMM/XMM register or memory operand specified by the {mod, r/m} field of the ModRM byte. For memory operands, the ModRM byte may be followed by a SIB byte to specify one of the indexed register-indirect addressing forms.

X A memory operand addressed by the DS.rSI registers. Used in string instructions.

Y A memory operand addressed by the ES.rDI registers. Used in string instructions.

The following list provides the key for the second part of the operand notation:

a Two 16-bit or 32-bit memory operands, depending on the effective operand size. Used in the BOUND instruction.

b A byte, irrespective of the effective operand size.

c A byte or a word, depending on the effective operand size.

d A doubleword (32 bits), irrespective of the effective operand size.

do A double octword (256 bits), irrespective of the effective operand size.

i A 16-bit integer.

j A 32-bit integer.

m A bit mask of size equal to the source operand.

mn Where *n* = 2,4,8, or 16. A bit mask of size *n*.

o An octword (128 bits), irrespective of the effective operand size.

o.q Operand is either the upper or lower half of a 128-bit value.

p A 32- or 48-bit far pointer, depending on 16- or 32-bit effective operand size.

pb Vector with byte-wide (8-bit) elements (packed byte).

pd A double-precision (64-bit) floating-point vector operand (packed double-precision).

pdw Vector composed of 32-bit doublewords.

ph A half-precision (16-bit) floating-point vector operand (packed half-precision)

pi Vector composed of 16-bit integers (packed integer).

pj Vector composed of 32-bit integers (packed double integer).

pk Vector composed of 8-bit integers (packed half-word integer).

pq Vector composed of 64-bit integers (packed quadword integer).

pqw Vector composed of 64-bit quadwords (packed quadword).

ps A single-precision floating-point vector operand (packed single-precision).

pw Vector composed of 16-bit words (packed word).

q A quadword (64 bits), irrespective of the effective operand size.

s A 6-byte or 10-byte pseudo-descriptor.

sd A scalar double-precision floating-point operand (scalar double).

sj A scalar doubleword (32-bit) integer operand (scalar double integer).

ss A scalar single-precision floating-point operand (scalar single).

v A word, doubleword, or quadword (in 64-bit mode), depending on the effective operand size.

w A word, irrespective of the effective operand size.

x Instruction supports both vector sizes (128 bits or 256 bits). Size is encoded using the VEX/XOP.L field. (L=0: 128 bits; L=1: 256 bits). This symbol may be appended to *ps* or *pd* to represent a packed single- or double-precision floating-point vector of either size; or to *pk*, *pi*, *pj*, or *pq*, to represent a packed 8-bit, 16-bit, 32-bit, or 64-bit packed integer vector of either size.

y A doubleword or quadword depending on effective operand size.

z A word if the effective operand size is 16 bits, or a doubleword if the effective operand size is 32 or 64 bits.

For some instructions, fields in the ModRM or SIB byte are used as encoding extensions. This is indicated using the following notation:

/n A ModRM-byte *reg* field or SIB-byte *base* field, where *n* is a value between zero (000b) and 7 (111b).

For SSE instructions that take scalar operands, VEX/XOP.L field is ignored.

For immediates and memory-based operands, only the size and not the datatype is indicated. Operand widths and datatypes are specified based on the source operands. For instructions where the result overwrites one of the source registers, the data width and datatype of the result may not match that of the source register. See individual instruction descriptions for more details.

A.1 Opcode Maps

In all of the following opcode maps, cells shaded grey represent reserved opcodes.

A.1.1 Legacy Opcode Maps

Primary Opcode Map. Tables A-1 and A-2 below show the primary opcode map (known in legacy terminology as one-byte opcodes).

Table A-1 below shows those instructions for which the low nibble is in the range 0–7h. Table A-2 on page 508 shows those instructions for which the low nibble is in the range 8–Fh. In both tables, the rows show the full range (0–Fh) of the high nibble, and the columns show the specified range of the low nibble.

Table A-1. Primary Opcode Map (One-byte Opcodes), Low Nibble 0–7h

Secondary Opcode Map. As described in "Encoding Syntax" on page 1, the escape code 0Fh indicates the switch from the primary to the secondary opcode map. In legacy terminology, the secondary opcode map is presented as a listing of "two-byte" opcodes where the first byte is 0Fh. Tables A-3 and A-4 show the secondary opcode map.

Table A-3 below shows those instructions for which the low nibble is in the range 0–7h. Table A-4 on page 512 shows those instructions for which the low nibble is in the range 8–Fh. In both tables, the rows show the full range (0–Fh) of the high nibble, and the columns show the specified range of the low nibble. Note the added column labeled “prefix.”

For the secondary opcode map shown below, the legacy prefixes 66h, F2h, and F3 are repurposed to provide additional opcode encoding space. For those rows that utilize them, the presence of a 66h, F2h, or F3h prefix changes the operation or the operand types specified by the corresponding opcode value.

As discussed in “Encoding Extensions Using the ModRM Byte” on page 515, some opcode values represent a group of instructions. This is denoted in the map entry by “Group *n*”, where n = [1:17,P]. Instructions within a group are encoded by the reg field of the ModRM byte. These encodings are specified in Table A-7 on page 517. For some opcodes, both the reg and the r/m field of the ModRM byte are used to extend the encoding. See Table A-8 on page 519.

Table A-3. Secondary Opcode Map (Two-byte Opcodes), Low Nibble 0–7h

rFLAGS Condition Codes for CMOV*cc*, J*cc*, and SET*cc* Instructions. Table A-5 shows the rFLAGS condition codes specified by the low nibble in the opcode of the CMOV*cc*, J*cc*, and SET*cc* instructions.

Table A-5. rFLAGS Condition Codes for CMOV*cc*, J*cc*, and SET*cc*

Low Nibble of Opcode (hex)	rFLAGS Value	*cc* Mnemonic	Arithmetic Type	Condition(s)
0	OF = 1	O	Signed	Overflow
1	OF = 0	NO		No Overflow
2	CF = 1	B, C, NAE	Unsigned	Below, Carry, Not Above or Equal
3	CF = 0	NB, NC, AE		Not Below, No Carry, Above or Equal
4	ZF = 1	Z, E		Zero, Equal
5	ZF = 0	NZ, NE		Not Zero, Not Equal
6	CF = 1 or ZF = 1	BE, NA		Below or Equal, Not Above
7	CF = 0 and ZF = 0	NBE, A		Not Below or Equal, Above
8	SF = 1	S	Signed	Sign
9	SF = 0	NS		Not Sign
A	PF = 1	P, PE	n/a	Parity, Parity Even
B	PF = 0	NP, PO		Not Parity, Parity Odd
C	(SF xor OF) = 1	L, NGE	Signed	Less than, Not Greater than or Equal to
D	(SF xor OF) = 0	NL, GE		Not Less than, Greater than or Equal to
E	(SF xor OF) = 1 or ZF = 1	LE, NG		Less than or Equal to, Not Greater than
F	(SF xor OF) = 0 and ZF = 0	NLE, G		Not Less than or Equal to, Greater than

Encoding Extensions Using the ModRM Byte. The ModRM byte, which immediately follows the opcode byte, is used in certain instruction encodings to provide additional opcode bits with which to define the function of the instruction. ModRM bytes have three fields—*mod*, *reg*, and *r/m*, as shown in Figure A-1.

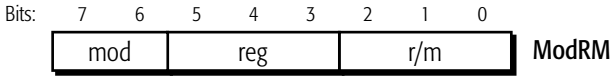

Figure A-1. ModRM-Byte Fields

In most cases, the *reg* field (bits [5:3]), and in some cases, the r/m field (bits [2:0]) provide the additional bits used to extend the encodings of the opcode byte. In the case of the x87 floating-point instructions, the entire ModRM byte is used to extend the opcode encodings.

Table A-6 shows how the ModRM.*reg* field is used to extend the range of opcodes in the primary opcode map. The opcode ranges are organized into *groups* of opcode extensions. The group number is shown in the left-most column. These groups are referenced in the primary opcode map shown in Table A-1 on page 507 and Table A-2 on page 508. An entry of "n.a." in the Prefix column means that prefixes are not applicable to the opcodes in that row. Prefixes only apply to certain 64-bit media and SSE instructions.

Table A-7 on page 517 shows how the ModRM.*reg* field is used to extend the range of the opcodes in the secondary opcode map.

The /0 through /7 notation for the ModRM *reg* field (bits [5:3]) in the tables below means that the three-bit field contains a value from zero (000b) to 7 (111b).

Table A-6. ModRM.reg Extensions for the Primary Opcode Map[1]

Group Number	Prefix	Opcode	ModRM *reg* Field							
			/0	/1	/2	/3	/4	/5	/6	/7
Group 1	n/a	80	ADD Eb, Ib	OR Eb, Ib	ADC Eb, Ib	SBB Eb, Ib	AND Eb, Ib	SUB Eb, Ib	XOR Eb, Ib	CMP Eb, Ib
		81	ADD Ev, Iz	OR Ev, Iz	ADC Ev, Iz	SBB Ev, Iz	AND Ev, Iz	SUB Ev, Iz	XOR Ev, Iz	CMP Ev, Iz
		82	ADD Eb, Ib[2]	OR Eb, Ib[2]	ADC Eb, Ib[2]	SBB Eb, Ib[2]	AND Eb, Ib[2]	SUB Eb, Ib[2]	XOR Eb, Ib[2]	CMP Eb, Ib[2]
		83	ADD Ev, Ib	OR Ev, Ib	ADC Ev, Ib	SBB Ev, Ib	AND Ev, Ib	SUB Ev, Ib	XOR Ev, Ib	CMP Ev, Ib

Notes:
1. *See Table A-7 on page 517 for ModRM extensions for the secondary (two-byte) ocode map.*
2. *Invalid in 64-bit mode.*
3. *This instruction takes a ModRM byte.*
4. *Reserved prefetch encodings are aliased to the /0 encoding (PREFETCH Exclusive) for future compatibility.*
5. *Redundant encoding generally unsupported by tools..*

ModRM.mod = 11b									

0F_38h and 0F_3Ah Opcode Maps. The 0F_38h and 0F_3Ah opcode maps are used primarily to encode the legacy SSE instructions. In legacy terminology, these maps are presented as three-byte opcodes where the first two bytes are {0Fh, 38h} and {0Fh, 3Ah} respectively.

In these maps the legacy prefixes F2h and F3h are repurposed to provide additional opcode encoding space. In rows [0:E] the legacy prefix 66h is also used to modify the opcode. However, in row F, 66h is used as an operand-size override. See the CRC32 instruction as an example.

The 0F_38h opcode map is presented below in Tables A-9 and A-10. The 0F_3Ah opcode map is presented in Tables A-11 and A-12.

A.1.2 3DNow!™ Opcodes

The 64-bit media instructions include the MMX™ instructions and the AMD 3DNow!™ instructions. The MMX instructions are encoded using two opcode bytes, as described in “Secondary Opcode Map” on page 508.

The 3DNow! instructions are encoded using two 0Fh opcode bytes and an immediate byte that is located at the last byte position of the instruction encoding. Thus, the format for 3DNow! instructions is:

```
0Fh 0Fh [ModRM] [SIB] [displacement] imm8_opcode
```

Table A-13 and Table A-14 on page 524 show the immediate byte following the opcode bytes for 3DNow! instructions. In these tables, rows show the high nibble of the immediate byte, and columns show the low nibble of the immediate byte. Table A-13 shows the immediate bytes whose low nibble is in the range 0–7h. Table A-14 shows the same for immediate bytes whose low nibble is in the range 8–Fh.

Byte values shown as *reserved* in these tables have implementation-specific functions, which can include an invalid-opcode exception.

Notes:

1. *All 3DNow!™ opcodes consist of two 0Fh bytes. This table shows the immediate byte for 3DNow! opcodes. Rows show the high nibble of the immediate byte. Columns show the low nibble of the immediate byte.*

A.1.3 x87 Encodings

All x87 instructions begin with an opcode byte in the range D8h to DFh, as shown in Table A-2 on page 508. These opcodes are followed by a ModRM byte that further defines the opcode. Table A-15 shows both the opcode byte and the ModRM byte for each x87 instruction.

There are two significant ranges for the ModRM byte for x87 opcodes: 00–BFh and C0–FFh. When the value of the ModRM byte falls within the first range, 00–BFh, the opcode uses only the *reg* field to further define the opcode. When the value of the ModRM byte falls within the second range, C0–FFh, the opcode uses the entire ModRM byte to further define the opcode.

Byte values shown as *reserved* or *invalid* in Table A-15 have implementation-specific functions, which can include an invalid-opcode exception.

The basic instructions FNSTENV, FNSTCW, FNCLEX, FNINIT, FNSAVE, FNSTSW, and FNSTSW do not check for possible floating point exceptions before operating. Utility versions of these mnemonics are provided that insert an FWAIT (opcode 9B) before the corresponding non-waiting instruction. These are FSTENV, FSTCW, FCLEX, FINIT, FSAVE, and FSTSW. For further information on wait and non-waiting versions of these instructions, see their corresponding pages in Volume 5.

A.1.4 rFLAGS Condition Codes for x87 Opcodes

Table A-16 shows the rFLAGS condition codes specified by the opcode and ModRM bytes of the FCMOV*cc* instructions.

Table A-16. rFLAGS Condition Codes for FCMOV*cc*

Opcode (hex)	ModRM *mod* Field	ModRM *reg* Field	rFLAGS Value	cc Mnemonic	Condition
DA	11	000	CF = 1	B	Below
		001	ZF = 1	E	Equal
		010	CF = 1 or ZF = 1	BE	Below or Equal
		011	PF = 1	U	Unordered
DB		000	CF = 0	NB	Not Below
		001	ZF = 0	NE	Not Equal
		010	CF = 0 and ZF = 0	NBE	Not Below or Equal
		011	PF = 0	NU	Not Unordered

A.1.5 Extended Instruction Opcode Maps

The following sections present the VEX and the XOP extended instruction opcode maps. The VEX.map_select field of the three-byte VEX encoding escape sequence selects VEX opcode maps: 01h, 02h, or 03h. The two-byte VEX encoding escape sequence implicitly selects the VEX map 01h.

The XOP.map_select field selects between the three XOP maps: 08h, 09h or 0Ah.

VEX Opcode Maps. Tables A-17 – A-23 below present the VEX opcode maps and Table A-24 on page 542 presents the VEX opcode groups.

Table A-17. VEX Opcode Map 1, Low Nibble = [0h:7h]

			VCMPccSS[1] Vd, Hss, Wss, Ib					
			VCMPccSD[1] Vq, Hsd, Wsd, Ib					

Note 1: The condition codes are: EQ, LT, LE, UNORD, NEQ, NLT, NLE, and ORD; encoded as [00:07h] using Ib.
VEX encoding adds: EQ_UQ, NGE, NGT, FALSE, NEQ_OQ, GE, GT, TRUE [08:0Fh];
EQ_OS, LT_OQ, LE_OQ, UNORD_S, NEQ_US, NLT_UQ, NLE_UQ, ORD_S [10h:17h]; and
EQ_US, NGE_UQ, NGT_UQ, FALSE_OS, NEQ_OS, GE_OQ, GT_OQ, TRUE_US [18:1Fh].
Note 2: Supports both 128 bit and 256 bit vector sizes. Vector size is specified using the VEX.L bit. When L = 0, size is 128 bits; when L = 1, size is 256 bits.
Note 3: Operands are scalars. VEX.L bit is ignored.

Note 1: Supports both 128 bit and 256 bit vector sizes. Vector size is specified using the VEX.L bit. When L = 0, size is 128 bits; when L = 1, size is 256 bits.
Note 2: Operands are scalars. VEX.L bit is ignored.
Note 3: For all VFMADDnnnPS instructions, the data type is packed single-precision floating point.
For all VFMADDnnnPD instructions, the data type is packed double-precision floating point.
Note 4: For all VFMSUBnnnPS instructions, the data type is packed single-precision floating point.
For all VFMSUBnnnPD instructions, the data type is packed double-precision floating point.

A.2 Operand Encodings

An operand is data that affects or is affected by the execution of an instruction. Operands may be located in registers, memory, or I/O ports. For some instructions, the location of one or more operands is implicitly specified based on the opcode alone. However, for most instructions, operands are specified using bytes that immediately follow the opcode byte. These bytes are designated the *mode-register-memory* (ModRM) byte, the *scale-index-base* (SIB) byte, the displacement byte(s), and the immediate byte(s). The presence of the SIB, displacement, and immediate bytes are optional depending on the instruction, and, for instructions that reference memory, the memory addressing mode.

The following sections describe the encoding of the ModRM and SIB bytes in various processor modes.

A.2.1 ModRM Operand References

Figure A-2 below shows the format of the ModRM byte. There are three fields—*mod, reg*, and *r/m*. The *reg* field is normally used to specify a register-based operand. The *mod* and *r/m* fields together provide a 5-bit field, augmented in 64-bit mode by the R and B bits of a REX, VEX, or XOP prefix, normally used to specify the location of a second memory- or register-based operand and, for a memory-based operand, the addressing mode.

As described in “Encoding Extensions Using the ModRM Byte” on page 515, certain instructions use either the reg field, the r/m field, or the entire ModRM byte to extend the opcode byte in the encoding of the instruction operation.

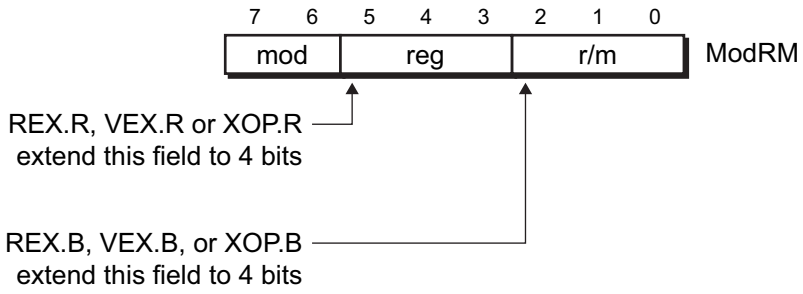

Figure A-2. ModRM-Byte Format

The two sections below describe the ModRM operand encodings, first for 16-bit references and then for 32-bit and 64-bit references.

16-Bit Register and Memory References. Table A-32 shows the notation and encoding conventions for register references using the ModRM *reg* field. This table is comparable to Table A-34 on page 548 but applies only when the address-size is 16-bit. Table A-33 on page 546 shows the

notation and encoding conventions for 16-bit memory references using the ModRM byte. This table is comparable to Table A-35 on page 549.

Table A-32. ModRM *reg* Field Encoding, 16-Bit Addressing

Mnemonic Notation	ModRM *reg* Field							
	/0	/1	/2	/3	/4	/5	/6	/7

Notes:

1. *See Table A-32 for complete specification of ModRM "reg" field.*

Register and Memory References for 32-Bit and 64-Bit Addressing. Table A-34 on page 548 shows the encoding for register references using the ModRM *reg* field. The first ten rows of Table A-34 show references when the REX.R bit is cleared to 0, and the last ten rows show references when the REX.R bit is set to 1. In this table, entries under the *Mnemonic Notation* heading correspond

to register notation described in "Mnemonic Syntax" on page 53, and the */r* notation under the *ModRM reg Field* heading corresponds to that described in "Opcode Syntax" on page 56.

Table A-34. ModRM *reg* Field Encoding, 32-Bit and 64-Bit Addressing

Mnemonic Notation	REX.R Bit	ModRM *reg* Field							
		/0	/1	/2	/3	/4	/5	/6	/7

Table A-35 on page 549 shows the encoding for 32-bit and 64-bit memory references using the ModRM byte. This table describes 32-bit and 64-bit addressing, with the REX.B bit set or cleared. The *Effective Address* is shown in the two left-most columns, followed by the binary encoding of the ModRM-byte *mod* field, followed by the eight possible hex values of the complete ModRM byte (one value for each binary encoding of the ModRM-byte *reg* field), followed by the binary encoding of the ModRM *r/m* field.

The /0 through /7 notation for the ModRM *reg* field (bits [5:3]) means that the three-bit field contains a value from zero (binary 000) to 7 (binary 111).

Table A-35. ModRM Byte Encoding, 32-Bit and 64-Bit Addressing

Effective Address		*ModRM mod* Field (binary)	ModRM *reg* Field[1]								*ModRM r/m* Field (binary)
			/0	/1	/2	/3	/4	/5	/6	/7

Notes:

1. *See Table A-34 for complete specification of ModRM "reg" field.*
2. *If SIB.base = 5, the SIB byte is followed by four-byte disp32 field and addressing mode is absolute.*
3. *In 64-bit mode, the effective address is [rIP]+disp32. In all other modes, the effective address is disp32. If the address-size prefix is used in 64-bit mode to override 64-bit addressing, the [RIP]+disp32 effective address is truncated after computation to 32 bits.*

A.2.2 SIB Operand References

Figure A-3 on page 551 shows the format of a scale-index-base (SIB) byte. Some instructions have an SIB byte following their ModRM byte to define memory addressing for the complex-addressing modes described in "Effective Addresses" in Volume 1. The SIB byte has three fields—*scale*, *index*, and *base*—that define the scale factor, index-register number, and base-register number for 32-bit and 64-bit complex addressing modes. In 64-bit mode, the REX.B and REX.X bits extend the encoding of the SIB byte's *base* and *index* fields.

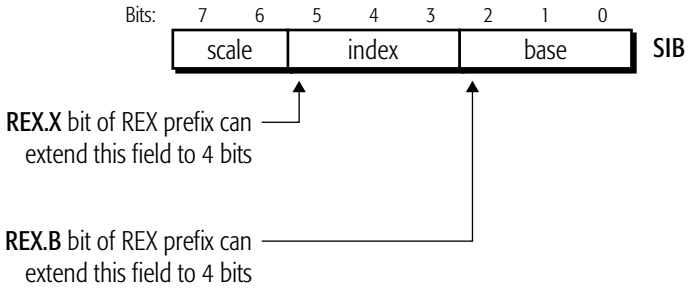

Figure A-3. SIB Byte Format

Table A-36 shows the encodings for the SIB byte's *base* field, which specifies the base register for addressing. Table A-37 on page 552 shows the encodings for the effective address referenced by a complete SIB byte, including its *scale* and *index* fields. The /0 through /7 notation for the SIB *base* field means that the three-bit field contains a value between zero (binary 000) and 7 (binary 111).

Table A-36. Addressing Modes: SIB *base* Field Encoding

REX.B Bit	ModRM *mod* Field	SIB *base* Field							
		/0	*/1*	*/2*	*/3*	*/4*	*/5*	*/6*	*/7*
0	00	[rAX]	[rCX]	[rDX]	[rBX]	[rSP]	*disp32*	[rSI]	[rDI]
	01						[rBP] + *disp8*		
	10						[rBP] + *disp32*		
1	00	[r8]	[r9]	[r10]	[r11]	[r12]	disp32	[r14]	[r15]
	01						[r13] + *disp8*

Notes:

1. *See Table A-36 on page 551 for complete specification of SIB base field.*

Appendix B General-Purpose Instructions in 64-Bit Mode

This appendix provides details of the general-purpose instructions in 64-bit mode and its differences from legacy and compatibility modes. The appendix covers only the general-purpose instructions (those described in *Chapter 3, "General-Purpose Instruction Reference"*). It does not cover the 128-bit media, 64-bit media, or x87 floating-point instructions because those instructions are not affected by 64-bit mode, other than in the access by such instructions to extended GPR and XMM registers when using a REX prefix.

B.1 General Rules for 64-Bit Mode

In 64-bit mode, the following general rules apply to instructions and their operands:

- **"Promoted to 64 Bit"**: If an instruction's operand size (16-bit or 32-bit) in legacy and compatibility modes depends on the CS.D bit and the operand-size override prefix, then the operand-size choices in 64-bit mode are extended from 16-bit and 32-bit to include 64 bits (with a REX prefix), or the operand size is fixed at 64 bits. Such instructions are said to be "*Promoted to 64 bits"* in Table B-1. However, byte-operand opcodes of such instructions are not promoted.
- **Byte-Operand Opcodes Not Promoted**: As stated above in "Promoted to 64 Bit", byte-operand opcodes of promoted instructions are not promoted. Those opcodes continue to operate only on bytes.
- **Fixed Operand Size**: If an instruction's operand size is fixed in legacy mode (thus, independent of CS.D and prefix overrides), that operand size is usually fixed at the same size in 64-bit mode. For example, CPUID operates on 32-bit operands, irrespective of attempts to override the operand size.
- **Default Operand Size**: The default operand size for most instructions is 32 bits, and a REX prefix must be used to change the operand size to 64 bits. However, two groups of instructions default to 64-bit operand size and do not need a REX prefix: (1) near branches and (2) all instructions, except far branches, that implicitly reference the RSP. See Table B-5 on page 583 for a list of all instructions that default to 64-bit operand size.
- **Zero-Extension of 32-Bit Results**: Operations on 32-bit operands in 64-bit mode zero-extend the high 32 bits of 64-bit GPR destination registers.
- **No Extension of 8-Bit and 16-Bit Results**: Operations on 8-bit and 16-bit operands in 64-bit mode leave the high 56 or 48 bits, respectively, of 64-bit GPR destination registers unchanged.
- **Shift and Rotate Counts**: When the operand size is 64 bits, shifts and rotates use one additional bit (6 bits total) to specify shift-count or rotate-count, allowing 64-bit shifts and rotates.
- **Immediates**: The maximum size of immediate operands is 32 bits, except that 64-bit immediates can be MOVed into 64-bit GPRs. Immediates that are less than 64 bits are a maximum of 32 bits, and are sign-extended to 64 bits during use.

- **Displacements and Offsets**: The maximum size of an address displacement or offset is 32 bits, except that 64-bit offsets can be used by specific MOV opcodes that read or write AL or rAX. Displacements and offsets that are less than 64 bits are a maximum of 32 bits, and are sign-extended to 64 bits during use.
- **Undefined High 32 Bits After Mode Change**: The processor does not preserve the upper 32 bits of the 64-bit GPRs across switches from 64-bit mode to compatibility or legacy modes. In compatibility or legacy mode, the upper 32 bits of the GPRs are undefined and not accessible to software.

B.2 Operation and Operand Size in 64-Bit Mode

Table B-1 lists the integer instructions, showing operand size in 64-bit mode and the state of the high 32 bits of destination registers when 32-bit operands are used. Opcodes, such as byte-operand versions of several instructions, that do not appear in Table B-1 are covered by the general rules described in "General Rules for 64-Bit Mode" on page 555.

Table B-1. Operations and Operands in 64-Bit Mode

Instruction and Opcode (hex)[1]	Type of Operation[2]	Default Operand Size[3]	For 32-Bit Operand Size[4]	For 64-Bit Operand Size[4]
AAA - ASCII Adjust after Addition 37	INVALID IN 64-BIT MODE (invalid-opcode exception)			
AAD - ASCII Adjust AX before Division D5	INVALID IN 64-BIT MODE (invalid-opcode exception)			
AAM - ASCII Adjust AX after Multiply D4	INVALID IN 64-BIT MODE (invalid-opcode exception)			
AAS - ASCII Adjust AL after Subtraction 3F	INVALID IN 64-BIT MODE (invalid-opcode exception)			

Notes:

1. *See "General Rules for 64-Bit Mode" on page 555, for opcodes that do not appear in this table.*
2. *The type of operation, excluding considerations of operand size or extension of results. See "General Rules for 64-Bit Mode" on page 555 for definitions of "Promoted to 64 bits" and related topics.*
3. *If "Type of Operation" is 64 bits, a REX prefix is needed for 64-bit operand size, unless the instruction size defaults to 64 bits. If the operand size is fixed, operand-size overrides are silently ignored.*
4. *Special actions in 64-bit mode, in addition to legacy-mode actions. Zero or sign extensions apply only to result operands, not source operands. Unless otherwise stated, 8-bit and 16-bit results leave the high 56 or 48 bits, respectively, of 64-bit destination registers unchanged. Immediates and branch displacements are sign-extended to 64 bits.*
5. *Any pointer registers (rDI, rSI) or count registers (rCX) are address-sized and default to 64 bits. For 32-bit address size, any pointer and count registers are zero-extended to 64 bits.*
6. *The default operand size can be overridden to 16 bits with 66h prefix, but there is no 32-bit operand-size override in 64-bit mode.*

Table B-1. Operations and Operands in 64-Bit Mode (continued)

Instruction and Opcode (hex)[1]	Type of Operation[2]	Default Operand Size[3]	For 32-Bit Operand Size[4]	For 64-Bit Operand Size[4]
ADC—Add with Carry 11 13 15 81 /2 83 /2	Promoted to 64 bits.	32 bits	Zero-extends 32-bit register results to 64 bits.	
ADD—Signed or Unsigned Add 01 03 05 81 /0 83 /0	Promoted to 64 bits.	32 bits	Zero-extends 32-bit register results to 64 bits.	
AND—Logical AND 21 23 25 81 /4 83 /4	Promoted to 64 bits.	32 bits	Zero-extends 32-bit register results to 64 bits.	
ARPL - Adjust Requestor Privilege Level 63	OPCODE USED as MOVSXD in 64-BIT MODE			
BOUND - Check Array Against Bounds 62	INVALID IN 64-BIT MODE (invalid-opcode exception)			
BSF—Bit Scan Forward 0F BC	Promoted to 64 bits.	32 bits	Zero-extends 32-bit register results to 64 bits.	

Notes:

1. *See “General Rules for 64-Bit Mode” on page 555, for opcodes that do not appear in this table.*
2. *The type of operation, excluding considerations of operand size or extension of results. See “General Rules for 64-Bit Mode” on page 555 for definitions of “Promoted to 64 bits” and related topics.*
3. *If “Type of Operation” is 64 bits, a REX prefix is needed for 64-bit operand size, unless the instruction size defaults to 64 bits. If the operand size is fixed, operand-size overrides are silently ignored.*
4. *Special actions in 64-bit mode, in addition to legacy-mode actions. Zero or sign extensions apply only to result operands, not source operands. Unless otherwise stated, 8-bit and 16-bit results leave the high 56 or 48 bits, respectively, of 64-bit destination registers unchanged. Immediates and branch displacements are sign-extended to 64 bits.*
5. *Any pointer registers (rDI, rSI) or count registers (rCX) are address-sized and default to 64 bits. For 32-bit address size, any pointer and count registers are zero-extended to 64 bits.*
6. *The default operand size can be overridden to 16 bits with 66h prefix, but there is no 32-bit operand-size override in 64-bit mode.*

Table B-1. Operations and Operands in 64-Bit Mode (continued)

Instruction and Opcode (hex)[1]	Type of Operation[2]	Default Operand Size[3]	For 32-Bit Operand Size[4]	For 64-Bit Operand Size[4]
BSR—Bit Scan Reverse 0F BD	Promoted to 64 bits.	32 bits	Zero-extends 32-bit register results to 64 bits.	
BSWAP—Byte Swap 0F C8 through 0F CF	Promoted to 64 bits.	32 bits	Zero-extends 32-bit register results to 64 bits.	Swap all 8 bytes of a 64-bit GPR.
BT—Bit Test 0F A3 0F BA /4	Promoted to 64 bits.	32 bits	No GPR register results.	
BTC—Bit Test and Complement 0F BB 0F BA /7	Promoted to 64 bits.	32 bits	Zero-extends 32-bit register results to 64 bits.	
BTR—Bit Test and Reset 0F B3 0F BA /6	Promoted to 64 bits.	32 bits	Zero-extends 32-bit register results to 64 bits.	
BTS—Bit Test and Set 0F AB 0F BA /5	Promoted to 64 bits.	32 bits	Zero-extends 32-bit register results to 64 bits.	
CALL—Procedure Call Near	See “Near Branches in 64-Bit Mode” in Volume 1.			
E8	Promoted to 64 bits.	64 bits	Can’t encode.[6]	RIP = RIP + 32-bit displacement sign-extended to 64 bits.
FF /2	Promoted to 64 bits.	64 bits	Can’t encode.[6]	RIP = 64-bit offset from register or memory.

Notes:

1. *See “General Rules for 64-Bit Mode” on page 555, for opcodes that do not appear in this table.*
2. *The type of operation, excluding considerations of operand size or extension of results. See “General Rules for 64-Bit Mode” on page 555 for definitions of “Promoted to 64 bits” and related topics.*
3. *If “Type of Operation” is 64 bits, a REX prefix is needed for 64-bit operand size, unless the instruction size defaults to 64 bits. If the operand size is fixed, operand-size overrides are silently ignored.*
4. *Special actions in 64-bit mode, in addition to legacy-mode actions. Zero or sign extensions apply only to result operands, not source operands. Unless otherwise stated, 8-bit and 16-bit results leave the high 56 or 48 bits, respectively, of 64-bit destination registers unchanged. Immediates and branch displacements are sign-extended to 64 bits.*
5. *Any pointer registers (rDI, rSI) or count registers (rCX) are address-sized and default to 64 bits. For 32-bit address size, any pointer and count registers are zero-extended to 64 bits.*
6. *The default operand size can be overridden to 16 bits with 66h prefix, but there is no 32-bit operand-size override in 64-bit mode.*

Table B-1. Operations and Operands in 64-Bit Mode (continued)

Instruction and Opcode (hex)[1]	Type of Operation[2]	Default Operand Size[3]	For 32-Bit Operand Size[4]	For 64-Bit Operand Size[4]
CALL—Procedure Call Far	See “Branches to 64-Bit Offsets” in Volume 1.			
9A	INVALID IN 64-BIT MODE (invalid-opcode exception)			
FF /3	Promoted to 64 bits.	32 bits	If selector points to a gate, then RIP = 64-bit offset from gate, else RIP = zero-extended 32-bit offset from far pointer referenced in instruction.	
CBW, CWDE, CDQE—Convert Byte to Word, Convert Word to Doubleword, Convert Doubleword to Quadword 98	Promoted to 64 bits.	32 bits (size of destination register)	CWDE: Converts word to doubleword. Zero-extends EAX to RAX.	CDQE (new mnemonic): Converts doubleword to quadword. RAX = sign-extended EAX.
CDQ	see **CWD, CDQ, CQO**			
CDQE (new mnemonic)	see **CBW, CWDE, CDQE**			
CDWE	see **CBW, CWDE, CDQE**			
CLC—Clear Carry Flag F8	Same as legacy mode.	Not relevant.	No GPR register results.	
CLD—Clear Direction Flag FC	Same as legacy mode.	Not relevant.	No GPR register results.	
CLFLUSH—Cache Line Invalidate 0F AE /7	Same as legacy mode.	Not relevant.	No GPR register results.	
CLGI—Clear Global Interrupt 0F 01 DD	Same as legacy mode	Not relevant	No GPR register results.	
CLI—Clear Interrupt Flag FA	Same as legacy mode.	Not relevant.	No GPR register results.	

Notes:

1. *See “General Rules for 64-Bit Mode” on page 555, for opcodes that do not appear in this table.*
2. *The type of operation, excluding considerations of operand size or extension of results. See “General Rules for 64-Bit Mode” on page 555 for definitions of “Promoted to 64 bits” and related topics.*
3. *If “Type of Operation” is 64 bits, a REX prefix is needed for 64-bit operand size, unless the instruction size defaults to 64 bits. If the operand size is fixed, operand-size overrides are silently ignored.*
4. *Special actions in 64-bit mode, in addition to legacy-mode actions. Zero or sign extensions apply only to result operands, not source operands. Unless otherwise stated, 8-bit and 16-bit results leave the high 56 or 48 bits, respectively, of 64-bit destination registers unchanged. Immediates and branch displacements are sign-extended to 64 bits.*
5. *Any pointer registers (rDI, rSI) or count registers (rCX) are address-sized and default to 64 bits. For 32-bit address size, any pointer and count registers are zero-extended to 64 bits.*
6. *The default operand size can be overridden to 16 bits with 66h prefix, but there is no 32-bit operand-size override in 64-bit mode.*

Table B-1. Operations and Operands in 64-Bit Mode (continued)

Instruction and Opcode (hex)[1]	Type of Operation[2]	Default Operand Size[3]	For 32-Bit Operand Size[4]	For 64-Bit Operand Size[4]
CLTS—Clear Task-Switched Flag in CR0 0F 06	Same as legacy mode.	Not relevant.	No GPR register results.	
CMC—Complement Carry Flag F5	Same as legacy mode.	Not relevant.	No GPR register results.	
CMOV*cc*—Conditional Move 0F 40 through 0F 4F	Promoted to 64 bits.	32 bits	Zero-extends 32-bit register results to 64 bits. This occurs even if the condition is false.	
CMP—Compare 39 3B 3D 81 /7 83 /7	Promoted to 64 bits.	32 bits	Zero-extends 32-bit register results to 64 bits.	
CMPS, **CMPSW**, **CMPSD, CMPSQ**—Compare Strings A7	Promoted to 64 bits.	32 bits	CMPSD: Compare String Doublewords. See footnote[5]	CMPSQ (new mnemonic): Compare String Quadwords See footnote[5]
CMPXCHG—Compare and Exchange 0F B1	Promoted to 64 bits.	32 bits	Zero-extends 32-bit register results to 64 bits.	

Notes:

1. *See "General Rules for 64-Bit Mode" on page 555, for opcodes that do not appear in this table.*
2. *The type of operation, excluding considerations of operand size or extension of results. See "General Rules for 64-Bit Mode" on page 555 for definitions of "Promoted to 64 bits" and related topics.*
3. *If "Type of Operation" is 64 bits, a REX prefix is needed for 64-bit operand size, unless the instruction size defaults to 64 bits. If the operand size is fixed, operand-size overrides are silently ignored.*
4. *Special actions in 64-bit mode, in addition to legacy-mode actions. Zero or sign extensions apply only to result operands, not source operands. Unless otherwise stated, 8-bit and 16-bit results leave the high 56 or 48 bits, respectively, of 64-bit destination registers unchanged. Immediates and branch displacements are sign-extended to 64 bits.*
5. *Any pointer registers (rDI, rSI) or count registers (rCX) are address-sized and default to 64 bits. For 32-bit address size, any pointer and count registers are zero-extended to 64 bits.*
6. *The default operand size can be overridden to 16 bits with 66h prefix, but there is no 32-bit operand-size override in 64-bit mode.*

Table B-1. Operations and Operands in 64-Bit Mode (continued)

Instruction and Opcode (hex)[1]	Type of Operation[2]	Default Operand Size[3]	For 32-Bit Operand Size[4]	For 64-Bit Operand Size[4]
CMPXCHG8B—Compare and Exchange Eight Bytes 0F C7 /1	Same as legacy mode.	32 bits.	Zero-extends EDX and EAX to 64 bits.	CMPXCHG16B (new mnemonic): Compare and Exchange 16 Bytes.
CPUID—Processor Identification 0F A2	Same as legacy mode.	Operand size fixed at 32 bits.	Zero-extends 32-bit register results to 64 bits.	
CQO (new mnemonic)	see **CWD, CDQ, CQO**			
CWD, CDQ, CQO—Convert Word to Doubleword, Convert Doubleword to Quadword, Convert Quadword to Double Quadword 99	Promoted to 64 bits.	32 bits (size of destination register)	CDQ: Converts doubleword to quadword. Sign-extends EAX to EDX. Zero-extends EDX to RDX. RAX is unchanged.	CQO (new mnemonic): Converts quadword to double quadword. Sign-extends RAX to RDX. RAX is unchanged.
DAA - Decimal Adjust AL after Addition 27	INVALID IN 64-BIT MODE (invalid-opcode exception)			
DAS - Decimal Adjust AL after Subtraction 2F	INVALID IN 64-BIT MODE (invalid-opcode exception)			

Notes:

1. *See “General Rules for 64-Bit Mode” on page 555, for opcodes that do not appear in this table.*
2. *The type of operation, excluding considerations of operand size or extension of results. See “General Rules for 64-Bit Mode” on page 555 for definitions of “Promoted to 64 bits” and related topics.*

Immediates and branch displacements are sign-extended to 64 bits.*
5. *Any pointer registers (rDI, rSI) or count registers (rCX) are address-sized and default to 64 bits. For 32-bit address size, any pointer and count registers are zero-extended to 64 bits.*
6. *The default operand size can be overridden to 16 bits with 66h prefix, but there is no 32-bit operand-size override in 64-bit mode.*

Table B-1. Operations and Operands in 64-Bit Mode (continued)

Instruction and Opcode (hex)[1]	Type of Operation[2]	Default Operand Size[3]	For 32-Bit Operand Size[4]	For 64-Bit Operand Size[4]
DEC—Decrement by 1 FF /1	Promoted to 64 bits.	32 bits	Zero-extends 32-bit register results to 64 bits.	
48 through 4F	OPCODE USED as REX PREFIX in 64-BIT MODE			
DIV—Unsigned Divide F7 /6	Promoted to 64 bits.	32 bits	Zero-extends 32-bit register results to 64 bits.	RDX:RAX contain a 64-bit quotient (RAX) and 64-bit remainder (RDX).
ENTER—Create Procedure Stack Frame C8	Promoted to 64 bits.	64 bits	Can't encode[6]	
HLT—Halt F4	Same as legacy mode.	Not relevant.	No GPR register results.	
IDIV—Signed Divide F7 /7	Promoted to 64 bits.	32 bits	Zero-extends 32-bit register results to 64 bits.	RDX:RAX contain a 64-bit quotient (RAX) and 64-bit remainder (RDX).

Notes:

1. *See "General Rules for 64-Bit Mode" on page 555, for opcodes that do not appear in this table.*
2. *The type of operation, excluding considerations of operand size or extension of results. See "General Rules for 64-Bit Mode" on page 555 for definitions of "Promoted to 64 bits" and related topics.*
3. *If "Type of Operation" is 64 bits, a REX prefix is needed for 64-bit operand size, unless the instruction size defaults to 64 bits. If the operand size is fixed, operand-size overrides are silently ignored.*
4. *Special actions in 64-bit mode, in addition to legacy-mode actions. Zero or sign extensions apply only to result operands, not source operands. Unless otherwise stated, 8-bit and 16-bit results leave the high 56 or 48 bits, respectively, of 64-bit destination registers unchanged. Immediates and branch displacements are sign-extended to 64 bits.*
5. *Any pointer registers (rDI, rSI) or count registers (rCX) are address-sized and default to 64 bits. For 32-bit address size, any pointer and count registers are zero-extended to 64 bits.*
6. *The default operand size can be overridden to 16 bits with 66h prefix, but there is no 32-bit operand-size override in 64-bit mode.*

Table B-1. Operations and Operands in 64-Bit Mode (continued)

Instruction and Opcode (hex)[1]	Type of Operation[2]	Default Operand Size[3]	For 32-Bit Operand Size[4]	For 64-Bit Operand Size[4]
IMUL - Signed Multiply F7 /5	Promoted to 64 bits.	32 bits	Zero-extends 32-bit register results to 64 bits.	RDX:RAX = RAX * reg/mem64 (i.e., 128-bit result)
0F AF				reg64 = reg64 * reg/mem64
69				reg64 = reg/mem64 * imm32
6B				reg64 = reg/mem64 * imm8
IN—Input From Port E5 ED	Same as legacy mode.	32 bits	Zero-extends 32-bit register results to 64 bits.	
INC—Increment by 1 FF /0	Promoted to 64 bits.	32 bits	Zero-extends 32-bit register results to 64 bits.	
40 through 47	OPCODE USED as REX PREFIX in 64-BIT MODE			
INS, INSW, INSD—Input String 6D	Same as legacy mode.	32 bits	INSD: Input String Doublewords. No GPR register results. See footnote[5]	
INT n—Interrupt to Vector CD	Promoted to 64 bits.	Not relevant.	See “Long-Mode Interrupt Control Transfers” in Volume 2.	
INT3—Interrupt to Debug Vector CC				
INTO - Interrupt to Overflow Vector CE	INVALID IN 64-BIT MODE (invalid-opcode exception)			

Notes:

1. *See “General Rules for 64-Bit Mode” on page 555, for opcodes that do not appear in this table.*
2. *The type of operation, excluding considerations of operand size or extension of results. See “General Rules for 64-Bit Mode” on page 555 for definitions of “Promoted to 64 bits” and related topics.*
3. *If “Type of Operation” is 64 bits, a REX prefix is needed for 64-bit operand size, unless the instruction size defaults to 64 bits. If the operand size is fixed, operand-size overrides are silently ignored.*

Unless otherwise stated, 8-bit and 16-bit results leave the high 56 or 48 bits, respectively, of 64-bit destination registers unchanged. Immediates and branch displacements are sign-extended to 64 bits.*
5. *Any pointer registers (rDI, rSI) or count registers (rCX) are address-sized and default to 64 bits. For 32-bit address size, any pointer and count registers are zero-extended to 64 bits.*
6. *The default operand size can be overridden to 16 bits with 66h prefix, but there is no 32-bit operand-size override in 64-bit mode.*

Table B-1. Operations and Operands in 64-Bit Mode (continued)

Instruction and Opcode (hex)[1]	Type of Operation[2]	Default Operand Size[3]	For 32-Bit Operand Size[4]	For 64-Bit Operand Size[4]
INVD—Invalidate Internal Caches 0F 08	Same as legacy mode.	Not relevant.	No GPR register results.	
INVLPG—Invalidate TLB Entry 0F 01 /7	Promoted to 64 bits.	Not relevant.	No GPR register results.	
INVLPGA—Invalidate TLB Entry in a Specified ASID	Same as legacy mode.	Not relevant.	No GPR register results.	
IRET, **IRETD, IRETQ**—Interrupt Return CF	Promoted to 64 bits.	32 bits	IRETD: Interrupt Return Doubleword. See “Long-Mode Interrupt Control Transfers” in Volume 2.	IRETQ (new mnemonic): Interrupt Return Quadword. See “Long-Mode Interrupt Control Transfers” in Volume 2.
Jcc—Jump Conditional	See “Near Branches in 64-Bit Mode” in Volume 1.			
70 through 7F	Promoted to 64 bits.	64 bits	Can’t encode.[6]	RIP = RIP + 8-bit displacement sign-extended to 64 bits.
0F 80 through 0F 8F				RIP = RIP + 32-bit displacement sign-extended to 64 bits.
JCXZ, **JECXZ, JRCXZ**—Jump on CX/ECX/RCX Zero E3	Promoted to 64 bits.	64 bits	Can’t encode.[6]	RIP = RIP + 8-bit displacement sign-extended to 64 bits. See footnote[5]

Notes:

1. *See “General Rules for 64-Bit Mode” on page 555, for opcodes that do not appear in this table.*
2. *The type of operation, excluding considerations of operand size or extension of results. See “General Rules for 64-Bit Mode” on page 555 for definitions of “Promoted to 64 bits” and related topics.*
3. *If “Type of Operation” is 64 bits, a REX prefix is needed for 64-bit operand size, unless the instruction size defaults to 64 bits. If the operand size is fixed, operand-size overrides are silently ignored.*
4. *Special actions in 64-bit mode, in addition to legacy-mode actions. Zero or sign extensions apply only to result operands, not source operands. Unless otherwise stated, 8-bit and 16-bit results leave the high 56 or 48 bits, respectively, of 64-bit destination registers unchanged. Immediates and branch displacements are sign-extended to 64 bits.*
5. *Any pointer registers (rDI, rSI) or count registers (rCX) are address-sized and default to 64 bits. For 32-bit address size, any pointer and count registers are zero-extended to 64 bits.*
6. *The default operand size can be overridden to 16 bits with 66h prefix, but there is no 32-bit operand-size override in 64-bit mode.*

Table B-1. Operations and Operands in 64-Bit Mode (continued)

Instruction and Opcode (hex)[1]	Type of Operation[2]	Default Operand Size[3]	For 32-Bit Operand Size[4]	For 64-Bit Operand Size[4]
JMP—Jump Near	See “Near Branches in 64-Bit Mode” in Volume 1.			
EB	Promoted to 64 bits.	64 bits	Can’t encode.[6]	RIP = RIP + 8-bit displacement sign-extended to 64 bits.
E9				RIP = RIP + 32-bit displacement sign-extended to 64 bits.
FF /4				RIP = 64-bit offset from register or memory.
JMP—Jump Far	See “Branches to 64-Bit Offsets” in Volume 1.			
EA	INVALID IN 64-BIT MODE (invalid-opcode exception)			
FF /5	Promoted to 64 bits.	32 bits	If selector points to a gate, then RIP = 64-bit offset from gate, else RIP = zero-extended 32-bit offset from far pointer referenced in instruction.	
LAHF - Load Status Flags into AH Register 9F	Same as legacy mode.	Not relevant.		
LAR—Load Access Rights Byte 0F 02	Same as legacy mode.	32 bits	Zero-extends 32-bit register results to 64 bits.	
LDS - Load DS Far Pointer C5	INVALID IN 64-BIT MODE (invalid-opcode exception)			

Notes:

1. *See “General Rules for 64-Bit Mode” on page 555, for opcodes that do not appear in this table.*
2. *The type of operation, excluding considerations of operand size or extension of results. See “General Rules for 64-Bit Mode” on page 555 for definitions of “Promoted to 64 bits” and related topics.*
3. *If “Type of Operation” is 64 bits, a REX prefix is needed for 64-bit operand size, unless the instruction size defaults to 64 bits. If the operand size is fixed, operand-size overrides are silently ignored.*
4. *Special actions in 64-bit mode, in addition to legacy-mode actions. Zero or sign extensions apply only to result operands, not source operands. Unless otherwise stated, 8-bit and 16-bit results leave the high 56 or 48 bits, respectively, of 64-bit destination registers unchanged. Immediates and branch displacements are sign-extended to 64 bits.*
5. *Any pointer registers (rDI, rSI) or count registers (rCX) are address-sized and default to 64 bits. For 32-bit address size, any pointer and count registers are zero-extended to 64 bits.*
6. *The default operand size can be overridden to 16 bits with 66h prefix, but there is no 32-bit operand-size override in 64-bit mode.*

Table B-1. Operations and Operands in 64-Bit Mode (continued)

Instruction and Opcode (hex)[1]	Type of Operation[2]	Default Operand Size[3]	For 32-Bit Operand Size[4]	For 64-Bit Operand Size[4]
LEA—Load Effective Address 8D	Promoted to 64 bits.	32 bits	Zero-extends 32-bit register results to 64 bits.	
LEAVE—Delete Procedure Stack Frame C9	Promoted to 64 bits.	64 bits	Can't encode[6]	
LES - Load ES Far Pointer C4	INVALID IN 64-BIT MODE (invalid-opcode exception)			
LFENCE—Load Fence 0F AE /5	Same as legacy mode.	Not relevant.	No GPR register results.	
LFS—Load FS Far Pointer 0F B4	Same as legacy mode.	32 bits	Zero-extends 32-bit register results to 64 bits.	
LGDT—Load Global Descriptor Table Register 0F 01 /2	Promoted to 64 bits.	Operand size fixed at 64 bits.	No GPR register results. Loads 8-byte base and 2-byte limit.	
LGS—Load GS Far Pointer 0F B5	Same as legacy mode.	32 bits	Zero-extends 32-bit register results to 64 bits.	
LIDT—Load Interrupt Descriptor Table Register 0F 01 /3	Promoted to 64 bits.	Operand size fixed at 64 bits.	No GPR register results. Loads 8-byte base and 2-byte limit.	
LLDT—Load Local Descriptor Table Register 0F 00 /2	Promoted to 64 bits.	Operand size fixed at 16 bits.	No GPR register results. References 16-byte descriptor to load 64-bit base.	
LMSW—Load Machine Status Word 0F 01 /6	Same as legacy mode.	Operand size fixed at 16 bits.	No GPR register results.	

Notes:

1. *See "General Rules for 64-Bit Mode" on page 555, for opcodes that do not appear in this table.*
2. *The type of operation, excluding considerations of operand size or extension of results. See "General Rules for 64-Bit Mode" on page 555 for definitions of "Promoted to 64 bits" and related topics.*

Immediates and branch displacements are sign-extended to 64 bits.*
5. *Any pointer registers (rDI, rSI) or count registers (rCX) are address-sized and default to 64 bits. For 32-bit address size, any pointer and count registers are zero-extended to 64 bits.*
6. *The default operand size can be overridden to 16 bits with 66h prefix, but there is no 32-bit operand-size override in 64-bit mode.*

Table B-1. Operations and Operands in 64-Bit Mode (continued)

Instruction and Opcode (hex)[1]	Type of Operation[2]	Default Operand Size[3]	For 32-Bit Operand Size[4]	For 64-Bit Operand Size[4]
LODS, **LODSW**, **LODSD, LODSQ**—Load String AD	Promoted to 64 bits.	32 bits	LODSD: Load String Doublewords. Zero-extends 32-bit register results to 64 bits. See footnote[5]	LODSQ (new mnemonic): Load String Quadwords. See footnote[5]
LOOP—Loop E2	Promoted to 64 bits.	64 bits	Can't encode.[6]	RIP = RIP + 8-bit displacement sign-extended to 64 bits. See footnote[5]
LOOPZ, **LOOPE**—Loop if Zero/Equal E1				
LOOPNZ, **LOOPNE**—Loop if Not Zero/Equal E0				
LSL—Load Segment Limit 0F 03	Same as legacy mode.	32 bits	Zero-extends 32-bit register results to 64 bits.	
LSS —Load SS Segment Register 0F B2	Same as legacy mode.	32 bits	Zero-extends 32-bit register results to 64 bits.	
LTR—Load Task Register 0F 00 /3	Promoted to 64 bits.	Operand size fixed at 16 bits.	No GPR register results. References 16-byte descriptor to load 64-bit base.	
LZCNT—Count Leading Zeros F3 0F BD	Promoted to 64 bits.	32 bits	Zero-extends 32-bit register results to 64 bits.	
MFENCE—Memory Fence 0F AE /6	Same as legacy mode.	Not relevant.	No GPR register results.	
MONITOR—Setup Monitor Address 0F 01 C8	Same as legacy mode.	Operand size fixed at 32 bits.	No GPR register results.	

Notes:

1. *See "General Rules for 64-Bit Mode" on page 555, for opcodes that do not appear in this table.*
2. *The type of operation, excluding considerations of operand size or extension of results. See "General Rules for 64-Bit Mode" on page 555 for definitions of "Promoted to 64 bits" and related topics.*
3. *If "Type of Operation" is 64 bits, a REX prefix is needed for 64-bit operand size, unless the instruction size defaults to 64 bits. If the operand size is fixed, operand-size overrides are silently ignored.*
4. *Special actions in 64-bit mode, in addition to legacy-mode actions. Zero or sign extensions apply only to result operands, not source operands. Unless otherwise stated, 8-bit and 16-bit results leave the high 56 or 48 bits, respectively, of 64-bit destination registers unchanged. Immediates and branch displacements are sign-extended to 64 bits.*
5. *Any pointer registers (rDI, rSI) or count registers (rCX) are address-sized and default to 64 bits. For 32-bit address size, any pointer and count registers are zero-extended to 64 bits.*
6. *The default operand size can be overridden to 16 bits with 66h prefix, but there is no 32-bit operand-size override in 64-bit mode.*

Table B-1. Operations and Operands in 64-Bit Mode (continued)

Instruction and Opcode (hex)[1]	Type of Operation[2]	Default Operand Size[3]	For 32-Bit Operand Size[4]	For 64-Bit Operand Size[4]
MOV—Move 89 8B C7 B8 through BF A1 (moffset) A3 (moffset)	Promoted to 64 bits.	32 bits	Zero-extends 32-bit register results to 64 bits.	
				32-bit immediate is sign-extended to 64 bits.
				64-bit immediate.
			Zero-extends 32-bit register results to 64 bits. Memory offsets are address-sized and default to 64 bits.	Memory offsets are address-sized and default to 64 bits.
MOV—Move to/from Segment Registers 8C	Same as legacy mode.	32 bits	Zero-extends 32-bit register results to 64 bits.	
8E		Operand size fixed at 16 bits.	No GPR register results.	
MOV(CR*n*)—Move to/from Control Registers 0F 22 0F 20	Promoted to 64 bits.	Operand size fixed at 64 bits.	The high 32 bits of control registers differ in their writability and reserved status. See “System Resources” in Volume 2 for details.	
MOV(DR*n*)—Move to/from Debug Registers 0F 21 0F 23	Promoted to 64 bits.	Operand size fixed at 64 bits.	The high 32 bits of debug registers differ in their writability and reserved status. See “Debug and Performance Resources” in Volume 2 for details.	

Notes:

1. *See “General Rules for 64-Bit Mode” on page 555, for opcodes that do not appear in this table.*
2. *The type of operation, excluding considerations of operand size or extension of results. See “General Rules for 64-Bit Mode” on page 555 for definitions of “Promoted to 64 bits” and related topics.*
3. *If “Type of Operation” is 64 bits, a REX prefix is needed for 64-bit operand size, unless the instruction size defaults to 64 bits. If the operand size is fixed, operand-size overrides are silently ignored.*
4. *Special actions in 64-bit mode, in addition to legacy-mode actions. Zero or sign extensions apply only to result operands, not source operands. Unless otherwise stated, 8-bit and 16-bit results leave the high 56 or 48 bits, respectively, of 64-bit destination registers unchanged. Immediates and branch displacements are sign-extended to 64 bits.*
5. *Any pointer registers (rDI, rSI) or count registers (rCX) are address-sized and default to 64 bits. For 32-bit address size, any pointer and count registers are zero-extended to 64 bits.*
6. *The default operand size can be overridden to 16 bits with 66h prefix, but there is no 32-bit operand-size override in 64-bit mode.*

Table B-1. Operations and Operands in 64-Bit Mode (continued)

Instruction and Opcode (hex)[1]	Type of Operation[2]	Default Operand Size[3]	For 32-Bit Operand Size[4]	For 64-Bit Operand Size[4]
MOVD—Move Doubleword or Quadword 0F 6E 0F 7E	Promoted to 64 bits.	32 bits	Zero-extends 32-bit register results to 64 bits.	
66 0F 6E 66 0F 7E			Zero-extends 32-bit register results to 128 bits.	Zero-extends 64-bit register results to 128 bits.
MOVNTI—Move Non-Temporal Doubleword 0F C3	Promoted to 64 bits.	32 bits	No GPR register results.	
MOVS, **MOVSW**, **MOVSD, MOVSQ**—Move String A5	Promoted to 64 bits.	32 bits	MOVSD: Move String Doublewords. See footnote[5]	MOVSQ (new mnemonic): Move String Quadwords. See footnote[5]
MOVSX—Move with Sign-Extend 0F BE	Promoted to 64 bits.	32 bits	Zero-extends 32-bit register results to 64 bits.	Sign-extends byte to quadword.
0F BF				Sign-extends word to quadword.

Notes:

1. *See “General Rules for 64-Bit Mode” on page 555, for opcodes that do not appear in this table.*
2. *The type of operation, excluding considerations of operand size or extension of results. See “General Rules for 64-Bit Mode” on page 555 for definitions of “Promoted to 64 bits” and related topics.*
3. *If “Type of Operation” is 64 bits, a REX prefix is needed for 64-bit operand size, unless the instruction size defaults to 64 bits. If the operand size is fixed, operand-size overrides are silently ignored.*
4. *Special actions in 64-bit mode, in addition to legacy-mode actions. Zero or sign extensions apply only to result operands, not source operands. Unless otherwise stated, 8-bit and 16-bit results leave the high 56 or 48 bits, respectively, of 64-bit destination registers unchanged. Immediates and branch displacements are sign-extended to 64 bits.*
5. *Any pointer registers (rDI, rSI) or count registers (rCX) are address-sized and default to 64 bits. For 32-bit address size, any pointer and count registers are zero-extended to 64 bits.*
6. *The default operand size can be overridden to 16 bits with 66h prefix, but there is no 32-bit operand-size override in 64-bit mode.*

Table B-1. Operations and Operands in 64-Bit Mode (continued)

Instruction and Opcode (hex)[1]	Type of Operation[2]	Default Operand Size[3]	For 32-Bit Operand Size[4]	For 64-Bit Operand Size[4]
MOVSXD—Move with Sign-Extend Doubleword 63	New instruction, available only in 64-bit mode. (In other modes, this opcode is ARPL instruction.)	32 bits	Zero-extends 32-bit register results to 64 bits.	Sign-extends doubleword to quadword.
MOVZX—Move with Zero-Extend 0F B6	Promoted to 64 bits.	32 bits	Zero-extends 32-bit register results to 64 bits.	Zero-extends byte to quadword.
0F B7				Zero-extends word to quadword.
MUL—Multiply Unsigned F7 /4	Promoted to 64 bits.	32 bits	Zero-extends 32-bit register results to 64 bits.	RDX:RAX=RAX * quadword in register or memory.
MWAIT—Monitor Wait 0F 01 C9	Same as legacy mode.	Operand size fixed at 32 bits.	No GPR register results.	
NEG—Negate Two's Complement F7 /3	Promoted to 64 bits.	32 bits	Zero-extends 32-bit register results to 64 bits.	
NOP—No Operation 90	Same as legacy mode.	Not relevant.	No GPR register results.	
NOT—Negate One's Complement F7 /2	Promoted to 64 bits.	32 bits	Zero-extends 32-bit register results to 64 bits.	

Notes:

1. *See "General Rules for 64-Bit Mode" on page 555, for opcodes that do not appear in this table.*
2. *The type of operation, excluding considerations of operand size or extension of results. See "General Rules for 64-Bit Mode" on page 555 for definitions of "Promoted to 64 bits" and related topics.*
3. *If "Type of Operation" is 64 bits, a REX prefix is needed for 64-bit operand size, unless the instruction size defaults to 64 bits. If the operand size is fixed, operand-size overrides are silently ignored.*
4. *Special actions in 64-bit mode, in addition to legacy-mode actions. Zero or sign extensions apply only to result operands, not source operands. Unless otherwise stated, 8-bit and 16-bit results leave the high 56 or 48 bits, respectively, of 64-bit destination registers unchanged. Immediates and branch displacements are sign-extended to 64 bits.*
5. *Any pointer registers (rDI, rSI) or count registers (rCX) are address-sized and default to 64 bits. For 32-bit address size, any pointer and count registers are zero-extended to 64 bits.*
6. *The default operand size can be overridden to 16 bits with 66h prefix, but there is no 32-bit operand-size override in 64-bit mode.*

Table B-1. Operations and Operands in 64-Bit Mode (continued)

Instruction and Opcode (hex)[1]	Type of Operation[2]	Default Operand Size[3]	For 32-Bit Operand Size[4]	For 64-Bit Operand Size[4]
OR—Logical OR 09 0B 0D 81 /1 83 /1	Promoted to 64 bits.	32 bits	Zero-extends 32-bit register results to 64 bits.	
OUT—Output to Port E7 EF	Same as legacy mode.	32 bits	No GPR register results.	
OUTS, OUTSW, OUTSD—Output String 6F	Same as legacy mode.	32 bits	Writes doubleword to I/O port. No GPR register results. See footnote[5]	
PAUSE—Pause F3 90	Same as legacy mode.	Not relevant.	No GPR register results.	
POP—Pop Stack 8F /0 58 through 5F	Promoted to 64 bits.	64 bits	Cannot encode[6]	No GPR register results.
POP—Pop (segment register from) Stack 0F A1 (POP FS) 0F A9 (POP GS)	Same as legacy mode.	64 bits	Cannot encode[6]	No GPR register results.
1F (POP DS) 07 (POP ES) 17 (POP SS)	INVALID IN 64-BIT MODE (invalid-opcode exception)			

Notes:

1. *See “General Rules for 64-Bit Mode” on page 555, for opcodes that do not appear in this table.*
2. *The type of operation, excluding considerations of operand size or extension of results. See “General Rules for 64-Bit Mode” on page 555 for definitions of “Promoted to 64 bits” and related topics.*
3. *If “Type of Operation” is 64 bits, a REX prefix is needed for 64-bit operand size, unless the instruction size defaults to 64 bits. If the operand size is fixed, operand-size overrides are silently ignored.*
4. *Special actions in 64-bit mode, in addition to legacy-mode actions. Zero or sign extensions apply only to result operands, not source operands. Unless otherwise stated, 8-bit and 16-bit results leave the high 56 or 48 bits, respectively, of 64-bit destination registers unchanged. Immediates and branch displacements are sign-extended to 64 bits.*
5. *Any pointer registers (rDI, rSI) or count registers (rCX) are address-sized and default to 64 bits. For 32-bit address size, any pointer and count registers are zero-extended to 64 bits.*
6. *The default operand size can be overridden to 16 bits with 66h prefix, but there is no 32-bit operand-size override in 64-bit mode.*

Table B-1. Operations and Operands in 64-Bit Mode (continued)

Instruction and Opcode (hex)[1]	Type of Operation[2]	Default Operand Size[3]	For 32-Bit Operand Size[4]	For 64-Bit Operand Size[4]
POPA, POPAD—Pop All to GPR Words or Doublewords 61	INVALID IN 64-BIT MODE (invalid-opcode exception)			
POPCNT—Bit Population Count F3 0F B8	Promoted to 64 bits.	32 bits	Zero-extends 32-bit register results to 64 bits.	
POPF, **POPFD, POPFQ**—Pop to rFLAGS Word, Doublword, or Quadword 9D	Promoted to 64 bits.	64 bits	Cannot encode[6]	POPFQ (new mnemonic): Pops 64 bits off stack, writes low 32 bits into EFLAGS and zero-extends the high 32 bits of RFLAGS.
PREFETCH—Prefetch L1 Data-Cache Line 0F 0D /0	Same as legacy mode.	Not relevant.	No GPR register results.	
PREFETCH*level*—Prefetch Data to Cache Level *level* 0F 18 /0-3	Same as legacy mode.	Not relevant.	No GPR register results.	
PREFETCHW—Prefetch L1 Data-Cache Line for Write 0F 0D /1	Same as legacy mode.	Not relevant.	No GPR register results.	
PUSH—Push onto Stack FF /6 50 through 57 6A 68	Promoted to 64 bits.	64 bits	Cannot encode[6]	

Notes:

1. *See “General Rules for 64-Bit Mode” on page 555, for opcodes that do not appear in this table.*
2. *The type of operation, excluding considerations of operand size or extension of results. See “General Rules for 64-Bit Mode” on page 555 for definitions of “Promoted to 64 bits” and related topics.*
3. *If “Type of Operation” is 64 bits, a REX prefix is needed for 64-bit operand size, unless the instruction size defaults to 64 bits. If the operand size is fixed, operand-size overrides are silently ignored.*
4. *Special actions in 64-bit mode, in addition to legacy-mode actions. Zero or sign extensions apply only to result operands, not source operands. Unless otherwise stated, 8-bit and 16-bit results leave the high 56 or 48 bits, respectively, of 64-bit destination registers unchanged. Immediates and branch displacements are sign-extended to 64 bits.*
5. *Any pointer registers (rDI, rSI) or count registers (rCX) are address-sized and default to 64 bits. For 32-bit address size, any pointer and count registers are zero-extended to 64 bits.*
6. *The default operand size can be overridden to 16 bits with 66h prefix, but there is no 32-bit operand-size override in 64-bit mode.*

Table B-1. Operations and Operands in 64-Bit Mode (continued)

Instruction and Opcode (hex)[1]	Type of Operation[2]	Default Operand Size[3]	For 32-Bit Operand Size[4]	For 64-Bit Operand Size[4]
PUSH—Push (segment register) onto Stack 0F A0 (PUSH FS) 0F A8 (PUSH GS)	Promoted to 64 bits.	64 bits	Cannot encode[6]	
0E (PUSH CS) 1E (PUSH DS) 06 (PUSH ES) 16 (PUSH SS)	INVALID IN 64-BIT MODE (invalid-opcode exception)			
PUSHA, PUSHAD - Push All to GPR Words or Doublewords 60	INVALID IN 64-BIT MODE (invalid-opcode exception)			
PUSHF, **PUSHFD, PUSHFQ**—Push rFLAGS Word, Doubleword, or Quadword onto Stack 9C	Promoted to 64 bits.	64 bits	Cannot encode[6]	PUSHFQ (new mnemonic): Pushes the 64-bit RFLAGS register.
RCL—Rotate Through Carry Left D1 /2 D3 /2 C1 /2	Promoted to 64 bits.	32 bits	Zero-extends 32-bit register results to 64 bits.	Uses 6-bit count.
RCR—Rotate Through Carry Right D1 /3 D3 /3 C1 /3	Promoted to 64 bits.	32 bits	Zero-extends 32-bit register results to 64 bits.	Uses 6-bit count.
RDMSR—Read Model-Specific Register 0F 32	Same as legacy mode.	Not relevant.	RDX[31:0] contains MSR[63:32], RAX[31:0] contains MSR[31:0]. Zero-extends 32-bit register results to 64 bits.	

Notes:

1. *See “General Rules for 64-Bit Mode” on page 555, for opcodes that do not appear in this table.*
2. *The type of operation, excluding considerations of operand size or extension of results. See “General Rules for 64-Bit Mode” on page 555 for definitions of “Promoted to 64 bits” and related topics.*
3. *If “Type of Operation” is 64 bits, a REX prefix is needed for 64-bit operand size, unless the instruction size defaults to 64 bits. If the operand size is fixed, operand-size overrides are silently ignored.*
4. *Special actions in 64-bit mode, in addition to legacy-mode actions. Zero or sign extensions apply only to result operands, not source operands. Unless otherwise stated, 8-bit and 16-bit results leave the high 56 or 48 bits, respectively, of 64-bit destination registers unchanged. Immediates and branch displacements are sign-extended to 64 bits.*
5. *Any pointer registers (rDI, rSI) or count registers (rCX) are address-sized and default to 64 bits. For 32-bit address size, any pointer and count registers are zero-extended to 64 bits.*
6. *The default operand size can be overridden to 16 bits with 66h prefix, but there is no 32-bit operand-size override in 64-bit mode.*

Table B-1. Operations and Operands in 64-Bit Mode (continued)

Instruction and Opcode (hex)[1]	Type of Operation[2]	Default Operand Size[3]	For 32-Bit Operand Size[4]	For 64-Bit Operand Size[4]
RDPMC—Read Performance-Monitoring Counters 0F 33	Same as legacy mode.	Not relevant.	RDX[31:0] contains PMC[63:32], RAX[31:0] contains PMC[31:0]. Zero-extends 32-bit register results to 64 bits.	
RDTSC—Read Time-Stamp Counter 0F 31	Same as legacy mode.	Not relevant.	RDX[31:0] contains TSC[63:32], RAX[31:0] contains TSC[31:0]. Zero-extends 32-bit register results to 64 bits.	
RDTSCP—Read Time-Stamp Counter and Processor ID 0F 01 F9	Same as legacy mode.	Not relevant.	RDX[31:0] contains TSC[63:32], RAX[31:0] contains TSC[31:0]. RCX[31:0] contains the TSC_AUX MSR C000_0103h[31:0]. Zero-extends 32-bit register results to 64 bits.	
REP INS—Repeat Input String F3 6D	Same as legacy mode.	32 bits	Reads doubleword I/O port. See footnote[5]	
REP LODS—Repeat Load String F3 AD	Promoted to 64 bits.	32 bits	Zero-extends EAX to 64 bits. See footnote[5]	See footnote[5]
REP MOVS—Repeat Move String F3 A5	Promoted to 64 bits.	32 bits	No GPR register results. See footnote[5]	
REP OUTS—Repeat Output String to Port F3 6F	Same as legacy mode.	32 bits	Writes doubleword to I/O port. No GPR register results. See footnote[5]	
REP STOS—Repeat Store String F3 AB	Promoted to 64 bits.	32 bits	No GPR register results. See footnote[5]	
REPx CMPS —Repeat Compare String F3 A7	Promoted to 64 bits.	32 bits	No GPR register results. See footnote[5]	

Notes:

1. *See “General Rules for 64-Bit Mode” on page 555, for opcodes that do not appear in this table.*
2. *The type of operation, excluding considerations of operand size or extension of results. See “General Rules for 64-Bit Mode” on page 555 for definitions of “Promoted to 64 bits” and related topics.*
3. *If “Type of Operation” is 64 bits, a REX prefix is needed for 64-bit operand size, unless the instruction size defaults to 64 bits. If the operand size is fixed, operand-size overrides are silently ignored.*
4. *Special actions in 64-bit mode, in addition to legacy-mode actions. Zero or sign extensions apply only to result operands, not source operands. Unless otherwise stated, 8-bit and 16-bit results leave the high 56 or 48 bits, respectively, of 64-bit destination registers unchanged. Immediates and branch displacements are sign-extended to 64 bits.*
5. *Any pointer registers (rDI, rSI) or count registers (rCX) are address-sized and default to 64 bits. For 32-bit address size, any pointer and count registers are zero-extended to 64 bits.*
6. *The default operand size can be overridden to 16 bits with 66h prefix, but there is no 32-bit operand-size override in 64-bit mode.*

Table B-1. Operations and Operands in 64-Bit Mode (continued)

Instruction and Opcode (hex)[1]	Type of Operation[2]	Default Operand Size[3]	For 32-Bit Operand Size[4]	For 64-Bit Operand Size[4]
REPx SCAS —Repeat Scan String F3 AF	Promoted to 64 bits.	32 bits	No GPR register results. See footnote[5]	
RET—Return from Call Near C2 C3	See “Near Branches in 64-Bit Mode” in Volume 1.			
	Promoted to 64 bits.	64 bits	Cannot encode.[6]	No GPR register results.
RET—Return from Call Far CB CA	Promoted to 64 bits.	32 bits	See “Control Transfers” in Volume 1 and “Control-Transfer Privilege Checks” in Volume 2.	
ROL—Rotate Left D1 /0 D3 /0 C1 /0	Promoted to 64 bits.	32 bits	Zero-extends 32-bit register results to 64 bits.	Uses 6-bit count.
ROR—Rotate Right D1 /1 D3 /1 C1 /1	Promoted to 64 bits.	32 bits	Zero-extends 32-bit register results to 64 bits.	Uses 6-bit count.
RSM—Resume from System Management Mode 0F AA	New SMM state-save area.	Not relevant.	See “System-Management Mode” in Volume 2.	
SAHF—Store AH into Flags 9E	Same as legacy mode.	Not relevant.	No GPR register results.	
SAL—Shift Arithmetic Left D1 /4 D3 /4 C1 /4	Promoted to 64 bits.	32 bits	Zero-extends 32-bit register results to 64 bits.	Uses 6-bit count.

Notes:

1. *See “General Rules for 64-Bit Mode” on page 555, for opcodes that do not appear in this table.*
2. *The type of operation, excluding considerations of operand size or extension of results. See “General Rules for 64-Bit Mode” on page 555 for definitions of “Promoted to 64 bits” and related topics.*
3. *If “Type of Operation” is 64 bits, a REX prefix is needed for 64-bit operand size, unless the instruction size defaults to 64 bits. If the operand size is fixed, operand-size overrides are silently ignored.*
4. *Special actions in 64-bit mode, in addition to legacy-mode actions. Zero or sign extensions apply only to result operands, not source operands. Unless otherwise stated, 8-bit and 16-bit results leave the high 56 or 48 bits, respectively, of 64-bit destination registers unchanged. Immediates and branch displacements are sign-extended to 64 bits.*
5. *Any pointer registers (rDI, rSI) or count registers (rCX) are address-sized and default to 64 bits. For 32-bit address size, any pointer and count registers are zero-extended to 64 bits.*
6. *The default operand size can be overridden to 16 bits with 66h prefix, but there is no 32-bit operand-size override in 64-bit mode.*

Table B-1. Operations and Operands in 64-Bit Mode (continued)

Instruction and Opcode (hex)[1]	Type of Operation[2]	Default Operand Size[3]	For 32-Bit Operand Size[4]	For 64-Bit Operand Size[4]
SAR—Shift Arithmetic Right D1 /7 D3 /7 C1 /7	Promoted to 64 bits.	32 bits	Zero-extends 32-bit register results to 64 bits.	Uses 6-bit count.
SBB—Subtract with Borrow 19 1B 1D 81 /3 83 /3	Promoted to 64 bits.	32 bits	Zero-extends 32-bit register results to 64 bits.	
SCAS, **SCASW**, **SCASD, SCASQ**—Scan String AF	Promoted to 64 bits.	32 bits	SCASD: Scan String Doublewords. Zero-extends 32-bit register results to 64 bits. See footnote[5]	SCASQ (new mnemonic): Scan String Quadwords. See footnote[5]
SFENCE—Store Fence 0F AE /7	Same as legacy mode.	Not relevant.	No GPR register results.	
SGDT—Store Global Descriptor Table Register 0F 01 /0	Promoted to 64 bits.	Operand size fixed at 64 bits.	No GPR register results. Stores 8-byte base and 2-byte limit.	
SHL—Shift Left D1 /4 D3 /4 C1 /4	Promoted to 64 bits.	32 bits	Zero-extends 32-bit register results to 64 bits.	Uses 6-bit count.

Notes:

1. *See “General Rules for 64-Bit Mode” on page 555, for opcodes that do not appear in this table.*
2. *The type of operation, excluding considerations of operand size or extension of results. See “General Rules for 64-Bit Mode” on page 555 for definitions of “Promoted to 64 bits” and related topics.*
3. *If “Type of Operation” is 64 bits, a REX prefix is needed for 64-bit operand size, unless the instruction size defaults to 64 bits. If the operand size is fixed, operand-size overrides are silently ignored.*
4. *Special actions in 64-bit mode, in addition to legacy-mode actions. Zero or sign extensions apply only to result operands, not source operands. Unless otherwise stated, 8-bit and 16-bit results leave the high 56 or 48 bits, respectively, of 64-bit destination registers unchanged. Immediates and branch displacements are sign-extended to 64 bits.*
5. *Any pointer registers (rDI, rSI) or count registers (rCX) are address-sized and default to 64 bits. For 32-bit address size, any pointer and count registers are zero-extended to 64 bits.*
6. *The default operand size can be overridden to 16 bits with 66h prefix, but there is no 32-bit operand-size override in 64-bit mode.*

Table B-1. Operations and Operands in 64-Bit Mode (continued)

Instruction and Opcode (hex)[1]	Type of Operation[2]	Default Operand Size[3]	For 32-Bit Operand Size[4]	For 64-Bit Operand Size[4]
SHLD—Shift Left Double 0F A4 0F A5	Promoted to 64 bits.	32 bits	Zero-extends 32-bit register results to 64 bits.	Uses 6-bit count.
SHR—Shift Right D1 /5 D3 /5 C1 /5	Promoted to 64 bits.	32 bits	Zero-extends 32-bit register results to 64 bits.	Uses 6-bit count.
SHRD—Shift Right Double 0F AC 0F AD	Promoted to 64 bits.	32 bits	Zero-extends 32-bit register results to 64 bits.	Uses 6-bit count.
SIDT—Store Interrupt Descriptor Table Register 0F 01 /1	Promoted to 64 bits.	Operand size fixed at 64 bits.	No GPR register results. Stores 8-byte base and 2-byte limit.	
SKINIT—Secure Init and Jump with Attestation 0F 01 DE	Same as legacy mode.	Not relevant	Zero-extends 32-bit register results to 64 bits.	
SLDT—Store Local Descriptor Table Register 0F 00 /0	Same as legacy mode.	32	Zero-extends 2-byte LDT selector to 64 bits.	
SMSW—Store Machine Status Word 0F 01 /4	Same as legacy mode.	32	Zero-extends 32-bit register results to 64 bits.	Stores 64-bit machine status word (CR0).
STC—Set Carry Flag F9	Same as legacy mode.	Not relevant.	No GPR register results.	
STD—Set Direction Flag FD	Same as legacy mode.	Not relevant.	No GPR register results.	

Notes:

1. *See “General Rules for 64-Bit Mode” on page 555, for opcodes that do not appear in this table.*
2. *The type of operation, excluding considerations of operand size or extension of results. See “General Rules for 64-Bit Mode” on page 555 for definitions of “Promoted to 64 bits” and related topics.*
3. *If “Type of Operation” is 64 bits, a REX prefix is needed for 64-bit operand size, unless the instruction size defaults to 64 bits. If the operand size is fixed, operand-size overrides are silently ignored.*
4. *Special actions in 64-bit mode, in addition to legacy-mode actions. Zero or sign extensions apply only to result operands, not source operands. Unless otherwise stated, 8-bit and 16-bit results leave the high 56 or 48 bits, respectively, of 64-bit destination registers unchanged. Immediates and branch displacements are sign-extended to 64 bits.*
5. *Any pointer registers (rDI, rSI) or count registers (rCX) are address-sized and default to 64 bits. For 32-bit address size, any pointer and count registers are zero-extended to 64 bits.*
6. *The default operand size can be overridden to 16 bits with 66h prefix, but there is no 32-bit operand-size override in 64-bit mode.*

Table B-1. Operations and Operands in 64-Bit Mode (continued)

Instruction and Opcode (hex)[1]	Type of Operation[2]	Default Operand Size[3]	For 32-Bit Operand Size[4]	For 64-Bit Operand Size[4]
STGI—Set Global Interrupt Flag 0F 01 DC	Same as legacy mode.	Not relevant.	No GPR register results.	
STI - Set Interrupt Flag FB	Same as legacy mode.	Not relevant.	No GPR register results.	
STOS, **STOSW**, **STOSD, STOSQ**- Store String AB	Promoted to 64 bits.	32 bits	STOSD: Store String Doublewords. See footnote[5]	STOSQ (new mnemonic): Store String Quadwords. See footnote[5]
STR—Store Task Register 0F 00 /1	Same as legacy mode.	32	Zero-extends 2-byte TR selector to 64 bits.	
SUB—Subtract 29 2B 2D 81 /5 83 /5	Promoted to 64 bits.	32 bits	Zero-extends 32-bit register results to 64 bits.	
SWAPGS—Swap GS Register with KernelGSbase MSR 0F 01 /7	New instruction, available only in 64-bit mode. (In other modes, this opcode is invalid.)	Not relevant.	See “SWAPGS Instruction” in Volume 2.	
SYSCALL—Fast System Call 0F 05	Promoted to 64 bits.	Not relevant.	See “SYSCALL and SYSRET Instructions” in Volume 2 for details.	

Notes:

1. *See “General Rules for 64-Bit Mode” on page 555, for opcodes that do not appear in this table.*
2. *The type of operation, excluding considerations of operand size or extension of results. See “General Rules for 64-Bit Mode” on page 555 for definitions of “Promoted to 64 bits” and related topics.*
3. *If “Type of Operation” is 64 bits, a REX prefix is needed for 64-bit operand size, unless the instruction size defaults to 64 bits. If the operand size is fixed, operand-size overrides are silently ignored.*
4. *Special actions in 64-bit mode, in addition to legacy-mode actions. Zero or sign extensions apply only to result operands, not source operands. Unless otherwise stated, 8-bit and 16-bit results leave the high 56 or 48 bits, respectively, of 64-bit destination registers unchanged. Immediates and branch displacements are sign-extended to 64 bits.*
5. *Any pointer registers (rDI, rSI) or count registers (rCX) are address-sized and default to 64 bits. For 32-bit address size, any pointer and count registers are zero-extended to 64 bits.*
6. *The default operand size can be overridden to 16 bits with 66h prefix, but there is no 32-bit operand-size override in 64-bit mode.*

Table B-1. Operations and Operands in 64-Bit Mode (continued)

Instruction and Opcode (hex)[1]	Type of Operation[2]	Default Operand Size[3]	For 32-Bit Operand Size[4]	For 64-Bit Operand Size[4]
SYSENTER—System Call 0F 34	INVALID IN LONG MODE (invalid-opcode exception)			
SYSEXIT—System Return 0F 35	INVALID IN LONG MODE (invalid-opcode exception)			
SYSRET—Fast System Return 0F 07	Promoted to 64 bits.	32 bits	See “SYSCALL and SYSRET Instructions” in Volume 2 for details.	
TEST—Test Bits 85 A9 F7 /0	Promoted to 64 bits.	32 bits	No GPR register results.	
UD2—Undefined Operation 0F 0B	Same as legacy mode.	Not relevant.	No GPR register results.	
VERR—Verify Segment for Reads 0F 00 /4	Same as legacy mode.	Operand size fixed at 16 bits	No GPR register results.	
VERW—Verify Segment for Writes 0F 00 /5	Same as legacy mode.	Operand size fixed at 16 bits	No GPR register results.	
VMLOAD—Load State from VMCB 0F 01 DA	Same as legacy mode.	Not relevant.	No GPR register results.	
VMMCALL—Call VMM 0F 01 D9	Same as legacy mode.	Not relevant.	No GPR register results.	
VMRUN—Run Virtual Machine 0F 01 D8	Same as legacy mode.	Not relevant.	No GPR register results.	
VMSAVE—Save State to VMCB 0F 01 DB	Same as legacy mode.	Not relevant.	No GPR register results.	

Notes:

1. *See “General Rules for 64-Bit Mode” on page 555, for opcodes that do not appear in this table.*
2. *The type of operation, excluding considerations of operand size or extension of results. See “General Rules for 64-Bit Mode” on page 555 for definitions of “Promoted to 64 bits” and related topics.*

6. *The default operand size can be overridden to 16 bits with 66h prefix, but there is no 32-bit operand-size override in 64-bit mode.*

B.3 Invalid and Reassigned Instructions in 64-Bit Mode

Table B-2 lists instructions that are illegal in 64-bit mode. Attempted use of these instructions generates an invalid-opcode exception (#UD).

Table B-2. Invalid Instructions in 64-Bit Mode

Mnemonic	Opcode (hex)	Description
AAA	37	ASCII Adjust After Addition
AAD	D5	ASCII Adjust Before Division
AAM	D4	ASCII Adjust After Multiply
AAS	3F	ASCII Adjust After Subtraction
BOUND	62	Check Array Bounds
CALL (far)	9A	Procedure Call Far (far absolute)
DAA	27	Decimal Adjust after Addition
DAS	2F	Decimal Adjust after Subtraction
INTO	CE	Interrupt to Overflow Vector
JMP (far)	EA	Jump Far (absolute)
LDS	C5	Load DS Far Pointer
LES	C4	Load ES Far Pointer
POP DS	1F	Pop Stack into DS Segment
POP ES	07	Pop Stack into ES Segment
POP SS	17	Pop Stack into SS Segment
POPA, POPAD	61	Pop All to GPR Words or Doublewords
PUSH CS	0E	Push CS Segment Selector onto Stack
PUSH DS	1E	Push DS Segment Selector onto Stack
PUSH ES	06	Push ES Segment Selector onto Stack
PUSH SS	16	Push SS Segment Selector onto Stack
PUSHA, PUSHAD	60	Push All to GPR Words or Doublewords
Redundant Grp1	82 /2	Redundant encoding of group1 Eb,Ib opcodes
SALC	D6	Set AL According to CF

Table B-3 lists instructions that are reassigned to different functions in 64-bit mode. Attempted use of these instructions generates the reassigned function.

Table B-3. Reassigned Instructions in 64-Bit Mode

Mnemonic	Opcode (hex)	Description
ARPL	63	Opcode for MOVSXD instruction in 64-bit mode. In all other modes, this is the Adjust Requestor Privilege Level instruction opcode.
DEC and INC	40-4F	REX prefixes in 64-bit mode. In all other modes, decrement by 1 and increment by 1.
LDS	C5	VEX Prefix. Introduces the VEX two-byte instruction encoding escape sequence.
LES	C4	VEX Prefix. Introduces the VEX three-byte instruction encoding escape sequence.

Table B-4 lists instructions that are illegal in long mode. Attempted use of these instructions generates an invalid-opcode exception (#UD).

Table B-4. Invalid Instructions in Long Mode

Mnemonic	Opcode (hex)	Description
SYSENTER	0F 34	System Call
SYSEXIT	0F 35	System Return

B.4 Instructions with 64-Bit Default Operand Size

In 64-bit mode, two groups of instructions default to 64-bit operand size without the need for a REX prefix:

- *Near branches* —CALL, J*cc*, JrCX, JMP, LOOP, and RET.
- *All instructions, except far branches, that implicitly reference the RSP*—CALL, ENTER, LEAVE, POP, PUSH, and RET (CALL and RET are in both groups of instructions).

Table B-5 lists these instructions.

Table B-5. Instructions Defaulting to 64-Bit Operand Size

Mnemonic	Opcode (hex)	Implicitly Reference RSP	Description
CALL	E8, FF /2	yes	Call Procedure Near
ENTER	C8	yes	Create Procedure Stack Frame
J*cc*	many	no	Jump Conditional Near
JMP	E9, EB, FF /4	no	Jump Near
LEAVE	C9	yes	Delete Procedure Stack Frame
LOOP	E2	no	Loop
LOOP*cc*	E0, E1	no	Loop Conditional
POP reg/mem	8F /0	yes	Pop Stack (register or memory)
POP reg	58-5F	yes	Pop Stack (register)
POP FS	0F A1	yes	Pop Stack into FS Segment Register
POP GS	0F A9	yes	Pop Stack into GS Segment Register
POPF, POPFD, POPFQ	9D	yes	Pop to rFLAGS Word, Doubleword, or Quadword
PUSH imm8	6A	yes	Push onto Stack (sign-extended byte)
PUSH imm32	68	yes	Push onto Stack (sign-extended doubleword)
PUSH reg/mem	FF /6	yes	Push onto Stack (register or memory)
PUSH reg	50-57	yes	Push onto Stack (register)
PUSH FS	0F A0	yes	Push FS Segment Register onto Stack
PUSH GS	0F A8	yes	Push GS Segment Register onto Stack
PUSHF, PUSHFD, PUSHFQ	9C	yes	Push rFLAGS Word, Doubleword, or Quadword onto Stack
RET	C2, C3	yes	Return From Call (near)

The 64-bit default operand size can be overridden to 16 bits using the 66h operand-size override. However, it is not possible to override the operand size to 32 bits because there is no 32-bit operand-size override prefix for 64-bit mode. See “Operand-Size Override Prefix” on page 7 for details.

B.5 Single-Byte INC and DEC Instructions in 64-Bit Mode

In 64-bit mode, the legacy encodings for the 16 single-byte INC and DEC instructions (one for each of the eight GPRs) are used to encode the REX prefix values, as described in “REX Prefix” on page 14. Therefore, these single-byte opcodes for INC and DEC are not available in 64-bit mode, although they are available in legacy and compatibility modes. The functionality of these INC and DEC instructions is still available in 64-bit mode, however, using the ModRM forms of those instructions (opcodes FF/0 and FF/1).

B.6 NOP in 64-Bit Mode

Programs written for the legacy x86 architecture commonly use opcode 90h (the XCHG EAX, EAX instruction) as a one-byte NOP. In 64-bit mode, the processor treats opcode 90h specially in order to preserve this legacy NOP use. Without special handling in 64-bit mode, the instruction would not be a true no-operation. Therefore, in 64-bit mode the processor treats XCHG EAX, EAX as a true NOP, regardless of operand size.

This special handling does not apply to the two-byte ModRM form of the XCHG instruction. Unless a 64-bit operand size is specified using a REX prefix byte, using the two byte form of XCHG to exchange a register with itself will not result in a no-operation because the default operation size is 32 bits in 64-bit mode.

B.7 Segment Override Prefixes in 64-Bit Mode

In 64-bit mode, the CS, DS, ES, SS segment-override prefixes have no effect. These four prefixes are no longer treated as segment-override prefixes in the context of multiple-prefix rules. Instead, they are treated as null prefixes.

The FS and GS segment-override prefixes are treated as true segment-override prefixes in 64-bit mode. Use of the FS and GS prefixes cause their respective segment bases to be added to the effective address calculation. See “FS and GS Registers in 64-Bit Mode” in Volume 2 for details.

Appendix C Differences Between Long Mode and Legacy Mode

Table C-1 summarizes the major differences between 64-bit mode and legacy protected mode. The third column indicates differences between 64-bit mode and legacy mode. The fourth column indicates whether that difference also applies to compatibility mode.

Table C-1. Differences Between Long Mode and Legacy Mode

Type	Subject	64-Bit Mode Difference	Applies To Compatibility Mode?
Application Programming	Addressing	RIP-relative addressing available	no
	Data and Address Sizes	Default data size is 32 bits	
		REX Prefix toggles data size to 64 bits	
		Default address size is 64 bits	
		Address size prefix toggles address size to 32 bits	
	Instruction Differences	Various opcodes are invalid or changed in 64-bit mode (see Table B-2 on page 581 and Table B-3 on page 582)	
		Various opcodes are invalid in long mode (see Table B-4 on page 582)	yes
		MOV reg,imm32 becomes MOV reg,imm64 (with REX operand size prefix)	no
		REX is always enabled	
		Direct-offset forms of MOV to or from accumulator become 64-bit offsets	
		MOVD extended to MOV 64 bits between MMX registers and long GPRs (with REX operand-size prefix)	

Table C-1. Differences Between Long Mode and Legacy Mode (continued)

Type	Subject	64-Bit Mode Difference	Applies To Compatibility Mode?
System Programming	x86 Modes	Real and virtual-8086 modes not supported	yes
	Task Switching	Task switching not supported	yes
	Addressing	64-bit virtual addresses	yes
		4-level paging structures	
		PAE must always be enabled	
	Segmentation	CS, DS, ES, SS segment bases are ignored	no
		CS, DS, ES, FS, GS, SS segment limits are ignored	
		CS, DS, ES, SS Segment prefixes are ignored	
	Exception and Interrupt Handling	All pushes are 8 bytes	yes
		16-bit interrupt and trap gates are illegal	
		32-bit interrupt and trap gates are redefined as 64-bit gates and are expanded to 16 bytes	
		SS is set to null on stack switch	
		SS:RSP is pushed unconditionally	
	Call Gates	All pushes are 8 bytes	yes
		16-bit call gates are illegal	
		32-bit call gate type is redefined as 64-bit call gate and is expanded to 16 bytes.	
		SS is set to null on stack switch	
	System-Descriptor Registers	GDT, IDT, LDT, TR base registers expanded to 64 bits	yes
	System-Descriptor Table Entries and Pseudo-descriptors	LGDT and LIDT use expanded 10-byte pseudo-descriptors.	no
		LLDT and LTR use expanded 16-byte table entries.	

Appendix D Instruction Subsets and CPUID Feature Flags

This appendix provides information that can be used to determine if a specific instruction within the AMD64 instruction-set architecture (ISA) is supported on a processor.

Originally the x86 ISA was composed of a set of instructions from the general-purpose and system instruction groups. This set forms the base of the AMD64 ISA. As the ISA expanded over time, new instructions were added. Each addition constituted either a single instruction or a set of instructions and each addition was assigned a specific processor feature flag.

Although most current processor products support the entire ISA, support for each added instruction or instruction subset is optional and must be confirmed by testing the corresponding feature flag. The presence of a particular instruction or subset is indicated by the corresponding feature flag being set. A feature flag is a single bit value located at a specific bit position within the 32-bit value returned in a register as a result of executing the CPUID instruction.

For more information on using the CPUID instruction, see the instruction reference page for CPUID on page 165. For a comprehensive list of processor feature flags accessed using the CPUID instruction, see Appendix E, “Obtaining Processor Information Via the CPUID Instruction” on page 593.

D.1 Instruction Set Overview

The AMD64 ISA can be organized into five instruction groups:

1. General-purpose instructions

   These instructions operate on the general-purpose registers (GP registers) and can be used at all privilege levels. This group includes instructions to load and store the contents of a GP register to and from memory, move values between the GP registers, and perform arithmetic and logical operations on the contents of the registers.

2. System instructions

   These instructions provide the means to manipulate the processor operating mode, access processor resources, handle program and system errors, and manage system memory. Many of these instructions require privilege level 0 to execute.

3. x87 instructions

   These instructions are available at all privilege levels and include legacy floating-point instructions that use the ST(0)–ST(7) stack registers (FPR0–FPR7 physical registers) and internally use extended precision (80-bit) binary floating-point representation and operations.

4. 64-bit media Instructions

   These instructions are available at all privilege levels and perform vector operations on packed integer and floating-point values held in the 64-bit MMX™ registers. The MMX register set overlays the FPR0–FPR7 physical registers. This group is composed of the MMX and 3DNow!™ instruction subsets and was subsequently expanded by the MMX and 3DNow! extensions subsets.

5. SSE instructions

   The SSE instructions operate on packed integer and floating-point values held in the XMM / YMM registers. SSE includes the original Streaming SIMD Extensions, all the subsequent named SSE subsets, and the AVX, XOP, and AES instructions.

Figure D-1 on page 589 represents the relationship between the five major instruction groups and the named instruction subsets. Circles represent the instruction subsets. These include the base instruction set labeled “Base Instructions” in the diagram and the named subsets. The diagram omits individual optional instructions and some of the minor named instruction subsets. Dashed-line polygons represent the instruction groups.

Note that the 128-bit and 256-bit media instructions are referred to collectively as the Streaming SIMD Extensions (SSE). This is also the name of the original SSE subset. In the diagram the original SSE subset is labeled “SSE1 Instructions.” Collectively the 64-bit media and the SSE instructions make up the single instruction / multiple data (SIMD) group (labeled “SIMD Instructions” in the diagram).

The overlapping of the SSE and 64-bit media instruction subsets indicates that these subsets share some common mnemonics. However, these common mnemonics either have distinct opcodes for each subset or they take operands in both the MMX and XMM register sets.

The horizontal axis of Figure D-1 shows how the subsets have evolved over time.

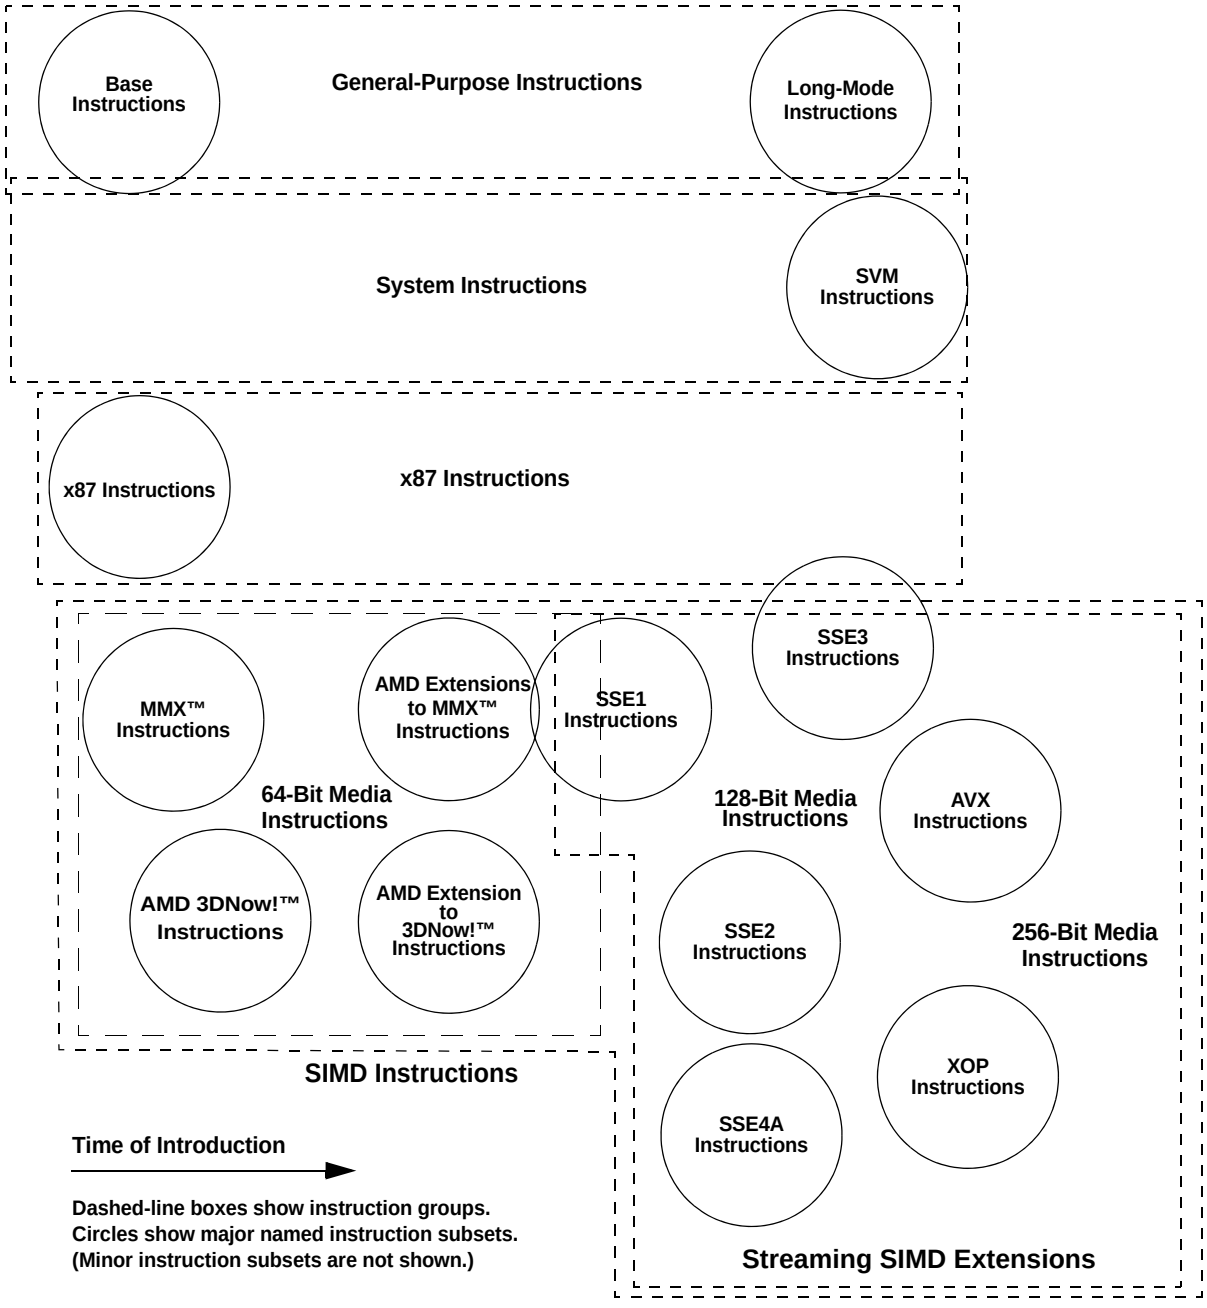

Figure D-1. AMD64 ISA Instruction Subsets

D.2 CPUID Feature Flags Related to Instruction Support

Only a subset of the CPUID feature flags provides information related to instruction support.

The feature flags related to supported instruction subsets are accessed via the *standard* function number 0000_0001h, the *extended* function number 8000_0001h, and the *structured extended* function number 0000_0007h.

The following table lists all flags related to instruction support. Entries for each flag provide the instruction or instruction subset corresponding to the flag, the CPUID function that must be executed to access the flag, and the bit position of the flag in the return value.

Table D-1. Feature Flags for Instruction / Instruction Subset Support

Feature Flag	Instruction or Subset	CPUID Function[1]	Feature Flag Bit Position[2]
3DNow	3DNow!	extended	EDX[31]
3DNowExt	3DNow! Extensions	extended	EDX[30]
3DNowPrefetch	PREFETCH / PREFETCHW	extended	ECX[8], EDX[29], or EDX[31]
ABM	LZCNT	extended	ECX[5]
ADX	ADCX, ADOX	0000_0007_0	EBX[19]
AES	AES	standard	ECX[25]
AVX	AVX	standard	ECX[28]
AVX2	AVX2	0000_0007_0	EBX[5]
BASE	Base Instruction set	—	—
BMI1	Bit Manipulation, group 1	0000_0007_0	EBX[3]
BMI2	Bit Manipulation, group 2	0000_0007_0	EBX[8]
CET_SS	Shadow Stack, CLRSSBSY, INCSSP, RDSSP, RSTORSSP, SAVEPREVSSP, SETSSBSY, WRSS, WRUSS	0000_0007_0	ECX[7]
CLFLOPT	CLFLUSHOPT	0000_0007_0	EBX[23]
CLFSH	CLFLUSH, CLWB	standard	EDX[19]
CLWB	CLWB	0000_0007_0	EBX[24]
CLZERO	CLZERO	8000_0008	EBX[0]
CMPXCHG8B	CMPXCHG8B	both	EDX[8]
CMPXCHG16B	CMPXCHG16B	standard	ECX[13]
CMOV	CMOV*cc*	both	EDX[15]

Notes:

1. *standard* = Fn0000_0001h; *extended* = Fn 8000_0001h; *both* means that both standard and extended CPUID functions return the same feature flag in the same bit position of the return value. For functions of the form xxxx-_xxxx_x, the trailing digit is the value required in ECX.
2. Register and bit position of the return value that corresponds to the feature flag.
3. FCMOVcc instruction is supported if x87 and CMOVcc instructions are both supported.
4. XSAVE (and related) instructions require separate enablement.

Table D-1. Feature Flags for Instruction / Instruction Subset Support (continued)

Feature Flag	Instruction or Subset	CPUID Function[1]	Feature Flag Bit Position[2]
F16C	16-bit floating-point conversion	standard	ECX[29]
FMA	FMA	standard	ECX[12]
FMA4	FMA4	extended	ECX[16]
FPU	x87	both	EDX[0]
FSGSBASE	FS and GS base read and write	0000_0007_0	EBX[0]
FXSR	FXSAVE / FXRSTOR	both	EDX[24]
INVLPGB	INVLPGB, TLBSYNC	8000_0008	EBX[3]
INVPCID	INVPCID	0000_0007_0	EBX[10]
LahfSahf	LAHF / SAHF	extended	ECX[0]
LM	Long Mode	extended	EDX[29]
MCOMMIT	MCOMMIT	8000_0008	EBX[8]
MMX	MMX	both	EDX[23]
MmxExt	MMX Extensions	extended	EDX[22]
MONITOR	MONITOR / MWAIT	standard	ECX[3]
MONITORX	MONITORX / MWAITX	extended	ECX[29]
MOVBE	MOVBE	standard	ECX[22]
MSR	RDMSR / WRMSR	both	EDX[5]
OSPKE	RDPKRU, WRPKRU	0000_0007_0	ECX[4]
PCLMULQDQ	PCLMULQDQ	standard	ECX[1]
POPCNT	POPCNT	standard	ECX[23]
RDPID	RDPID	0000_0007_0	ECX[22]
RDPRU	RDPRU	8000_0008	EBX[4]
RDRAND	RDRAND	standard	ECX[30]
RDTSCP	RDTSCP	extended	EDX[27]
RDSEED	RDSEED	0000_0007_0	EBX[18]
SevEs	VMGEXIT	8000_001F	EAX[3]
SHA	SHA	0000_0007_0	EBX[29]
SKINIT	SKINIT / STGI	extended	ECX[12]
SMAP	CLAC, STAC	0000_0007_0	EBX[20]
SNP	PSMASH, PVALIDATE, RMPADJUST, RMPUPDATE	8000_001F	EAX[4]
SSE	SSE1	standard	EDX[25]
SSE2	SSE2	standard	EDX[26]

Notes:

1. *standard* = Fn0000_0001h; *extended* = Fn 8000_0001h; *both* means that both standard and extended CPUID functions return the same feature flag in the same bit position of the return value. For functions of the form xxxx-_xxxx_x, the trailing digit is the value required in ECX.
2. Register and bit position of the return value that corresponds to the feature flag.
3. FCMOVcc instruction is supported if x87 and CMOVcc instructions are both supported.
4. XSAVE (and related) instructions require separate enablement.

Table D-1. Feature Flags for Instruction / Instruction Subset Support (continued)

Feature Flag	Instruction or Subset	CPUID Function[1]	Feature Flag Bit Position[2]
SSE3	SSE3	standard	ECX[0]
SSSE3	SSSE3	standard	ECX[9]
SSE4A	SSE4A	extended	ECX[6]
SSE41	SSE4.1	standard	ECX[19]
SSE42	SSE4.2	standard	ECX[20]
SVM	Secure Virtual Machine	extended	ECX[2]
SysCallSysRet	SYSCALL / SYSRET	extended	EDX[11]
SysEnterSysExit	SYSENTER / SYSEXIT	standard	EDX[11]
TBM	Trailing bit manipulation	extended	ECX[21]
TSC	RDTSC	both	EDX[4]
VAES	VAES 256-bit instructions	0000_0007_0	ECX[9]
VPCMULQDQ	VPCMULQDQ 256-bit instructions	0000_0007_0	ECX[10]
WBNOINVD	WBNOINVD	8000_0008	EBX[9]
x87 && CMOV	FCMOV*cc*[3]	both	EDX[0] && EDX[15]
XGETBV w/ ECX=1	XGETBV w/ ECX=1	0000_000D_1	EAX[2]
XOP	XOP	extended	ECX[11]
XSAVE	XSAVE / XRSTOR[4]	standard	ECX[26]
XSAVEC	XSAVEC	0000_000D_1	EAX[1]
XSAVEOPT	XSAVEOPT	0000_000D_1	EAX[0]
XSAVES/XRSTORS	XSAVES / XRSTORS	0000_000D_1	EAX[3]

Notes:

1. *standard* = Fn0000_0001h; *extended* = Fn 8000_0001h; *both* means that both standard and extended CPUID functions return the same feature flag in the same bit position of the return value. For functions of the form xxxx-_xxxx_x, the trailing digit is the value required in ECX.
2. Register and bit position of the return value that corresponds to the feature flag.
3. FCMOVcc instruction is supported if x87 and CMOVcc instructions are both supported.
4. XSAVE (and related) instructions require separate enablement.

Appendix E Obtaining Processor Information Via the CPUID Instruction

This appendix specifies the information that software can obtain about the processor on which it is running by executing the CPUID instruction. The information in this appendix supersedes the contents of the *CPUID Specification*, order #25481, which is now obsolete.

The CPUID instruction is described on page 165. This appendix does not replace the CPUID instruction reference information presented there.

The CPUID instruction behaves much like a function call. Parameters are passed to the instruction via registers and on execution the instruction loads specific registers with return values. These return values can be interpreted by software based on the field definitions and their assigned meanings.

The first input parameter is the *function number* which is passed to the instruction via the EAX register. Some functions also accept a second input parameter passed via the ECX register. Values are returned via the EAX, EBX, ECX, and EDX registers. Software should not assume that any values written to these registers prior to the execution of CPUID instruction will be retained after the instruction executes (even those that are marked reserved).

The description of each return value breaks the value down into one or more named *fields* which represent a bit position or contiguous range of bits. All bit positions that are not defined as fields are reserved. The value of bits within reserved ranges cannot be relied upon to be zero. Software must mask off all reserved bits in the return value prior to making any value comparisons of represented information.

This appendix applies to all AMD processors with a family designation of 0Fh or greater.

E.1 Special Notational Conventions

The following special notation conventions are used in this appendix:

- The notation (standard throughout this APM) for representing the function number, optional input parmeter, and the information returned is as follows:

  CPUID Fn*XXXX_XXXX_RRR*[*FieldName*]_x*YYY*.

  Where:

  - *XXXX_XXXX* is the function number represented in hexadecimal (passed to the instruction in EAX).
  - *RRR* is one of {EDX, ECX, EBX, EAX} and represents a register holding a return value.
  - *YYY* represents the optional input parameter passed in the ECX register expressed as a hexadecimal number. If this parameter is not used, the characters represented by _x*YYY* are ommitted from the notation.

  - *FieldName* identifies a specific named element of processor information represented by a specific bit range (1 or more bits wide) within the *RRR* register.
- The notation CPUID Fn*XXXX_XXXX _RRR* is used when refering to one of the registers that holds information returned by the instruction.
- The notation CPUID Fn*XXXX_XXXX* or Fn*XXXX_XXXX* is used to refer to a specific function number.
- Most one-bit fields indicate support or non-support of a specific processor feature. By convention, (unless otherwise noted) a value of 1 means that the feature is supported by the processor and a value of 0 means that the feature is not supported by the processor.

E.2 Standard and Extended Function Numbers

The CPUID instruction supports two sets or ranges of function numbers: standard and extended.

- The smallest function number of the standard function range is Fn0000_0000. The largest function number of the standard function range, for a particular implementation, is returned in CPUID Fn0000_0000_EAX.
- The smallest function number of the extended function range is Fn8000_0000. The largest function number of the extended function range, for a particular implementation, is returned in CPUID Fn8000_0000_EAX.

E.3 Standard Feature Function Numbers

This section describes each of the defined CPUID functions in the standard range.

E.3.1 Function 0h—Maximum Standard Function Number and Vendor String

This function number provides information about the maximum standard function number supported on this processor and a string that identifies the vendor of the product.

CPUID Fn0000_0000_EAX Largest Standard Function Number

The value returned in EAX provides the largest standard function number supported by this processor.

Bits	Field Name	Description
31:0	LFuncStd	Largest standard function. The largest CPUID standard function input value supported by the processor implementation.

CPUID Fn0000_0000_E[D,C,B]X Processor Vendor

The values returned in EBX, EDX, and ECX together provide a 12-character string identifying the vendor of this processor. Each register supplies 4 characters. The leftmost character of each substring

is stored in the least significant bit position in the register. The string is the concatenation of the contents of EBX, EDX, and ECX in left to right order. No null terminator is included in the string.

CPUID Fn8000_0000_E[D,C,B]X return the same values as this function.

Bits	Field Name	Description
31:0	Vendor	Four characters of the 12-byte character string (encoded in ASCII) “AuthenticAMD”. See Table E-1 below.

Table E-1. CPUID Fn0000_0000_E[D,C,B]X values

Register	Value	Description
CPUID Fn0000_0000_EBX	6874_7541h	The ASCII characters “h t u A”.
CPUID Fn0000_0000_ECX	444D_4163h	The ASCII characters “D M A c”.
CPUID Fn0000_0000_EDX	6974_6E65h	The ASCII characters “i t n e”.

E.3.2 Function 1h—Processor and Processor Feature Identifiers

This function number identifies the processor family, model, and stepping and provides feature support information.

CPUID Fn0000_0001_EAX Family, Model, Stepping Identifiers

The value returned in EAX provides the family, model, and stepping identifiers. Three values are used by software to identify a processor: Family, Model, and Stepping.

Bits	Field Name	Description
31:28	—	Reserved.
27:20	ExtFamily	Processor extended family. See above for definition of Family[7:0].
19:16	ExtModel	Processor extended model. See above for definition of Model[7:0].
15:12	—	Reserved.
11:8	BaseFamily	Base processor family. See above for definition of Family[7:0].
7:4	BaseModel	Base processor model. See above for definition of Model[7:0].
3:0	Stepping	Processor stepping. Processor stepping (revision) for a specific model.

The processor *Family* identifies one or more processors as belonging to a group that possesses some common definition for software or hardware purposes. The *Model* specifies one instance of a processor family. The *Stepping* identifies a particular version of a specific model. Therefore, Family, Model and Stepping, when taken together, form a unique identification or signature for a processor.

The **Family** is an 8-bit value and is defined as: **Family[7:0] =** ({0000b,BaseFamily[3:0]} + ExtFamily[7:0]). For example, if BaseFamily[3:0] = Fh and ExtFamily[7:0] = 01h, then Family[7:0] =

10h. If BaseFamily[3:0] is less than Fh, then ExtFamily is reserved and Family is equal to BaseFamily[3:0].

Model is an 8-bit value and is defined as: **Model[7:0]** = {ExtModel[3:0],BaseModel[3:0]}. For example, if ExtModel[3:0] = Eh and BaseModel[3:0] = 8h, then Model[7:0] = E8h. If BaseFamily[3:0] is less than 0Fh, then ExtModel is reserved and Model is equal to BaseModel[3:0].

The value returned by CPUID Fn8000_0001_EAX is equivalent to CPUID Fn0000_0001_EAX.

CPUID Fn0000_0001_EBX LocalApicId, LogicalProcessorCount, CLFlush

The value returned in EBX provides miscellaneous information regarding the processor brand, the number of logical threads per processor socket, the CLFLUSH instruction, and APIC.

Bits	Field Name	Description
31:24	LocalApicId	Initial local APIC physical ID. The 8-bit value assigned to the local APIC physical ID register at power-up. Some of the bits of LocalApicId represent the core within a processor and other bits represent the processor ID. See the APIC20 “APIC ID” register in the processor BKDG or PPR for details.
23:16	LogicalProcessor Count	Logical processor count. If CPUID Fn0000_0001_EDX[HTT] = 1 then LogicalProcessorCount is the number of logic processors per package. If CPUID Fn0000_0001_EDX[HTT] = 0 then LogicalProcessorCount is reserved. See E.5.1 [Legacy Method].
15:8	CLFlush	CLFLUSH size. Specifies the size of a cache line in quadwords flushed by the CLFLUSH instruction. See “CLFLUSH” in APM3.
7:0	8BitBrandId	8-bit brand ID. This field, in conjunction with CPUID Fn8000_0001_EBX[BrandId], is used by the system firmware to generate the processor name string. See the appropriate processor revision guide for how to program the processor name string.

CPUID Fn0000_0001_ECX Feature Identifiers

The value returned in ECX contains the following miscellaneous feature identifiers:

Bits	Field Name	Description
31	—	RAZ. Reserved for use by hypervisor to indicate guest status.
30	RDRAND	RDRAND instruction support.
29	F16C	Half-precision convert instruction support. See "Half-Precision Floating-Point Conversion" in APM1 and listings for individual F16C instructions in APM5.
28	AVX	AVX instruction support. See APM4.
27	OSXSAVE	XSAVE (and related) instructions are enabled. See “OSXSAVE” in APM2. .
26	XSAVE	XSAVE (and related) instructions are supported by hardware. See “XSAVE/XRSTOR Instructions” in APM2.

Bits	Field Name	Description
25	AES	AES instruction support. See “AES Instructions” in APM4.
24	—	Reserved.
23	POPCNT	POPCNT instruction. See “POPCNT” in APM3.
22		MOVBE: MOVBE instruction support.
21	—	Reserved.
20	SSE42	SSE4.2 instruction support. "Determining Media and x87 Feature Support" in APM2 and individual SSE4.2 instruction listings in APM4.
19	SSE41	SSE4.1 instruction support. See individual instruction listings in APM4. .
18:14	—	Reserved.
13	CMPXCHG16B	CMPXCHG16B instruction support. See “CMPXCHG16B” in APM3.
12	FMA	FMA instruction support.
11:10	—	Reserved.
9	SSSE3	Supplemental SSE3 instruction support.
8:4	—	Reserved.
3	MONITOR	MONITOR/MWAIT instructions. See “MONITOR” and “MWAIT” in APM3.
2	—	Reserved.
1	PCLMULQDQ	PCLMULQDQ instruction support. See instruction reference page for the PCLMULQDQ / VPCLMULQDQ instruction in APM4.
0	SSE3	SSE3 instruction support. See Appendix D “Instruction Subsets and CPUID Feature Sets” in APM3 for the list of instructions covered by the SSE3 feature bit. See APM4 for the definition of the SSE3 instructions.

CPUID Fn0000_0001_EDX Feature Identifiers

The value returned in EDX contains the following miscellaneous feature identifiers:

Bits	Field Name	Description
31:29	—	Reserved.
28	HTT	Hyper-threading technology. Indicates either that there is more than one thread per core or more than one core per compute unit.See “Legacy Method” on page 633.
27	—	Reserved.
26	SSE2	SSE2 instruction support. See Appendix D “CPUID Feature Sets” in APM3.
25	SSE	SSE instruction support. See Appendix D “CPUID Feature Sets” in APM3 appendix and “64-Bit Media Programming” in APM1.
24	FXSR	FXSAVE and FXRSTOR instructions. See “FXSAVE” and “FXRSTOR” in APM5.
23	MMX	MMX™ instructions. See Appendix D “CPUID Feature Sets” in APM3 and “128-Bit Media and Scientific Programming” in APM1.
22:20	—	Reserved.
19	CLFSH	CLFLUSH instruction support. See “CLFLUSH” in APM3.

Bits	Field Name	Description
18	—	Reserved.
17	PSE36	Page-size extensions. The PDE[20:13] supplies physical address [39:32]. See “Page Translation and Protection” in APM2.
16	PAT	Page attribute table. See “Page-Attribute Table Mechanism” in APM2.
15	CMOV	Conditional move instructions. See “CMOV”, “FCMOV” in APM3.
14	MCA	Machine check architecture. See “Machine Check Mechanism” in APM2.
13	PGE	Page global extension. See “Page Translation and Protection” in APM2.
12	MTRR	Memory-type range registers. See “Page Translation and Protection” in APM2.
11	SysEnterSysExit	SYSENTER and SYSEXIT instructions. See “SYSENTER”, “SYSEXIT“ in APM3.
10	—	Reserved.
9	APIC	Avanced programmable interrupt controller. Indicates APIC exists and is enabled. See “Exceptions and Interrupts” in APM2.
8	CMPXCHG8B	CMPXCHG8B instruction. See “CMPXCHG8B” in APM3.
7	MCE	Machine check exception. See “Machine Check Mechanism” in APM2.
6	PAE	Physical-address extensions. Indicates support for physical addresses [3] 32b. Number of physical address bits above 32b is implementation specific. See “Page Translation and Protection” in APM2.
5	MSR	AMD model-specific registers. Indicates support for AMD model-specific registers (MSRs), with RDMSR and WRMSR instructions. See “Model Specific Registers” in APM2.
4	TSC	Time stamp counter. RDTSC and RDTSCP instruction support. See “Debug and Performance Resources” in APM2.
3	PSE	Page-size extensions. See “Page Translation and Protection” in APM2.
2	DE	Debugging extensions. See “Debug and Performance Resources” in APM2.
1	VME	Virtual-mode enhancements. CR4.VME, CR4.PVI, software interrupt indirection, expansion of the TSS with the software, indirection bitmap, EFLAGS.VIF, EFLAGS.VIP. See “System Resources” in APM2.
0	FPU	x87 floating point unit on-chip. See “x87 Floating Point Programming” in APM1.

E.3.3 Functions 2h–4h—Reserved

CPUID Fn0000_000[4:2] Reserved

These function numbers are reserved.

E.3.4 Function 5h—Monitor and MWait Features

This function provides feature identifiers for the MONITOR and MWAIT instructions. For more information see the description of the MONITOR instruction on page 414 and the MWAIT instruction on page 420.

CPUID Fn0000_0005_EAX Monitor/MWait

The value returned in EAX provides the following information:

Bits	Field Name	Description
31:16	—	Reserved.
15:0	MonLineSizeMin	Smallest monitor-line size in bytes.

CPUID Fn0000_0005_EBX Monitor/MWait

The value returned in EBX provides the following information:

Bits	Field Name	Description
31:16	—	Reserved.
15:0	MonLineSizeMax	Largest monitor-line size in bytes.

CPUID Fn0000_0005_ECX Monitor/MWait

The value returned in ECX provides the following information:

Bits	Field Name	Description
31:2	—	Reserved.
1	IBE	Interrupt break-event. Indicates MWAIT can use ECX bit 0 to allow interrupts to cause an exit from the monitor event pending state, even if EFLAGS.IF=0.
0	EMX	Enumerate MONITOR/MWAIT extensions: Indicates enumeration MONITOR/MWAIT extensions are supported.

CPUID Fn0000_0005_EDX Monitor/MWait

The value returned in EDX is undefined and is reserved.

E.3.5 Function 6h—Power Management Related Features

This function provides information about the local APIC timer timebase and the effective frequency interface for the processor.

CPUID Fn0000_0006_EAX Local APIC Timer Invariance

The value returned in EAX is undefined and is reserved.

Bits	Field Name	Description
31:3	—	Reserved.
2	ARAT	If set, indicates that the timebase for the local APIC timer is not affected by processor p-state.
1:0	—	Reserved.

CPUID Fn0000_0006_EBX Reserved

The value returned in EBX is undefined and is reserved.

CPUID Fn0000_0006_ECX Effective Processor Frequency Interface

The value returned in ECX indicates support of the processor effective frequency interface. For more information on this feature, see "Determining Processor Effective Frequency" in APM2.

Bits	Field Name	Description
31:1	—	Reserved.
0	EffFreq	Effective frequency interface support. If set, indicates presence of MSR0000_00E7 (MPERF) and MSR0000_00E8 (APERF).

CPUID Fn0000_0006_EDX Reserved

The value returned in EDX is undefined and is reserved.

E.3.6 Function 7h—Structured Extended Feature Identifiers

CPUID Fn0000_0007_EAX_x0 Structured Extended Feature Identifiers (ECX=0)

Bits	Field Name	Description
31:0	MaxSubFn	Returns the number of subfunctions supported.

CPUID Fn0000_0007_EBX_x0 Structured Extended Feature Identifiers (ECX=0)

Bits	Field Name	Description
31:30	—	Reserved.
29	SHA	Secure Hash Algorithm instruction extension.
28:25	—	Reserved.
24	CLWB	CLWB instruction support.
23	CLFLUSHOPT	CLFLUSHOPT instruction support.
22	RDPID	RDPID instruction and TSC_AUX MSR support.
21	—	Reserved.

Bits	Field Name	Description
20	SMAP	Supervisor mode access prevention.
19	ADX	ADCX, ADOX instruction support.
18	RDSEED	RDSEED instruction support.
17:11	—	Reserved.
10	INVPCID	INVPCID instruction support.
9	—	Reserved.
8	BMI2	Bit manipulation group 2 instruction support.
7	SMEP	Supervisor mode execution prevention.
6	—	Reserved.
5	AVX2	AVX2 instruction subset support.
4	—	Reserved.
3	BMI1	Bit manipulation group 1 instruction support.
2:1	—	Reserved.
0	FSGSBASE	FS and GS base read/write instruction support.

CPUID Fn0000_0007_ECX_x0 Structured Extended Feature Identifiers (ECX=0)

Bits	Field Name	Description
31:11	—	Reserved.
10	VPCMULQDQ	Support for VPCLMULQDQ 256-bit instruction.
9	VAES	Support for VAES 256-bit instructions.
8	—	Reserved.
7	CET_SS	Shadow Stacks supported.
6:5	—	Reserved.
4	OSPKE	OS has enabled Memory Protection Keys and use of the RDPKRU/WRPKRU instructions by setting CR4.PKE=1.
3	PKU	Memory Protection Keys supported.
2	UMIP	User mode instruction prevention support.
1:0	—	Reserved.

CPUID Fn0000_0007_EDX_x0 Structured Extended Feature Identifiers (ECX=0)

Bits	Field Name	Description
31:0	—	Reserved.

E.3.7 Functions 8h–Ah—Reserved

E.3.8 Function Bh — Extended Topology Enumeration

CPUID Fn0000_000B enumerates each level in the processor's topological hierarchy. The level number is specified by the input value passed in the ECX register.

If this function is executed with an unimplemented level (passed in ECX), the instruction returns all zeros in the EAX register.

Subfunction 0 of Fn0000_000B - Thread Level

Subfunction 0 provides information about the thread-level topology.

CPUID Fn0000_000B_EAX_x0 Extended Topology Enumeration (ECX=0)

Bits	Field Name	Description
31:5	—	Reserved.
4:0	ThreadMaskWidth	Number of bits to shift x2APIC_ID right to get to the topology ID of the next level

CPUID Fn0000_000B_EBX_x0 Extended Topology Enumeration (ECX=0)

Bits	Field Name	Description
31:16	—	Reserved.
15:0		Number of threads in a core

CPUID Fn0000_000B_ECX_x0 Extended Topology Enumeration (ECX=0)

Bits	Field Name	Description
31:16	—	Reserved.
15:8	level number	returns '1' indicating thread level
7:0	ECX input value	returns '0'

CPUID Fn0000_000B_EDX_x0 Extended Topology Enumeration (ECX=0)

Bits	Field Name	Description
31:0	x2APIC_ID	32-bit Extended APIC_ID

Subfunction 1 of Fn0000_000B - Core Level

Subfunction 1 provides information about the core-level topology.

CPUID Fn0000_000B_EAX_x1 Extended Topology Enumeration (ECX=1)

Bits	Field Name	Description
31:5	—	Reserved.
4:0	CoreMaskWidth	Number of bits to shift x2APIC_ID right to get to the topology ID of the next level

CPUID Fn0000_000B_EBX_x1 Extended Topology Enumeration (ECX=1)

Bits	Field Name	Description
31:16	—	Reserved.
15:0		Number of logical cores in socket

CPUID Fn0000_000B_ECX_x1 Extended Topology Enumeration (ECX=1)

Bits	Field Name	Description
31:16	—	Reserved.
15:8	level numbers	returns ‘2’, indicating core-level
7:0	ECX input value	returns ‘1’

CPUID Fn0000_000B_EDX_x1 Extended Topology Enumeration (ECX=1)

Bits	Field Name	Description
31:0	x2APIC_ID	32-bit Extended APIC_ID

E.3.9 Function Ch—Reserved

E.3.10 Function Dh—Processor Extended State Enumeration

The XSAVE / XRSTOR instructions are used to save and restore x87/MMX FPU and SSE processor state. These instructions allow processor state associated with specific architected features to be selectively saved and restored. This function provides information about extended state support and save area size requirements.

The function has a number of subfunctions specified by the input value passed to the CPUID instruction in the ECX register. If CPUID Fn0000_000D is executed with an unimplemented subfunction (passed in ECX), the instruction returns all zeros in the EAX, EBX, ECX, and EDX registers.

Subfunction 0 of Fn0000_000D

Subfunction 0 provides information about features within the extended processor state management architecture that are supported by the processor.

CPUID Fn0000_000D_EAX_x0 Processor Extended State Enumeration (ECX=0)

The value returned in EAX provides a bit mask specifying which of the features defined by the extended processor state architecture are supported by the processor.

Bits	Field Name	Description
31:0	XFeatureSupportedMask[31:0]	Reports the valid bit positions for the lower 32 bits of the XFeatureEnabledMask register. If a bit is set, the corresponding feature is supported. See “XSAVE/XRSTOR Instructions” in APM2.

CPUID Fn0000_000D_EBX_x0 Processor Extended State Enumeration (ECX=0)

The value returned in EBX gives the save area size requirement in bytes based on the features currently enabled in the XFEATURE_ENABLED_MASK (XCR0).

Bits	Field Name	Description
31:0	XFeatureEnabledSizeMax	Size in bytes of XSAVE/XRSTOR area for the currently enabled features in XCR0.

CPUID Fn0000_000D_ECX_x0 Processor Extended State Enumeration (ECX=0)

The value returned in ECX gives the save area size requirement in bytes for all extended state management features supported by the processor (whether enabled or not).

Bits	Field Name	Description
31:0	XFeatureSupportedSizeMax	Size in bytes of XSAVE/XRSTOR area for all features that the logical processor supports. See XFeatureEnabledSizeMax.

CPUID Fn0000_000D_EDX_x0 Processor Extended State Enumeration (ECX=0)

The value returned in EDX provides a bit mask specifying which of the features defined by the extended processor state architecture are supported by the processor.

Bits	Field Name	Description
31:0	XFeatureSupportedMask[63:32]	Reports the valid bit positions for the upper 32 bits of the XFeatureEnabledMask register. If a bit is set, the corresponding feature is supported.

See “XSAVE/XRSTOR Instructions” in APM2 and reference pages for the individual instructions in APM4.

Subfunction 1 of Fn0000_000D

Subfunction 1 provides additional information about features within the extended processor state management architecture that are supported by the processor.

CPUID Fn0000_000D_EAX_x1 Processor Extended State Enumeration (ECX=1)

Bits	Field Name	Description
31:4		Reserved.
3	XSAVES	XSAVES, XRSTOR, and XSS are supported.
2	XGETBV	XGETBV with ECX = 1 supported.
1	XSAVEC	XSAVEC and compact XRSTOR supported.
0	XSAVEOPT	XSAVEOPT is available.

CPUID Fn0000_000D_EBX_x1 Processor Extended State Enumeration (ECX=1)

The value returned on EBX represents the fixed size of the save area (240h) plus the state size of each enabled extended feature:

EBX = 0240h
+ ((XCR0[AVX] == 1) ? 0000_0100h : 0)
+ ((XCR0[MPK] == 1) ? 0000_0008h : 0)
+ ((XSS[CET_U] == 1) ? 0000_0010h : 0)
+ ((XSS[CET_S] == 1) ? 0000_0018h : 0)

CPUID Fn0000_000D_ECX_x1 Processor Extended State Enumeration (ECX=1)

The value returned on ECX returns a "1" for each bit that is settable in the XSS MSR. The following bits are defined:

Bits	Field Name	Description
31:13	—	Reserved.
12	CET_S	CET supervisor.
11	CET_U	CET user state.
10:0	—	Reserved

CPUID Fn0000_000D_EDX_x1 Processor Extended State Enumeration (ECX=1)

The value returned in EDX for subfunction 1 is undefined and reserved.

Subfunction 2 of Fn0000_000D

Subfunction 2 provides information about the size and offset of the 256-bit SSE vector floating point processor unit state save area.

CPUID Fn0000_000D_EAX_x2 Processor Extended State Enumeration (ECX=2)

The value returned in EAX provides information about the size of the 256-bit SSE vector floating point processor unit state save area.

Bits	Field Name	Description
31:0	YmmSaveStateSize	YMM state save size. The state save area size in bytes for The YMM registers.

CPUID Fn0000_000D_EBX_x2 Processor Extended State Enumeration (ECX=2)

The value returned in EBX provides information about the offset of the 256-bit SSE vector floating point processor unit state save area from the base of the extended state (XSAVE/XRSTOR) save area.

Bits	Field Name	Description
31:0	YmmSaveStateOffset	YMM state save offset. The offset in bytes from the base of the extended state save area of the YMM register state save area.

CPUID Fn0000_000D_E[D,C]X_x2 Processor Extended State Enumeration (ECX=2)

The values returned in ECX and EDX for subfunction 2 are undefined and are reserved.

Subfunction 11 of Fn0000_000D

Subfunction 11 provides information about the CET user state save area.

CPUID Fn0000_000D_E[A, B, C, D]X_x11 Processor Extended State Emulation (ECX=11)

The value returned in EAX, EBX, ECX and EDX provides information about the CET user state save area.

Register	Bits	Field Name	Description
EAX	31:0	CetUserSize	CET user state save size in bytes
EBX	31:0	CetUserOffset	CET user state offset from the base of the extended state save area
ECX	0	U/S	Set to '1', indicating a supervisor state component
ECX	31:0	—	Cleared to 0
EDX	31:0	—	Unused, cleared to 0

Subfunction 12 of Fn0000_000D

Subfunction 12 provides information about the CET supervisor state save area.

CPUID Fn0000_000D_E[A, B, C, D]X_x12 Processor Extended State Emulation (ECX=12)

The value returned in EAX, EBX, ECX and EDX provides information about the CET supervisor state save area.

Register	Bits	Field Name	Description
EAX	31:0	CetSupervisorSize	CET supervisor state save size in bytes
EBX	31:0	CetSupervisorOffset	CET supervisor state offset from the base of the extended state save area
ECX	0	U/S	Set to '1', indicating a supervisor state component
ECX	31:0	—	Cleared to 0
EDX	31:0	—	Unused, cleared to 0

Subfunction 3Eh of Fn0000_000D

Subfunction 3Eh provides information about the size and offset of the Lightweight Profiling (LWP) unit state save area.

CPUID Fn0000_000D_EAX_x3E Processor Extended State Enumeration (ECX=62)

The value returned in EAX provides the size of the Lightweight Profiling (LWP) unit state save area.

Bits	Field Name	Description
31:0	LwpSaveStateSize	LWP state save area size. The size of the save area for LWP state in bytes. See “Lightweight Profiling” in APM2.

CPUID Fn0000_000D_EBX_x3E Processor Extended State Enumeration (ECX=62)

The value returned in EBX provides the offset of the Lightweight Profiling (LWP) unit state save area from the base of the extended state (XSAVE/XRSTOR) save area.

Bits	Field Name	Description
31:0	LwpSaveStateOffset	LWP state save byte offset. The offset in bytes from the base of the extended state save area of the state save area for LWP. See “Lightweight Profiling” in APM2.

CPUID Fn0000_000D_E[D,C]X_x3E Processor Extended State Enumeration (ECX=62)

The values returned in ECX and EDX for subfunction 3Eh are undefined and are reserved.

Subfunctions of Fn0000_000D greater than 3Eh

For CPUID Fn0000_000D, if the subfunction (specified by contents of ECX) passed as input to the instruction is greater than 3Eh, the instruction returns zero in the EAX, EBX, ECX, and EDX registers.

E.3.11 Functions 4000_0000h–4000_FFh—Reserved for Hypervisor Use

CPUID Fn4000_00[FF:00] Reserved

These function numbers are reserved for use by the virtual machine monitor.

E.4 Extended Feature Function Numbers

This section describes each of the defined CPUID functions in the extended range.

E.4.1 Function 8000_0000h—Maximum Extended Function Number and Vendor String

This function provides information about the maximum extended function number supported on this processor and a string that identifies the vendor of the product.

CPUID Fn8000_0000_EAX Largest Extended Function Number

The value returned in EAX provides the largest extended function number supported by the processor.

Bits	Field Name	Description
31:0	LFuncExt	Largest extended function. The largest CPUID extended function input value supported by the processor implementation.

CPUID Fn8000_0000_E[D,C,B]X Processor Vendor

The values returned in EBX, ECX, and EDX together provide a 12-character string identifying the vendor of this processor. The output string is the same as the one returned by Fn0000_0000. See CPUID Fn0000_0000_E[D,C,B]X on page 594 for more details.

Bits	Field Name	Description
31:0	Vendor	Four characters of the 12-byte character string (encoded in ASCII) “AuthenticAMD”. See Table E-2 below.

Table E-2. CPUID Fn8000_0000_E[D,C,B]X values

Register	Value	Description
CPUID Fn8000_0000_EBX	6874_7541h	The ASCII characters “h t u A”.
CPUID Fn8000_0000_ECX	444D_4163h	The ASCII characters “D M A c”.
CPUID Fn8000_0000_EDX	6974_6E65h	The ASCII characters “i t n e”.

E.4.2 Function 8000_0001h—Extended Processor and Processor Feature Identifiers

CPUID Fn8000_0001_EAX AMD Family, Model, Stepping

The value returned in EAX provides the family, model, and stepping identifiers. Three values are used by software to identify a processor: Family, Model, and Stepping. The value returned in EAX is the same as the value returned in EAX for Fn0000_0001. See CPUID Fn0000_0001_EAX on page 595 for more details on the field definitions.

Bits	Field Names	Description
31:0	Family, Model, Stepping	See: CPUID Fn0000_0001_EAX.

CPUID Fn8000_0001_EBX BrandId Identifier

The value returned in EBX provides package type and a 16-bit processor name string identifiers.

Bits	Field Name	Description
31:28	PkgType	Package type. If (Family[7:0] >= 10h), this field is valid. If (Family[7:0]<10h), this field is reserved.
27:16	—	Reserved.
15:0	BrandId	Brand ID. This field, in conjunction with CPUID Fn0000_0001_EBX[8BitBrandId], is used by system firmware to generate the processor name string. See your processor revision guide for how to program the processor name string.

For processor families 10h and greater, PkgType is described in the *BIOS and Kernel Developer’s Guide* for the product.

CPUID Fn8000_0001_ECX Feature Identifiers

This function contains the following miscellaneous feature identifiers:

Bits	Field Name	Description
31	—	Reserved.
30	AddrMaskExt	Breakpoint Addressing masking extended to bit 31.
29	MONITORX	Support for MWAITX and MONITORX instructions.
28	PerfCtrExtLLC	Support for L3 performance counter extension.
27	PerfTsc	Performance time-stamp counter. Indicates support for MSRC001_0280 [Performance Time Stamp Counter].
26	DataBkptExt	Data access breakpoint extension. Indicates support for MSRC001_1027 and MSRC001_101[B:9].
25	—	Reserved
24	PerfCtrExtNB	NB performance counter extensions support. Indicates support for MSRC001_024[6,4,2,0] and MSRC001_024[7,5,3,1].
23	PerfCtrExtCore	Processor performance counter extensions support. Indicates support for MSRC001_020[A,8,6,4,2,0] and MSRC001_020[B,9,7,5,3,1].
22	TopologyExtensions	Topology extensions support. Indicates support for CPUID Fn8000_001D_EAX_x[N:0]-CPUID Fn8000_001E_EDX.
21	TBM	Trailing bit manipulation instruction support.
20	—	Reserved.
19	—	Reserved.
18	—	Reserved.
17	TCE	Translation Cache Extension support.
16	FMA4	Four-operand FMA instruction support.
15	LWP	Lightweight profiling support. See “Lightweight Profiling” in APM2 and reference pages for individual LWP instructions in APM3.
14	—	Reserved.
13	WDT	Watchdog timer support. See APM2 and APM3. Indicates support for MSRC001_0074.
12	SKINIT	SKINIT and STGI are supported. Indicates support for SKINIT and STGI, independent of the value of MSRC000_0080[SVME]. See APM2 and APM3.
11	XOP	Extended operation support.
10	IBS	Instruction based sampling. See “Instruction Based Sampling” in APM2.
9	OSVW	OS visible workaround. Indicates OS-visible workaround support. See “OS Visible Work-around (OSVW) Information” in APM2.
8	3DNowPrefetch	PREFETCH and PREFETCHW instruction support. See “PREFETCH” and “PREFETCHW” in APM3.
7	MisAlignSse	Misaligned SSE mode. See “Misaligned Access Support Added for SSE Instructions” in APM1.
6	SSE4A	EXTRQ, INSERTQ, MOVNTSS, and MOVNTSD instruction support. See “EXTRQ”, “INSERTQ”, “MOVNTSS”, and “MOVNTSD” in APM4.
5	ABM	Advanced bit manipulation. LZCNT instruction support. See “LZCNT” in APM3.
4	AltMovCr8	LOCK MOV CR0 means MOV CR8. See “MOV(CRn)” in APM3.

Bits	Field Name	Description
3	ExtApicSpace	Extended APIC space. This bit indicates the presence of extended APIC register space starting at offset 400h from the “APIC Base Address Register,” as specified in the BKDG.
2	SVM	Secure virtual machine. See “Secure Virtual Machine” in APM2.
1	CmpLegacy	Core multi-processing legacy mode. See “Legacy Method” on page 633.
0	LahfSahf	LAHF and SAHF instruction support in 64-bit mode. See “LAHF” and “SAHF” in APM3.

CPUID Fn8000_0001_EDX Feature Identifiers

This function contains the following miscellaneous feature identifiers:

Bits	Field Name	Description
31	3DNow	3DNow!™ instructions. See Appendix D “Instruction Subsets and CPUID Feature Sets” in APM3.
30	3DNowExt	AMD extensions to 3DNow! instructions. See Appendix D “Instruction Subsets and CPUID Feature Sets” in APM3.
29	LM	Long mode. See “Processor Initialization and Long-Mode Activation” in APM2.
28	—	Reserved.
27	RDTSCP	RDTSCP instruction. See “RDTSCP” in APM3.
26	Page1GB	1-GB large page support. See “1-GB Paging Support” in APM2.
25	FFXSR	FXSAVE and FXRSTOR instruction optimizations. See “FXSAVE” and “FXRSTOR” in APM5.
24	FXSR	FXSAVE and FXRSTOR instructions. Same as CPUID Fn0000_0001_EDX[FXSR].
23	MMX	MMX™ instructions. Same as CPUID Fn0000_0001_EDX[MMX].
22	MmxExt	AMD extensions to MMX instructions. See Appendix D “Instruction Subsets and CPUID Feature Sets” in APM3 and “128-Bit Media and Scientific Programming” in APM1.
21	—	Reserved.
20	NX	No-execute page protection. See “Page Translation and Protection” in APM2.
19:18	—	Reserved.
17	PSE36	Page-size extensions. Same as CPUID Fn0000_0001_EDX[PSE36].
16	PAT	Page attribute table. Same as CPUID Fn0000_0001_EDX[PAT].
15	CMOV	Conditional move instructions. Same as CPUID Fn0000_0001_EDX[CMOV].
14	MCA	Machine check architecture. Same as CPUID Fn0000_0001_EDX[MCA].
13	PGE	Page global extension. Same as CPUID Fn0000_0001_EDX[PGE].
12	MTRR	Memory-type range registers. Same as CPUID Fn0000_0001_EDX[MTRR].
11	SysCallSysRet	SYSCALL and SYSRET instructions. See “SYSCALL” and “SYSRET” in APM3.
10	—	Reserved.

Bits	Field Name	Description
9	APIC	Advanced programmable interrupt controller. Same as CPUID Fn0000_0001_EDX[APIC].
8	CMPXCHG8B	CMPXCHG8B instruction. Same as CPUID Fn0000_0001_EDX[CMPXCHG8B].
7	MCE	Machine check exception. Same as CPUID Fn0000_0001_EDX[MCE].
6	PAE	Physical-address extensions. Same as CPUID Fn0000_0001_EDX[PAE].
5	MSR	AMD model-specific registers. Same as CPUID Fn0000_0001_EDX[MSR].
4	TSC	Time stamp counter. Same as CPUID Fn0000_0001_EDX[TSC].
3	PSE	Page-size extensions. Same as CPUID Fn0000_0001_EDX[PSE].
2	DE	Debugging extensions. Same as CPUID Fn0000_0001_EDX[DE].
1	VME	Virtual-mode enhancements. Same as CPUID Fn0000_0001_EDX[VME].
0	FPU	x87 floating-point unit on-chip. Same as CPUID Fn0000_0001_EDX[FPU].

E.4.3 Functions 8000_0002h–8000_0004h—Extended Processor Name String

CPUID Fn8000_000[4:2]_E[D,C,B,A]X Processor Name String Identifier

The three extended functions from Fn8000_0002 to Fn8000_0004 are programmed to return a null terminated ASCII string up to 48 characters in length corresponding to the processor name.

Bits	Field Name	Description
31:0	ProcName	Four characters of the extended processor name string.

The 48 character maximum includes the terminating null character. The 48 character string is ordered first to last (left to right) as follows:

Fn8000_0002[EAX[7:0],..., EAX[31:24], EBX[7:0],..., EBX[31:24], ECX[7:0],..., ECX[31:24],EDX[7:0],..., EDX[31:24]],
Fn8000_0003[EAX[7:0],..., EAX[31:24], EBX[7:0],..., EBX[31:24], ECX[7:0],..., ECX[31:24], EDX[7:0],..., EDX[31:24]],
Fn8000_0004[EAX[7:0],..., EAX[31:24], EBX[7:0],..., EBX[31:24], ECX[7:0],..., ECX[31:24], EDX[7:0],..., EDX[31:24]].

The extended processor name string is programmed by system firmware. See your processor revision guide for information about how to display the extended processor name string.

E.4.4 Function 8000_0005h—L1 Cache and TLB Information

This function provides first level cache TLB characteristics for the processor that executes the instruction.

CPUID Fn8000_0005_EAX L1 TLB 2M/4M Information

The value returned in EAX provides information about the L1 TLB for 2-MB and 4-MB pages.

Bits	Field Name	Description
31:24	L1DTlb2and4MAssoc	Data TLB associativity for 2-MB and 4-MB pages. Encoding is per Table E-3 below.
23:16	L1DTlb2and4MSize	Data TLB number of entries for 2-MB and 4-MB pages. The value returned is for the number of entries available for the 2-MB page size; 4-MB pages require two 2-MB entries, so the number of entries available for the 4-MB page size is one-half the returned value.
15:8	L1ITlb2and4MAssoc	Instruction TLB associativity for 2-MB and 4-MB pages. Encoding is per Table E-3 below.
7:0	L1ITlb2and4MSize	Instruction TLB number of entries for 2-MB and 4-MB pages. The value returned is for the number of entries available for the 2-MB page size; 4-MB pages require two 2-MB entries, so the number of entries available for the 4-MB page size is one-half the returned value.

The associativity fields (L1DTlb2and4MAssoc and L1ITlb2and4MAssoc) are encoded as follows:

Table E-3. L1 Cache and TLB Associativity Field Encodings

Associativity [7:0]	Definition
00h	Reserved
01h	1 way (direct mapped)
02h–FEh	*n*-way associative. (field encodes *n*)
FFh	Fully associative

CPUID Fn8000_0005_EBX L1 TLB 4K Information

The value returned in EBX provides information about the L1 TLB for 4-KB pages.

Bits	Field Name	Description
31:24	L1DTlb4KAssoc	Data TLB associativity for 4 KB pages. Encoding is per Table E-3 above.
23:16	L1DTlb4KSize	Data TLB number of entries for 4 KB pages.
15:8	L1ITlb4KAssoc	Instruction TLB associativity for 4 KB pages. Encoding is per Table E-3 above.
7:0	L1ITlb4KSize	Instruction TLB number of entries for 4 KB pages.

The associativity fields (L1DTlb4KAssoc and L1ITlb4KAssoc) are encoded as specified in Table E-3 on page 613.

CPUID Fn8000_0005_ECX L1 Data Cache Information

The value returned in ECX provides information about the first level data cache.

Bits	Field Name	Description
31:24	L1DcSize	L1 data cache size in KB.
23:16	L1DcAssoc	L1 data cache associativity. Encoding is per Table E-3.
15:8	L1DcLinesPerTag	L1 data cache lines per tag.
7:0	L1DcLineSize	L1 data cache line size in bytes.

The associativity field (L1DcAssoc) is encoded as specified in Table E-3 on page 613.

CPUID Fn8000_0005_EDX L1 Instruction Cache Information

The value returned in EDX provides information about the first level instruction cache.

Bits	Field Name	Description
31:24	L1IcSize	L1 instruction cache size KB.
23:16	L1IcAssoc	L1 instruction cache associativity. Encoding is per Table E-3.
15:8	L1IcLinesPerTag	L1 instruction cache lines per tag.
7:0	L1IcLineSize	L1 instruction cache line size in bytes.

The associativity field (L1IcAssoc) is encoded as specified in Table E-3 on page 613.

E.4.5 Function 8000_0006h—L2 Cache and TLB and L3 Cache Information

This function provides the second level cache and TLB characteristics for the logical processor that executes the instruction. The EDX register returns the processor's third level cache characteristics that are shared by all logical processors in the package.

CPUID Fn8000_0006_EAX L2 TLB 2M/4M Information

The value returned in EAX provides information about the L2 TLB for 2-MB and 4-MB pages.

Bits	Field Name	Description
31:28	L2DTlb2and4MAssoc	L2 data TLB associativity for 2-MB and 4-MB pages. Encoding is per Table E-4 below.
27:16	L2DTlb2and4MSize	L2 data TLB number of entries for 2-MB and 4-MB pages. The value returned is for the number of entries available for the 2 MB page size; 4 MB pages require two 2 MB entries, so the number of entries available for the 4 MB page size is one-half the returned value.

15:12	L2ITlb2and4MAssoc	L2 instruction TLB associativity for 2-MB and 4-MB pages. Encoding is per Table E-4 below.
11:0	L2ITlb2and4MSize	L2 instruction TLB number of entries for 2-MB and 4-MB pages. The value returned is for the number of entries available for the 2 MB page size; 4 MB pages require two 2 MB entries, so the number of entries available for the 4 MB page size is one-half the returned value.

The associativity fields (L2DTlb2and4MAssoc and L2ITlb2and4MAssoc) are encoded as follows:

Table E-4. L2/L3 Cache and TLB Associativity Field Encoding

Associativity [3:0]	Definition
0h	L2/L3 cache or TLB is disabled.
1h	Direct mapped.
2h	2-way associative.
3h	3-way associative.
4h	4-way associative.
5h	6-way associative.
6h	8-way associative.
8h	16-way associative.
9h	Value for all fields should be determined from Fn8000_001D
Ah	32-way associative.
Bh	48-way associative.
Ch	64-way associative.
Dh	96-way associative.
Eh	128-way associative.
Fh	Fully associative.
All other encodings are reserved.	

CPUID Fn8000_0006_EBX L2 TLB 4K Information

The value returned in EBX provides information about the L2 TLB for 4-KB pages.

Bits	Field Name	Description
31:28	L2DTlb4KAssoc	L2 data TLB associativity for 4-KB pages. Encoding is per Table E-4 above.
27:16	L2DTlb4KSize	L2 data TLB number of entries for 4-KB pages.
15:12	L2ITlb4KAssoc	L2 instruction TLB associativity for 4-KB pages. Encoding is per Table E-4 above.
11:0	L2ITlb4KSize	L2 instruction TLB number of entries for 4-KB pages.

The associativity fields (L2DTlb4KAssoc and L2ITlb4KAssoc) are encoded per Table E-4 above.

CPUID Fn8000_0006_ECX L2 Cache Information

The value returned in ECX provides information about the L2 cache.

Bits	Field Name	Description
31:16	L2Size	L2 cache size in KB.
15:12	L2Assoc	L2 cache associativity. Encoding is per Table E-4 on page 615.
11:8	L2LinesPerTag	L2 cache lines per tag.
7:0	L2LineSize	L2 cache line size in bytes.

The associativity field (L2Assoc) is encoded per Table E-4 on page 615.

CPUID Fn8000_0006_EDX L3 Cache Information

The value returned in EDX provides the third level cache characteristics shared by all logical processors in the package.

Bits	Field Name	Description
31:18	L3Size	Specifies the L3 cache size range: (L3Size[31:18] * 512KB) ≤ L3 cache size < ((L3Size[31:18]+1) * 512KB).
17:16	—	Reserved.
15:12	L3Assoc	L3 cache associativity. Encoded per Table E-4 on page 615.
11:8	L3LinesPerTag	L3 cache lines per tag.
7:0	L3LineSize	L3 cache line size in bytes.

The associativity field (L3Assoc) is encoded per Table E-4 on page 615.

E.4.6 Function 8000_0007h—Processor Power Management and RAS Capabilities

This function provides information about the power management, power reporting, and RAS capabilities of the processor that executes the instruction.There may be other processor-specific features and reporting capabilities not covered here. Refer to the *BIOS and Kernel Developer's Guide* for your specific product to otain more information.

CPUID Fn8000_0007_EAX Reserved

Bits	Field Name	Description
31:0	—	Reserved.

CPUID Fn8000_0007_EBX RAS Capabilities

The value returned in EBX provides information about RAS features that allow system software to detect specific hardware errors.

Bits	Field Name	Description
31:4	—	Reserved.
3	ScalableMca	0=MCAX is not supported. 1=MCAX is supported; the MCAX MSR addresses are supported; MCA_CONFIG[Mcax] is present in all MCA banks.
2	HWA	Hardware assert supported. Indicates support for MSRC001_10[DF:C0].
1	SUCCOR	Software uncorrectable error containment and recovery capability. The processor supports software containment of uncorrectable errors through context synchronizing data poisoning and deferred error interrupts; see APM2, Chapter 9, “Determining Machine-Check Architecture Support.”
0	McaOverflowRecov	MCA overflow recovery support. If set, indicates that MCA overflow conditions (MCi_STATUS[Overflow]=1) are not fatal; software may safely ignore such conditions. If clear, MCA overflow conditions require software to shut down the system. See APM2, Chapter 9, “Handling Machine Check Exceptions.”

CPUID Fn8000_0007_ECX Processor Power Monitoring Interface

The value returned in ECX provides information about the implementation of the processor power monitoring interface.

Bits	Field Name	Description
31:0	CpuPwrSampleTimeRatio	Specifies the ratio of the compute unit power accumulator sample period to the TSC counter period. Returns a value of 0 if not applicable for the system.

CPUID Fn8000_0007_EDX Advanced Power Management Features

The value returned in EDX provides information about the advanced power management and power reporting features available. Refer to the *BIOS and Kernel Developer’s Guide* for your specific product for a detailed description of the definition of each power management feature.

Bits	Field Name	Description
31:13	—	Reserved.
12	ProcPowerReporting	Processor power reporting interface supported.
11	ProcFeedbackInterface	Processor feedback interface. Value: 1. 1=Indicates support for processor feedback interface. **Note:** This feature is deprecated.
10	EffFreqRO	Read-only effective frequency interface. 1=Indicates presence of MSRC000_00E7 [Read-Only Max Performance Frequency Clock Count (MPerfReadOnly)] and MSRC000_00E8 [Read-Only Actual Performance Frequency Clock Count (APerfReadOnly)].
9	CPB	Core performance boost.

8	TscInvariant	TSC invariant. The TSC rate is ensured to be invariant across all P-States, C-States, and stop grant transitions (such as STPCLK Throttling); therefore the TSC is suitable for use as a source of time. 0 = No such guarantee is made and software should avoid attempting to use the TSC as a source of time.
7	HwPstate	Hardware P-state control. MSRC001_0061 [P-state Current Limit], MSRC001_0062 [P-state Control] and MSRC001_0063 [P-state Status] exist.
6	100MHzSteps	100 MHz multiplier Control.
5	—	Reserved.
4	TM	Hardware thermal control (HTC).
3	TTP	THERMTRIP.
2	VID	Voltage ID control. Function replaced by HwPstate.
1	FID	Frequency ID control. Function replaced by HwPstate.
0	TS	Temperature sensor.

E.4.7 Function 8000_0008h—Processor Capacity Parameters and Extended Feature Identification

This function provides the size or capacity of various architectural parameters that vary by implementation, as well as an extension to the Fn8000_0001 feature identifiers.

CPUID Fn8000_0008_EAX Long Mode Size Identifiers

The value returned in EAX provides information about the maximum host and guest physical and linear address width (in bits) supported by the processor.

Bits	Field Name	Description
31:24	—	Reserved.
23:16	GuestPhysAddrSize	Maximum guest physical address size in bits. This number applies only to guests using nested paging. When this field is zero, refer to the PhysAddrSize field for the maximum guest physical address size. See “Secure Virtual Machine” in APM2.
15:8	LinAddrSize	Maximum linear address size in bits.
7:0	PhysAddrSize	Maximum physical address size in bits. When GuestPhysAddrSize is zero, this field also indicates the maximum guest physical address size.

The address width reported is the maximum supported in any mode. For long mode capable processors, the size reported is independent of whether long mode is enabled. See “Processor Initialization and Long-Mode Activation” in APM2.

CPUID Fn8000_0008_EBX Extended Feature Identifiers

The value returned in EBX is an extension to the Fn8000_0001 feature flags and indicates the presence of various ISA extensions.

Bit	Field Name	Description
31:29	—	Reserved
28	PSFD	Predictive Store Forward Disable
27	—	Reserved
26	SsbdNotRequired	SSBD not needed on this processor
25	SsbdVirtSpecCtrl	Use VIRT_SPEC_CTL for SSBD
24	SSBD	Speculative Store Bypass Disable
23:22	—	Reserved
21	INVLPGBnestedPages	INVLPGB support for invalidating guest nested translations
20	EferLmsleUnsupported	EFER.LMSLE is unsupported.
19	IbrsSameMode	IBRS provides same mode speculation limits
18	IbrsPreferred	IBRS is preferred over software solution
17	StibpAlwaysOn	Processor prefers that STIBP be left on
16	IbrsAlwaysOn	Processor prefers that IBRS be left on
15	STIBP	Single Thread Indirect Branch Prediction mode
14	IBRS	Indirect Branch Restricted Speculation
13	INT_WBINVD	WBINVD/WBNOINVD are interruptible.
12	IBPB	Indirect Branch Prediction Barrier
11:10	—	Reserved
9	WBNOINVD	WBNOINVD instruction supported
8	MCOMMIT	MCOMMIT instruction supported
7:5	—	Reserved
4	RDPRU	RDPRU instruction supported
3	INVLPGB	INVLPGB and TLBSYNC instruction supported
2	RstrFpErrPtrs	FP Error Pointers Restored by XRSTOR
1	InstRetCntMsr	Instruction Retired Counter MSR available
0	CLZERO	CLZERO instruction supported

CPUID Fn8000_0008_ECX Size Identifiers

The value returned in ECX provides information about the number of cores supported by the processor, the width of the APIC ID, and the width of the performance time-stamp counter.

Bits	Field Name	Description
31:18	—	Reserved.
17:16	PerfTscSize	Performance time-stamp counter size. Indicates the size of MSRC001_0280[PTSC]. Bits Description 00b 40 bits 01b 48 bits 10b 56 bits 11b 64 bits

15:12	ApicIdSize	APIC ID size. The number of bits in the initial APIC20[ApicId] value that indicate logical processor ID within a package. The size of this field determines the maximum number of logical processors (MNLP) that the package could theoretically support, and not the actual number of logical processors that are implemented or enabled in the package, as indicated by CPUID Fn8000_0008_ECX[NC]. A value of zero indicates that legacy methods must be used to determine the maximum number of logical processors, as indicated by CPUID Fn8000_0008_ECX[NC].
		
		if (ApicIdSize[3:0] == 0) {
		// Used by legacy dual-core/single-core processors
		MNLP = CPUID Fn8000_0008_ECX[NC] + 1;
		} else {
		// use ApicIdSize[3:0] field
		MNLP = (2 raised to the power of ApicIdSize[3:0]);
		}

11:8	—	Reserved.
7:0	NT	Number of physical threads - 1. The number of threads in the processor is NT+1 (e.g., if NT = 0, then there is one thread). See “Legacy Method” on page 633.

CPUID Fn8000_0008_EDX RDPRU Register Identifier Range

The value returned in EDX identifies the maximum recognized register identifier for the RDPRU instruction.

Bits	Field Name	Description
63:32	—	Reserved.
31:16	MaxRdpruID	The maximum ECX value recognized by RDPRU.
15:0	InvlpgbCountMax	Maximum page count for INVLPGB instruction.

E.4.8 Function 8000_0009h—Reserved

CPUID Fn8000_0009 Reserved

This function is reserved.

E.4.9 Function 8000_000Ah—SVM Features

This function provides information about the SVM features that the processory supports. If SVM is not supported (CPUID Fn8000_0001_ECX[SVM] = 0), this function is reserved.

CPUID Fn8000_000A_EAX SVM Revision and Feature Identification

The value returned in EAX provides the SVM revision number. I

Bits	Field Name	Description
31:8	—	Reserved.
7:0	SvmRev	SVM revision number.

CPUID Fn8000_000A_EBX SVM Revision and Feature Identification

The value returned in EBX provides the number of address space identifiers (ASIDs) that the processor supports.

Bits	Field Name	Description
31:0	NASID	Number of available address space identifiers (ASID).

CPUID Fn8000_000A_ECX Reserved

The value returned in ECX for this function is undefined and is reserved.

CPUID Fn8000_000A_EDX SVM Feature Identification

The value returned in EDX provides Secure Virtual Machine architecture feature information. All cross references in the table below are to sections within the *Secure Virtual Machine* chapter of APM2.

Bits	Field Name	Description
31:25	—	Reserved.
24	TlbiCtl	Support for INVLPGB/TLBSYNC hypervisor enable in VMCB and TLBSYNC intercept.
23	HOST_MCE_OVERRIDE	When host CR4.MCE=1 and guest CR4.MCE=0, machine check exceptions (#MC) in a guest do not cause shutdown and are always intercepted.
22:21	—	Reserved.

Bits	Field Name	Description
20	SpecCtrl	SPEC_CTRL virtualization.
19	SSSCheck	SVM supervisor shadow stack restrictions. See “Supervisor Shadow Stack Restrictions” in Volume 2.
18	—	Reserved.
17	GMET	Guest Mode Execution Trap.
16	VGIF	Virtualize the Global Interrupt Flag. See "Nested Virtualization"
15	VMSAVEvirt	VMSAVE and VMLOAD virtualization. See "Nested Virtualization"
14	—	Reserved.
13	AVIC	Support for the AMD advanced virtual interrupt controller. See “Advanced Virtual Interrupt Controller.”
12	PauseFilterThreshold	PAUSE filter threshold. Indicates support for the PAUSE filter cycle count threshold. See "Pause Intercept Filtering” in Volume 2.
11	—	Reserved.
10	PauseFilter	Pause intercept filter. Indicates support for the pause intercept filter. See “Pause Intercept Filtering.”
9:8	—	Reserved.
7	DecodeAssists	Decode assists. Indicates support for the decode assists. See “Decode Assists.”
6	FlushByAsid	Flush by ASID. Indicates that TLB flush events, including CR3 writes and CR4.PGE toggles, flush only the current ASID's TLB entries. Also indicates support for the extended VMCB TLB_Control. See “TLB Control.”
5	VmcbClean	VMCB clean bits. Indicates support for VMCB clean bits. See “VMCB Clean Bits.”
4	TscRateMsr	MSR based TSC rate control. Indicates support for MSR TSC ratio MSRC000_0104. See “TSC Ratio MSR (C000_0104h).”
3	NRIPS	NRIP save. Indicates support for NRIP save on #VMEXIT. See “State Saved on Exit.”
2	SVML	SVM lock. Indicates support for SVM-Lock. See “Enabling SVM.”
1	LbrVirt	LBR virtualization. Indicates support for LBR Virtualization. See “Enabling LBR Virtualization.”
0	NP	Nested paging. Indicates support for nested paging. See “Nested Paging.”

E.4.10 Functions 8000_000Bh–8000_0018h—Reserved

CPUID Fn8000_00[18:0B] Reserved

These functions are reserved.

E.4.11 Function 8000_0019h—TLB Characteristics for 1GB pages

This function provides information about the TLB for 1 GB pages for the processor that executes the instruction.

CPUID Fn8000_0019_EAX L1 TLB 1G Information

The value returned in EAX provides information about the L1 TLB for 1 GB pages.

Bits	Field Name	Description
31:28	L1DTlb1GAssoc	L1 data TLB associativity for 1 GB pages. See Table E-4 on page 615.
27:16	L1DTlb1GSize	L1 data TLB number of entries for 1 GB pages.
15:12	L1ITlb1GAssoc	L1 instruction TLB associativity for 1 GB pages. See Table E-4 on page 615.
11:0	L1ITlb1GSize	L1 instruction TLB number of entries for 1 GB pages.

CPUID Fn8000_0019_EBX L2 TLB 1G Information

The value returned in EBX provides information about the L2 TLB for 1 GB pages.

Bits	Field Name	Description
31:28	L2DTlb1GAssoc	L2 data TLB associativity for 1 GB pages. See Table E-4 on page 615.
27:16	L2DTlb1GSize	L2 data TLB number of entries for 1 GB pages.
15:12	L2ITlb1GAssoc	L2 instruction TLB associativity for 1 GB pages. See Table E-4 on page 615.
11:0	L2ITlb1GSize	L2 instruction TLB number of entries for 1 GB pages.

CPUID Fn8000_0019_E[D,C]X Reserved

The values returned in ECX and EDX for this function are undefined and reserved for future use.

E.4.12 Function 8000_001Ah—Instruction Optimizations

CPUID Fn8000_001A_EAX Performance Optimization Identifiers

This function returns performance related information. For more details on how to use these bits to optimize software, see the *Software Optimization Guide* applicable to your product.

Bits	Field Name	Description
31:3	—	Reserved.
2	FP256	The internal FP/SIMD execution datapath is 256 bits wide.
1	MOVU	MOVU SSE nstructions are more efficient and should be preferred to SSE MOVL/MOVH. MOVUPS is more efficient than MOVLPS/MOVHPS. MOVUPD is more efficient than MOVLPD/MOVHPD.
0	FP128	The internal FP/SIMD execution datapath is 128 bits wide.

CPUID Fn8000_001A_E[D,C,B]X Reserved

The values returned in EBX, ECX, and EDX are undefined for this function and are reserved.

E.4.13 Function 8000_001Bh—Instruction-Based Sampling Capabilities

If instruction-based sampling (IBS) is supported (CPUID Fn8000_0001_ECX[IBS] = 1), this CPUID function can be used to obtain IBS feature information. If IBS is not supported (CPUID Fn8000_0001_ECX[IBS] = 0), this function number is reserved. For more information on using IBS, see “Instruction-Based Sampling” in APM2.

CPUID Fn8000_001B_EAX Instruction-Based Sampling Feature Indicators

The value returned in EAX provides the following information about the specific features of IBS that the processor supports:

Bits	Field Name	Description
31:9		Reserved.
8	OpBrnFuse	Fused branch micro-op indication supported.
7	RipInvalidChk	Invalid RIP indication supported.
6	OpCntExt	IbsOpCurCnt and IbsOpMaxCnt extend by 7 bits.
5	BrnTrgt	Branch target address reporting supported.
4	OpCnt	Op counting mode supported.
3	RdWrOpCnt	Read write of op counter supported.
2	OpSam	IBS execution sampling supported.
1	FetchSam	IBS fetch sampling supported.
0	IBSFFV	IBS feature flags valid.

CPUID Fn8000_001B_E[D,C,B]X Reserved

The values returned in EBX, ECX, and EDX are undefined and are reserved.

E.4.14 Function 8000_001Ch—Lightweight Profiling Capabilities

If lightweight profilling (LWP) is supported (CPUID Fn8000_0001_ECX[LWP] = 1), this CPUID function can be used to obtain information about LWP features supported by the processor. If LWP is not supported (CPUID Fn8000_0001_ECX[LWP] = 0), this function number is reserved. For more information on using LWP, see “Lightweight Profiling” in APM2.

CPUID Fn8000_001C_EAX Lightweight Profiling Capabilities 0

The value returned in EAX provides the following information about LWP capabilities supported by the processor:

Bits	Field Name	Description
31	LwpInt	Interrupt on threshold overflow available.
30	LwpPTSC	Performance time stamp counter in event record is available.
29	LwpCont	Sampling in continuous mode is available.
28:7	—	Reserved.
6	LwpRNH	Core reference clocks not halted event available.
5	LwpCNH	Core clocks not halted event available.
4	LwpDME	DC miss event available.
3	LwpBRE	Branch retired event available.
2	LwpIRE	Instructions retired event available.
1	LwpVAL	LWPVAL instruction available.
0	LwpAvail	The LWP feature is available.

CPUID Fn8000_001C_EBX Lightweight Profiling Capabilities 0

The value returned in EBX provides the following additional information about LWP capabilities supported by the processor:

Bits	Field Name	Description
31:24	LwpEventOffset	Offset in bytes from the start of the LWPCB to the EventInterval1 field.
23:16	LwpMaxEvents	Maximum EventId value supported.
15:8	LwpEventSize	Event record size. Size in bytes of an event record in the LWP event ring buffer.
7:0	LwpCbSize	Control block size. Size in quadwords of the LWPCB.

CPUID Fn8000_001C_ECX Lightweight Profiling Capabilities 0

The value returned in ECX provides the following additional information about LWP capabilities supported by the processor:

Bits	Field Name	Description
31	LwpCacheLatency	Cache latency filtering supported. Cache-related events can be filtered by latency.
30	LwpCacheLevels	Cache level filtering supported. Cache-related events can be filtered by the cache level that returned the data.
29	LwpIpFiltering	IP filtering supported.
28	LwpBranchPrediction	Branch prediction filtering supported. Branches Retired events can be filtered based on whether the branch was predicted properly.

Bits	Field Name	Description
27:24	—	Reserved.
23:16	LwpMinBufferSize	Event ring buffer size. Minimum size of the LWP event ring buffer, in units of 32 event records.
15:9	LwpVersion	Version of LWP implementation.
8:6	LwpLatencyRnd	Amount by which cache latency is rounded.
5	LwpDataAddress	Data cache miss address valid. Address is valid for cache miss event records.
4:0	LwpLatencyMax	Latency counter size. Size in bits of the cache latency counters.

CPUID Fn8000_001C_EDX Lightweight Profiling Capabilities 0

The value returned in EDX provides the following additional information about LWP capabilities supported by the processor:

Bits	Field Name	Description
31	LwpInt	Interrupt on threshold overflow supported.
30	LwpPTSC	Performance time stamp counter in event record is supported.
29	LwpCont	Sampling in continuous mode is supported.
28:7	—	Reserved.
6	LwpRNH	Core reference clocks not halted event is supported.
5	LwpCNH	Core clocks not halted event is supported.
4	LwpDME	DC miss event is supported.
3	LwpBRE	Branch retired event is supported.
2	LwpIRE	Instructions retired event is supported.
1	LwpVAL	LWPVAL instruction is supported.
0	LwpAvail	Lightweight profiling is supported.

E.4.15 Function 8000_001Dh—Cache Topology Information

CPUID Fn8000_001D_E[D,C,B,A]X reports cache topology information for the cache enumerated by the value passed to the instruction in ECX, referred to as Cache *n* in the following description. To gather information for all cache levels, software must repeatedly execute CPUID with 8000_001Dh in EAX and ECX set to increasing values beginning with 0 until a value of 00h is returned in the field CacheType (EAX[4:0]) indicating no more cache descriptions are available for this processor.

If CPUID Fn8000_0001_ECX[TopologyExtensions] = 0, then CPUID Fn8000_001Dh is reserved. Any value in ECX which does not select an existing cache will return a Null cache type in EAX[4:0].

CPUID Fn8000_001D_EAX_x[N:0] Cache Properties

Bits	Field Name	Description
31:26	—	Reserved.
25:14	NumSharingCache	Specifies the number of logical processors sharing the cache enumerated by *N*, the value passed to the instruction in ECX. The number of logical processors sharing this cache is the value of this field incremented by 1. To determine which logical processors are sharing a cache, determine a Share Id for each processor as follows: ShareId = LocalApicId >> log2(NumSharingCache+1) Logical processors with the same ShareId then share a cache. If NumSharingCache+1 is not a power of two, round it up to the next power of two.
13:10	—	Reserved.
9	FullyAssociative	Fully associative cache. When set, indicates that the cache is fully associative. If 0 is returned in this field, the cache is set associative.
8	SelfInitialization	Self-initializing cache. When set, indicates that the cache is self initializing; software initialization not required. If 0 is returned in this field, hardware does not initialize this cache.
7:5	CacheLevel	Cache level. Identifies the level of this cache. Note that the enumeration value is not necessarily equal to the cache level. Bits — Description 000b — Reserved. 001b — Level 1 010b — Level 2 011b — Level 3 111b-100b — Reserved.
4:0	CacheType	Cache type. Identifies the type of cache. Bits — Description 00h — Null; no more caches. 01h — Data cache 02h — Instruction cache 03h — Unified cache 1Fh-04h — Reserved.

CPUID Fn8000_001D_EBX_x[N:0] Cache Properties

See CPUID Fn8000_001D_EAX_x[N:0].

Bits	Field Name	Description
31:22	CacheNumWays	Number of ways for this cache. The number of ways is the value returned in this field incremented by 1.
21:12	CachePhysPartitions	Number of physical line partitions. The number of physical line partitions is the value returned in this field incremented by 1.
11:0	CacheLineSize	Cache line size. The cache line size in bytes is the value returned in this field incremented by 1.

CPUID Fn8000_001D_ECX_x[N:0] Cache Properties

See CPUID Fn8000_001D_EAX_x[N:0].

Bits	Field Name	Description
31:0	CacheNumSets	Number of ways for set associative cache. Number of ways is the value returned in this field incremented by 1. Only valid for caches that are not fully associative (Fn8000_001D_EAX_x*n*[FullyAssociative] = 0).

CPUID Fn8000_001D_EDX_x[N:0] Cache Properties

See CPUID Fn8000_001D_EAX_x[N:0].

Bits	Field Name	Description
31:2	—	Reserved.
1	CacheInclusive	Cache inclusivity. A value of 0 indicates that this cache is not inclusive of lower cache levels. A value of 1 indicates that the cache is inclusive of lower cache levels.
0	WBINVD	Write-Back Invalidate/Invalidate execution scope. A value of 0 returned in this field indicates that the WBINVD/INVD instruction invalidates all lower level caches of non-originating logical processors sharing this cache. When set, this field indicates that the WBINVD/INVD instruction is not guaranteed to invalidate all lower level caches of non-originating logical processors sharing this cache.

E.4.16 Function 8000_001Eh—Processor Topology Information

CPUID Fn8000_001E_EAX Extended APIC ID

If CPUID Fn8000_0001_ECX[TopologyExtensions] = 0, this function number is reserved.

Bits	Field Name	Description
31:0	ExtendedApicId	Extended APIC ID. If MSR0000_001B[ApicEn] = 0, this field is reserved..

CPUID Fn8000_001E_EBX Compute Unit Identifiers

See CPUID Fn8000_001E_EAX.

Bits	Field Name	Description
31:16	—	Reserved.
15:8	ThreadsPerComputeUnit	Threads per compute unit (zero-based count). The actual number of threads per compute unit is the value of this field + 1. To determine which logical processors (threads) belong to a given Compute Unit, determine a ShareId for each processor as follows: ShareId = LocalApicId >> log2(ThreadsPerComputeUnit+1) Logical processors with the same ShareId then belong to the same Compute Unit. (If ThreadsPerComputeUnit+1 is not a power of two, round it up to the next power of two).
7:0	ComputeUnitId	Compute unit ID. Identifies a Compute Unit, which may be one or more physical cores that each implement one or more logical processors.

CPUID Fn8000_001E_ECX Node Identifiers

See CPUID Fn8000_001E_EAX.

Bits	Field Name	Description
31:0	—	Reserved.
10:8	NodesPerProcessor	Specifies the number of nodes in the package/socket in which this logical processor resides. Node in this context corresponds to a processor die. Encoding is N-1, where N is the number of nodes present in the socket.
7:0	NodeId	Specifies the ID of the node containing the current logical processor. NodeId values are unique across the system..

CPUID Fn8000_001E_EDX Reserved

The value returned in EDX is undefined and is reserved.

E.4.17 Function 8000_001Fh—Encrypted Memory Capabilities

CPUID Fn8000_001F_EAX Secure Encryption

Bits	Field Name	Description
31:25	—	Reserved.
24	VmsaRegProt	VMSA Register Protection supported
23:17	—	Reserved.
16	VTE	Virtual Transparent Encryption supported
15	PreventHostIbs	Disallowing IBS use by the host supported

Bits	Field Name	Description
14	DebugSwap	Full debug state swap supported for SEV-ES guests
13	AlternateInjection	Alternate Injection supported
12	RestrictedInjection	Restricted Injection supported
11	64BitHost	SEV guest execution only allowed from a 64-bit host
10	HwEnfCacheCoh	Hardware cache coherency across encryption domains enforced
9	—	Reserved.
8	SecureTsc	Secure TSC supported
7:6	—	Reserved.
5	VMPL	VM Permission Levels supported
4	SEV-SNP	SEV Secure Nested Paging supported
3	SEV-ES	SEV Encrypted State supported
2	PageFlushMsr	Page Flush MSR available
1	SEV	Secure Encrypted Virtualization supported
0	SME	Secure Memory Encryption supported

CPUID Fn8000_001F_EBX Secure Encryption

Bits	Field Name	Description
31:16	—	Reserved.
15:12	NumVMPL	Number of VM Permission Levels supported
11:6	PhysAddrReduction	Physical Address bit reduction
5:0	CbitPosition	C-bit location in page table entry

CPUID Fn8000_001F_ECX Secure Encryption

Bits	Field Name	Description
31:0	NumEncryptedGuests	Number of encrypted guests supported simultaneously

CPUID Fn8000_001F_EDX Minimum ASID

Bits	Field Name	Description
31:0	MinSevNoEsAsid	Minimum ASID value for an SEV enabled, SEV-ES disabled guest

E.4.18 Function 8000_0020—Reserved

E.4.19 Function 8000_0021—Extended Feature Identification 2

CPUID Fn8000_0021_EAX Extended Feature 2

Bits	Field Name	Description
31:14	—	Reserved
13	PrefetchCtlMsr	Prefetch control MSR supported. See Core::X86::Msr::PrefetchControl in BKDG or PPR for details
12:10	—	Reserved
9	NoSmmCtlMSR	SMM_CTL MSR (C001_0116h) is not supported.
8	—	Reserved
7	UpperAddressIgnore	Upper Address Ignore is supported.
6	NullSelectClearsBase	Null segment selector loads also clear the destination segment register base and limit.
5:4	—	Reserved
3	SmmPgCfgLock	SMM paging configuration lock supported.
2	LFenceAlwaysSerializing	LFENCE is always dispatch serializing.
1	—	Reserved
0	NoNestedDataBp	Processor ignores nested data breakpoints

CPUID Fn8000_0021_EBX Extended Feature 2

Bits	Field Name	Description
31:12	—	Reserved.
11:0	MicrocodePatchSize	The size of the Microcode patch in 16-byte multiples. If 0, the size of the patch is at most 5568 (15C0h) bytes.

CPUID Fn8000_0021_E[C,D]X Reserved

The values returned in ECX and EDX are undefined and are reserved.

CPUID Fn8000_0022_EAX Reserved

Bits	Field Name	Description
31:0	—	Reserved

CPUID Fn8000_0022_EBX Extended Performance Monitoring and Debug

Bits	Field Name	Description
31:16	—	Reserved
15:10	NumDfPmc	Number of available Northbridge Performance Monitor Counters
9:4	—	Reserved
3:0	NumCorePmc	Number of Core Performance Counters

CPUID Fn8000_0022_E[C,D]X Reserved

The values returned in ECX and EDX are undefined and are reserved.

E.5 Multiple Processor Calculation

Operating systems may use one of two possible methods to calculate the actual number of logical processors per package (NC), and the maximum possible number of logical processors per package (MNLP). The extended method is recommended, but a legacy method is also available.

E.5.1 Legacy Method

The CPUID identification of total number of logical processors per package is derived from information returned by the following fields:

- CPUID Fn0000_0001_EBX[LogicalProcessorCount]
- CPUID Fn0000_0001_EDX[HTT] (Hyper-Threading Technology)
- CPUID Fn8000_0001_ECX[CmpLegacy]
- CPUID Fn8000_0008_ECX[NC]

Table E-5 defines LogicalProcessorCount, HTT, CmpLegacy, and NC as a function of the number of logical processors per package (n).

When HTT = 0, LogicalProcessorCount is reserved and the package contains one logical processor.

When HTT = 1 and CmpLegacy = 1, LogicalProcessorCount represents the number of logical processors per package (n).

Table E-5. LogicalProcessorCount, CmpLegacy, HTT, and NC

Logical Processors per package	CmpLegacy	HTT	LogicalProcessorCount	NC
1	0	0	Reserved	0
2 or more	1	1	n	n-1

The use of CmpLegacy and LogicalProcessorCount for determining the number of logical processors is deprecated. Instead, use NC to determine the number of logical processors per package.

E.5.2 Extended Method (Recommended)

The CPUID identification of total number of logical processors per package is derived from information returned by the CPUID Fn8000_0008_ECX[ApicIdSize[3:0]]. This field indicates the number of least significant bits in the CPUID Fn0000_0001_EBX[LocalApicId] that indicates logical processor ID within the package. The size of this field determines the maximum number of logical processors (MNLP) that the package could theoretically support, and not the actual number of logical processors that are implemented or enabled in the package, as indicated by CPUID Fn8000_0008_ECX[NC].

A value of zero for ApicIdSize[3:0] indicates that the legacy method (section E5.1) should be used to derive the maximum number of logical processors:

MNLP = CPUID Fn8000_0008_ECX[NC] + 1.

And for non-zero values of ApicIdSize[3:0]:

MNLP = 2 raised to the power of ApicIdSize[3:0]

Appendix F Instruction Effects on RFLAGS

The flags in the RFLAGS register are described in “Flags Register” in Volume 1 and “RFLAGS Register” in Volume 2. Table F-1 summarizes the effect that instructions have on these flags. The table includes all instructions that affect the flags. Instructions not shown have no effect on RFLAGS.

The following codes are used within the table:

- 0—The flag is always cleared to 0.
- 1—The flag is always set to 1.
- AH—The flag is loaded with value from AH register.
- Mod—The flag is modified, depending on the results of the instruction.
- Pop—The flag is loaded with value popped off of the stack.
- Tst—The flag is tested.
- U—The effect on the flag is undefined.
- Gray shaded cells indicate that the flag is not affected by the instruction.

Table F-1. Instruction Effects on RFLAGS

Revision History

Date	Revision	Description
November 2021	3.25	Corrections to XRSTOR, XRSTORS, XSAVE, XSAVEC, XSAVEOPT, XSAVES, XGETBV, and XSETBV descriptions.
May 2020	3.24	Chapter 2: Sections: Updated VAESDEC, VAESDECLAST, VAESENC, VAESENCLAST, VCMPPS, VPCLMULQDQ, and VPCMPGTQ.
January 2019	3.23	Updated the Exceptions table for MOVNTDAQA and VMOVNTDAQA. Corrections to VPMACSSDD and VPMACSSWW. Corrected scr1 to src1 throughout the document.
May 2018	3.22	Update Packed String Compare Algorithm Fixed a number of erroneous references to double precision that should be single precision Separate out MOVQ from MOVD
December 2017	3.21	Clarifications to XGETBV, XRSTOR, XRSTORS, XSAVE, XSAVEC, XSAVEOPT, XSAVES, and XSETBV instructions.
March 2017	3.20	Corrections to ROUNDPD, VROUNDPD, ROUNDPS, VROUNDPS, ROUNDSD, VROUNDSD, ROUNDSS, VROUNDSS, VPERMD, VPERMPD, VPERMPS, VPERMQ, VTESTPD, VTESTPS, XGETBV, XSETBV, XSAVE, and AVX instruction descriptions. Added SHA1RNDS4, SHA1NEXTE, SHA1MSG1, SHA1MSG2, SHA256RNDS2, SHA256MSG1, SHA256MSG2, XRSTOR, XRSTORS and XSAVEC instructions.
June 2015	3.19	Corrections to the MOVLPD, PHSUBW, PHSUBSW instruction descriptions.
October 2013	3.18	Added AVX2 Instructions. Added “Instruction Support” subsection to each instruction reference page that lists CPUID feature bit information in a table.
May 2013	3.17	Removed all references to the CPUID specification which has been superseded by Volume 3, Appendix E, "Obtaining Processor Information Via the CPUID Instruction." Corrected exceptions table for the explicitly-aligned load/store instructions. General protection exception does not depend on state of MXCSR.MM bit.

Date	Revision	Description
September 2012	3.16	Corrected REX.W bit encoding for the MOVD instruction. (See page 186.) Corrected L bit encoding for the VMOVQ (D6h opcode) instruction. (See page 222.) Corrected statement about zero extension for third encoding (11h opcode) of MOVSS instruction. (See page 230.)
March 2012	3.15	Corrected instruction encoding for VPCOMUB, VPCOMUD, VPCOMUQ, VPCOMUW, and VPHSUBDQ instructions. Other minor corrections.
December 2011	3.14	Reworked Section 1.5, "String Compare Instructions" on page 10. Revised descriptions of the string compare instructions in instruction reference. Moved AES overview to Appendix A. Clarified trap and exception behavior for elements not selected for writing. See MASKMOVDQU VMASKMOVDQU on page 160. Additional minor corrections and clarifications.
September 2011	3.13	Moved discussion of extended instruction encoding; VEX and XOP prefixes to Volume 3. Added FMA instructions. Described on the corresponding FMA4 reference page. Moved BMI and TBM instructions to Volume 3. Added XSAVEOPT instruction. Corrected descriptions of VSQRTSD and VSQRTSS.
May 2011	3.12	Added F16C, BMI, and TBM instructions.
December 2010	3.11	Complete revision and reformat accommodating 128-bit and 256-bit media instructions. Includes revised definitions of legacy SSE, SSE2, SSE3, SSE4.1, SSE4.2, and SSSE3 instructions, as well as new definitions of extended AES, AVX, CLMUL, FMA4, and XOP instructions. Introduction includes supplemental information concerning encoding of extended instructions, enhanced processor state management provided by the XSAVE/XRSTOR instructions, cryptographic capabilities of the AES instructions, and functionality of extended string comparison instructions.
September 2007	3.10	Added minor clarifications and corrected typographical and formatting errors.

Date	Revision	Description
July 2007	3.09	Added the following instructions: EXTRQ, INSERTQ, MOVNTSD, and MOVNTSS. Added misaligned exception mask (MXCSR.MM) information. Added imm8 values with corresponding mnemonics to (V)CMPPD, (V)CMPPS, (V)CMPSD, and (V)CMPSS. Reworded CPUID information in condition tables. Added minor clarifications and corrected typographical and formatting errors.
September 2006	3.08	Made minor corrections.
December 2005	3.07	Made minor editorial and formatting changes.
January 2005	3.06	Added documentation on SSE3 instructions. Corrected numerous minor factual errors and typos.
September 2003	3.05	Made numerous small factual corrections.
April 2003	3.04	Made minor corrections.

Preface

About This Book

This book is part of a multivolume work entitled the *AMD64 Architecture Programmer's Manual*. The complete set includes the following volumes.

Title	Order No.
Volume 1: Application Programming	24592
Volume 2: System Programming	24593
Volume 3: General-Purpose and System Instructions	24594
Volume 4: 128-Bit and 256-Bit Media Instructions	26568
Volume 5: 64-Bit Media and x87 Floating-Point Instructions	26569

Audience

This volume is intended for programmers who develop application or system software.

Organization

Volumes 3, 4, and 5 describe the AMD64 instruction set in detail, providing mnemonic syntax, instruction encoding, functions, affected flags, and possible exceptions.

The AMD64 instruction set is divided into five subsets:

- General-purpose instructions
- System instructions
- Streaming SIMD Extensions (includes 128-bit and 256-bit media instructions)
- 64-bit media instructions (MMX™)
- x87 floating-point instructions

Several instructions belong to, and are described identically in, multiple instruction subsets.

This volume describes the Streaming SIMD Extensions (SSE) instruction set which includes 128-bit and 256-bit media instructions. SSE includes both legacy and extended forms. The index at the end cross-references topics within this volume. For other topics relating to the AMD64 architecture, and for information on instructions in other subsets, see the tables of contents and indexes of the other volumes.

Conventions and Definitions

The section which follows, **Notational Conventions,** describes notational conventions used in this volume. The next section, **Definitions,** lists a number of terms used in this volume along with their technical definitions. Some of these definitions assume knowledge of the legacy x86 architecture. See "Related Documents" on page xl for further information about the legacy x86 architecture. Finally, the **Registers** section lists the registers which are a part of the system programming model.

Notational Conventions

Section 1.1, "Syntax and Notation" on page 2 describes notation relating specifically to instruction encoding.

#GP(0)

An instruction exception—in this example, a general-protection exception with error code of 0.

1011b

A binary value, in this example, a 4-bit value.

F0EA_0B40h

A hexadecimal value, in this example a 32-bit value. Underscore characters may be used to improve readability.

128

Numbers without an alpha suffix are decimal unless the context indicates otherwise.

7:4

A bit range, from bit 7 to 4, inclusive. The high-order bit is shown first. Commas may be inserted to indicate gaps.

#GP(0)

A general-protection exception (#GP) with error code of 0.

CPUID Fn*XXXX_XXXX_RRR*[*FieldName*]

Support for optional features or the value of an implementation-specific parameter of a processor can be discovered by executing the CPUID instruction on that processor. To obtain this value, software must execute the CPUID instruction with the function code *XXXX_XXXX*h in EAX and then examine the field *FieldName* returned in register *RRR*. If the "*_RRR*" notation is followed by "_x*YYY*", register ECX must be set to the value *YYY*h before executing CPUID. When *FieldName* is not given, the entire contents of register *RRR* contains the desired value. When determining optional feature support, if the bit identified by *FieldName* is set to a one, the feature is supported on that processor.

CR0–CR4

A register range, from register CR0 through CR4, inclusive, with the low-order register first.

CR4[OSXSAVE], CR4.OSXSAVE

The OSXSAVE bit of the CR4 register.

CR0[PE] = 1, CR0.PE = 1

The PE bit of the CR0 register has a value of 1.

EFER[LME] = 0, EFER.LME = 0

The LME field of the EFER register is cleared (contains a value of 0).

DS:rSI

The content of a memory location whose segment address is in the DS register and whose offset relative to that segment is in the rSI register.

RFLAGS[13:12]

A field within a register identified by its bit range. In this example, corresponding to the IOPL field.

Definitions

128-bit media instruction

Instructions that operate on the various 128-bit vector data types. Supported within both the legacy SSE and extended SSE instruction sets.

256-bit media instruction

Instructions that operate on the various 256-bit vector data types. Supported within the extended SSE instruction set.

64-bit media instructions

Instructions that operate on the 64-bit vector data types. These are primarily a combination of MMX and 3DNow!™ instruction sets and their extensions, with some additional instructions from the SSE1 and SSE2 instruction sets.

16-bit mode

Legacy mode or compatibility mode in which a 16-bit address size is active. See *legacy mode* and *compatibility mode*.

32-bit mode

Legacy mode or compatibility mode in which a 32-bit address size is active. See *legacy mode* and *compatibility mode*.

64-bit mode

A submode of *long mode*. In 64-bit mode, the default address size is 64 bits and new features, such as register extensions, are supported for system and application software.

absolute

A displacement that references the base of a code segment rather than an instruction pointer. See *relative*.

AES

Advance Encryption Standard (AES) algorithm acceleration instructions; part of Streaming SIMD Extensions (SSE).

ASID

Address space identifier.

AVX

Extension of the SSE instruction set supporting 256-bit vector (packed) operands. See Streaming SIMD Extensions.

biased exponent

The sum of a floating-point value's exponent and a constant bias for a particular floating-point data type. The bias makes the range of the biased exponent always positive, which allows reciprocation without overflow.

byte

Eight bits.

clear, cleared

To write the value 0 to a bit or a range of bits. See *set*.

compatibility mode

A submode of *long mode*. In compatibility mode, the default address size is 32 bits, and legacy 16-bit and 32-bit applications run without modification.

commit

To irreversibly write, in program order, an instruction's result to software-visible storage, such as a register (including flags), the data cache, an internal write buffer, or memory.

CPL

Current privilege level.

direct

Referencing a memory address included in the instruction syntax as an immediate operand. The address may be an absolute or relative address. See *indirect*.

displacement

A signed value that is added to the base of a segment (absolute addressing) or an instruction pointer (relative addressing). Same as *offset*.

doubleword

Two words, or four bytes, or 32 bits.

double quadword

Eight words, or 16 bytes, or 128 bits. Also called *octword*.

effective address size

The address size for the current instruction after accounting for the default address size and any address-size override prefix.

effective operand size

The operand size for the current instruction after accounting for the default operand size and any operand-size override prefix.

element

See *vector*.

exception

An abnormal condition that occurs as the result of instruction execution. Processor response to an exception depends on the type of exception. For all exceptions except SSE floating-point exceptions and x87 floating-point exceptions, control is transferred to a handler (or service routine) for that exception as defined by the exception's vector. For floating-point exceptions defined by the IEEE 754 standard, there are both masked and unmasked responses. When unmasked, the exception handler is called, and when masked, a default response is provided instead of calling the handler.

extended SSE instructions

Enhanced set of SIMD instructions supporting 256-bit vector data types and allowing the specification of up to four operands. A subset of the *Streaming SIMD Extensions (SSE)*. Includes the AVX, FMA, FMA4, and XOP instructions. Compare *legacy SSE*.

flush

An often ambiguous term meaning (1) writeback, if modified, and invalidate, as in "flush the cache line," or (2) invalidate, as in "flush the pipeline," or (3) change a value, as in "flush to zero."

FMA4

Fused Multiply Add, four operand. Part of the extended SSE instruction set.

FMA

Fused Multiply Add. Part of the extended SSE instruction set.

GDT

Global descriptor table.

GIF

Global interrupt flag.

IDT

Interrupt descriptor table.

IGN

Ignored. Value written is ignored by hardware. Value returned on a read is indeterminate. See *reserved*.

indirect

Referencing a memory location whose address is in a register or other memory location. The address may be an absolute or relative address. See *direct*.

IRB

The virtual-8086 mode interrupt-redirection bitmap.

IST

The long-mode interrupt-stack table.

IVT

The real-address mode interrupt-vector table.

LDT

Local descriptor table.

legacy x86

The legacy x86 architecture.

legacy mode

An operating mode of the AMD64 architecture in which existing 16-bit and 32-bit applications and operating systems run without modification. A processor implementation of the AMD64 architecture can run in either *long mode* or *legacy mode*. Legacy mode has three submodes, *real mode*, *protected mode*, and *virtual-8086 mode*.

legacy SSE instructions

All Streaming SIMD Extensions instructions prior to AVX, XOP, and FMA4. Legacy SSE instructions primarily utilize operands held in XMM registers. The legacy SSE instructions include the original Streaming SIMD Extensions (SSE1) and the subsequent extensions SSE2, SSE3, SSSE3, SSE4, SSE4A, SSE4.1, and SSE4.2. See *Streaming SIMD instructions*.

long mode

An operating mode unique to the AMD64 architecture. A processor implementation of the AMD64 architecture can run in either *long mode* or *legacy mode*. Long mode has two submodes, *64-bit mode* and *compatibility mode*.

lsb
: Least-significant bit.

LSB
: Least-significant byte.

main memory
: Physical memory, such as RAM and ROM (but not cache memory) that is installed in a particular computer system.

mask
: (1) A control bit that prevents the occurrence of a floating-point exception from invoking an exception-handling routine. (2) A field of bits used for a control purpose.

MBZ
: Must be zero. If software attempts to set an MBZ bit to 1, a general-protection exception (#GP) occurs. See *reserved*.

memory
: Unless otherwise specified, *main memory*.

moffset
: A 16, 32, or 64-bit offset that specifies a memory operand directly, without using a ModRM or SIB byte.

msb
: Most-significant bit.

MSB
: Most-significant byte.

octword
: Same as *double quadword*.

offset
: Same as *displacement*.

overflow
: The condition in which a floating-point number is larger in magnitude than the largest, finite, positive or negative number that can be represented in the data-type format being used.

packed
: See *vector*.

PAE
: Physical-address extensions.

physical memory

Actual memory, consisting of *main memory* and cache.

probe

A check for an address in processor caches or internal buffers. *External probes* originate outside the processor, and *internal probes* originate within the processor.

protected mode

A submode of *legacy mode*.

quadword

Four words, eight bytes, or 64 bits.

RAZ

Read as zero. Value returned on a read is always zero (0) regardless of what was previously written. See *reserved*.

real-address mode, real mode

A short name for *real-address mode,* a submode of *legacy mode*.

relative

Referencing with a *displacement* (*offset*) from an instruction pointer rather than the base of a code segment. See *absolute*.

reserved

Fields marked as reserved may be used at some future time.

To preserve compatibility with future processors, reserved fields require special handling when read or written by software. Software must not depend on the state of a reserved field (unless qualified as RAZ), nor upon the ability of such fields to return a previously written state.

If a field is marked reserved without qualification, software must not change the state of that field; it must reload that field with the same value returned from a prior read.

Reserved fields may be qualified as IGN, MBZ, RAZ, or SBZ (see definitions).

REX

A legacy instruction modifier prefix that specifies 64-bit operand size and provides access to additional registers.

RIP-relative addressing

Addressing relative to the 64-bit relative instruction pointer.

SBZ

Should be zero. An attempt by software to set an SBZ bit to 1 results in undefined behavior. See *reserved*.

scalar

An atomic value existing independently of any specification of location, direction, etc., as opposed to vectors.

set

To write the value 1 to a bit or a range of bits. See *clear*.

SIMD

Single instruction, multiple data. See *vector*.

Streaming SIMD Extensions (SSE)

Instructions that operate on scalar or vector (packed) integer and floating point numbers. The SSE instruction set comprises the legacy SSE and extended SSE instruction sets.

SSE1

Original SSE instruction set. Includes instructions that operate on vector operands in both the MMX and the XMM registers.

SSE2

Extensions to the SSE instruction set.

SSE3

Further extensions to the SSE instruction set.

SSSE3

Further extensions to the SSE instruction set.

SSE4.1

Further extensions to the SSE instruction set.

SSE4.2

Further extensions to the SSE instruction set.

SSE4A

A minor extension to the SSE instruction set adding the instructions EXTRQ, INSERTQ, MOVNTSS, and MOVNTSD.

sticky bit

A bit that is set or cleared by hardware and that remains in that state until explicitly changed by software.

TSS

Task-state segment.

underflow

The condition in which a floating-point number is smaller in magnitude than the smallest nonzero, positive or negative number that can be represented in the data-type format being used.

vector

(1) A set of integer or floating-point values, called *elements*, that are packed into a single operand. Most media instructions use vectors as operands. Also called *packed* or *SIMD* operands.

(2) An *interrupt descriptor table* index, used to access exception handlers. See *exception*.

VEX prefix

Extended instruction encoding escape prefix. Introduces a two- or three-byte encoding escape sequence used in the encoding of AVX instructions. Opens a new extended instruction encoding space. Fields select the opcode map and allow the specification of operand vector length and an additional operand register. See *XOP prefix*.

virtual-8086 mode

A submode of *legacy mode*.

VMCB

Virtual machine control block.

VMM

Virtual machine monitor.

word

Two bytes, or 16 bits.

x86

See *legacy x86*.

XOP instructions

Part of the extended SSE instruction set using the XOP prefix. See Streaming SIMD Extensions.

XOP prefix

Extended instruction encoding escape prefix. Introduces a three-byte escape sequence used in the encoding of XOP instructions. Opens a new extended instruction encoding space distinct from the VEX opcode space. Fields select the opcode map and allow the specification of operand vector length and an additional operand register. See *VEX prefix*.

Registers

In the following list of registers, mnemonics refer either to the register itself or to the register content:

AH–DH

The high 8-bit AH, BH, CH, and DH registers. See *[AL–DL]*.

AL–DL

The low 8-bit AL, BL, CL, and DL registers. See *[AH–DH]*.

AL–r15B

The low 8-bit AL, BL, CL, DL, SIL, DIL, BPL, SPL, and [r8B–r15B] registers, available in 64-bit mode.

BP

Base pointer register.

CR*n*

Control register number *n*.

CS

Code segment register.

eAX–eSP

The 16-bit AX, BX, CX, DX, DI, SI, BP, and SP registers or the 32-bit EAX, EBX, ECX, EDX, EDI, ESI, EBP, and ESP registers. See *[rAX–rSP]*.

EFER

Extended features enable register.

eFLAGS

16-bit or 32-bit flags register. See *rFLAGS*.

EFLAGS

32-bit (extended) flags register.

eIP

16-bit or 32-bit instruction-pointer register. See *rIP*.

EIP

32-bit (extended) instruction-pointer register.

FLAGS

16-bit flags register.

GDTR

Global descriptor table register.

GPRs

General-purpose registers. For the 16-bit data size, these are AX, BX, CX, DX, DI, SI, BP, and SP. For the 32-bit data size, these are EAX, EBX, ECX, EDX, EDI, ESI, EBP, and ESP. For the 64-bit data size, these include RAX, RBX, RCX, RDX, RDI, RSI, RBP, RSP, and R8–R15.

IDTR
: Interrupt descriptor table register.

IP
: 16-bit instruction-pointer register.

LDTR
: Local descriptor table register.

MSR
: Model-specific register.

r8–r15
: The 8-bit R8B–R15B registers, or the 16-bit R8W–R15W registers, or the 32-bit R8D–R15D registers, or the 64-bit R8–R15 registers.

rAX–rSP
: The 16-bit AX, BX, CX, DX, DI, SI, BP, and SP registers, or the 32-bit EAX, EBX, ECX, EDX, EDI, ESI, EBP, and ESP registers, or the 64-bit RAX, RBX, RCX, RDX, RDI, RSI, RBP, and RSP registers. Replace the placeholder *r* with nothing for 16-bit size, “E” for 32-bit size, or “R” for 64-bit size.

RAX
: 64-bit version of the EAX register.

RBP
: 64-bit version of the EBP register.

RBX
: 64-bit version of the EBX register.

RCX
: 64-bit version of the ECX register.

RDI
: 64-bit version of the EDI register.

RDX
: 64-bit version of the EDX register.

rFLAGS
: 16-bit, 32-bit, or 64-bit flags register. See *RFLAGS*.

RFLAGS
: 64-bit flags register. See *rFLAGS*.

rIP

16-bit, 32-bit, or 64-bit instruction-pointer register. See *RIP*.

RIP

64-bit instruction-pointer register.

RSI

64-bit version of the ESI register.

RSP

64-bit version of the ESP register.

SP

Stack pointer register.

SS

Stack segment register.

TPR

Task priority register (CR8).

TR

Task register.

YMM/XMM

Set of sixteen (eight accessible in legacy and compatibility modes) 256-bit wide registers that hold scalar and vector operands used by the SSE instructions.

Endian Order

The x86 and AMD64 architectures address memory using little-endian byte-ordering. Multibyte values are stored with the least-significant byte at the lowest byte address, and illustrated with their least significant byte at the right side. Strings are illustrated in reverse order, because the addresses of string bytes increase from right to left.

1 Introduction

Processors capable of performing the same mathematical operation simultaneously on multiple data streams are classified as *single-instruction, multiple-data (SIMD)*. Instructions that utilize this hardware capability are called SIMD instructions.

Software can utilize SIMD instructions to drastically increase the performance of media applications which typically employ algorithms that perform the same mathematical operation on a set of values in parallel. The original SIMD instruction set was called MMX and operated on 64-bit wide vectors of integer and floating-point elements. Subsequently a new SIMD instruction set called the Streaming SIMD Extensions (SSE) was added to the architecture.

The SSE instruction set defines a new programming model with its own array of vector data registers (YMM/XMM registers) and a control and status register (MXCSR). Most SSE instructions pull their operands from one or more YMM/XMM registers and store results in a YMM/XMM register, although some instructions use a GPR as either a source or destination. Most instructions allow one operand to be loaded from memory. The set includes instructions to load a YMM/XMM register from memory (aligned or unaligned) and store the contents of a YMM/XMM register.

An overview of the SSE instruction set is provided in Volume 1, Chapter 4.

This volume provides detailed descriptions of each instruction within the SSE instruction set. The SSE instruction set comprises the *legacy* SSE instructions and the *extended* SSE instructions.

Legacy SSE instructions comprise the following subsets:

- The original Streaming SIMD Extensions (herein referred to as SSE1)
- SSE2
- SSE3
- SSSE3
- SSE4.1
- SSE4.2
- SSE4A
- Advanced Encryption Standard (AES)

Extended SSE instructions comprise the following subsets:

- AVX
- AVX2
- FMA
- FMA4
- XOP

Legacy SSE architecture supports operations involving 128-bit vectors and defines the base programming model including the SSE registers, the Media eXtension Control and Status Register (MXCSR), and the instruction exception behavior.

The Streaming SIMD Extensions (SSE) instruction set is extended to include the AVX, FMA, FMA4, and XOP instruction sets. The AVX instruction set provides an extended form for most legacy SSE instructions and several new instructions. Extensions include providing for the specification of a unique destination register for operations with two or more source operands and support for 256-bit wide vectors. Some AVX instructions also provide enhanced functionality compared to their legacy counterparts.

A significant feature of the extended SSE instruction set architecture is the doubling of the width of the XMM registers. These registers are referred to as the YMM registers. The XMM registers overlay the lower octword (128 bits) of the YMM registers. Registers YMM/XMM0–7 are accessible in legacy and compatibility mode. Registers YMM/XMM8–15 are available in 64-bit mode (a subset of long mode). VEX/XOP instruction prefixes allow instruction encodings to address the additional registers.

The SSE instructions can be used in processor legacy mode or long (64-bit) mode. CPUID Fn8000_0001_EDX[LM] indicates the availability of long mode.

Compilation for execution in 64-bit mode offers the following advantages:

- Access to an additional eight YMM/XMM registers for a total of 16
- Access to an additional eight 64-bit general-purpose registers for a total of 16
- Access to the 64-bit virtual address space and the RIP-relative addressing mode

Hardware support for each of the subsets of SSE instructions listed above is indicated by CPUID feature flags. Refer to Volume 3, Appendix D, “Instruction Subsets and CPUID Feature Flags,” for a complete list of instruction-related feature flags. The CPUID feature flags that pertain to each instruction are also given in the instruction descriptions below. For information on using the CPUID instruction, see the instruction description in Volume 3.

Chapter 2, “Instruction Reference” contains detailed descriptions of each instruction, organized in alphabetic order by mnemonic. For those legacy SSE instructions that have an AVX form, the extended form of the instruction is described together with the legacy instruction in one entry. For these instructions, the instruction reference page is located based on the instruction mnemonic of the legacy SSE and not the extended (AVX) form. Those AVX instructions without a legacy form are listed in order by their AVX mnemonic. The mnemonic for all extended SSE instructions including the FMA and XOP instructions begin with the letter *V*.

1.1 Syntax and Notation

The descriptive synopsis of opcode syntax for legacy SSE instructions follows the conventions described in *Volume 3: General Purpose and System Instructions*. See Chapter 2 and the section entitled “Notation.”

For general information on the programming model and overview descriptions of the SSE instruction set, see:

- “Streaming SIMD Extensions Media and Scientific Programming” in Volume 1.
- “Instruction Encoding” in Volume 3
- “Summary of Registers and Data Types” in Volume 3.

The syntax of the extended instruction sets requires an expanded synopsis. The expanded synopsis includes a mnemonic summary and a summary of prefix sequence fields. Figure 1-1 shows the descriptive synopsis of a typical XOP instruction. The synopsis of VEX-encoded instructions have the same format, differing only in regard to the instruction encoding escape prefix, that is, VEX instead of XOP.

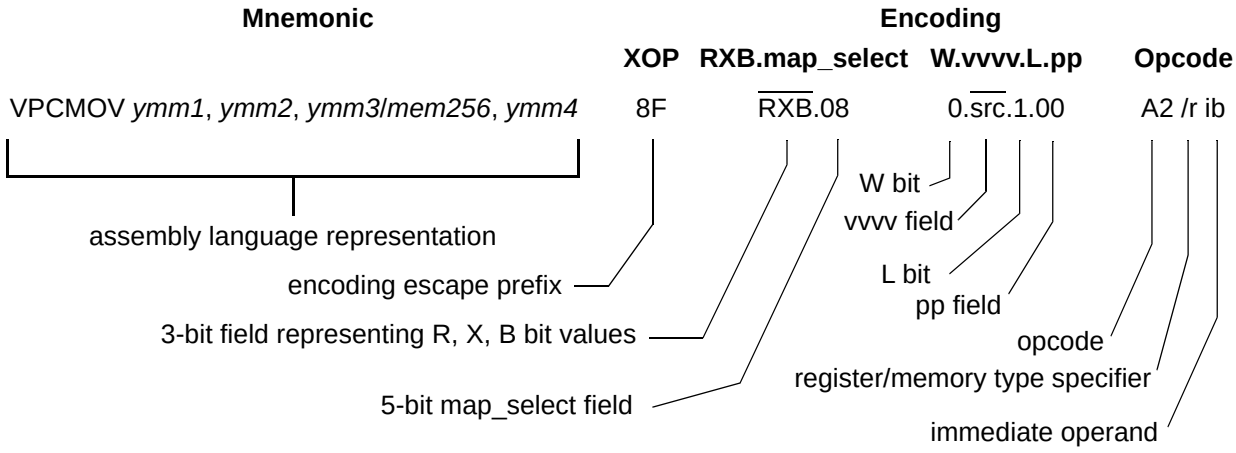

Figure 1-1. Typical Descriptive Synopsis - Extended SSE Instructions

1.2 Extended Instruction Encoding

The legacy SSE instructions are encoded using the legacy encoding syntax and the extended instructions are encoded using an enhanced encoding syntax which is compatible with the legacy syntax. Both are described in detail in Chapter 1 of Volume 3.

As described in Volume 3, the extended instruction encoding syntax utilizes multi-byte escape sequences to both select alternate opcode maps as well as augment the encoding of the instruction. Multi-byte escape sequences are introduced by one of the two VEX prefixes or the XOP prefix.

The AVX and AVX2 instructions utilize either the two-byte (introduced by the VEX C5h prefix) or the three-byte (introduced by the VEX C4h prefix) encoding escape sequence. XOP instructions are encoded using a three-byte encoding escape sequence introduced by the XOP prefix (except for the XOP instructions VPERMIL2PD and VPERMIL2PS which are encoded using the VEX prefix). The XOP prefix is 8Fh. The three-byte encoding escape sequences utilize the map_select field of the second byte to select the opcode map used to interpret the opcode byte.

The two-byte VEX prefix sequence implicitly selects the secondary (“two-byte”) opcode map.

1.2.1 Immediate Byte Usage Unique to the SSE instructions

An *immediate* is a value, typically an operand, explicitly provided within the instruction encoding. Depending on the opcode and the operating mode, the size of an immediate operand can be 1, 2, 4, or 8 bytes. Legacy and extended media instructions typically use an immediate byte operand (*imm8)*.

A one-byte immediate is generally shown in the instruction synopsis as “ib” suffix. For extended SSE instructions with four source operands, the suffix “is4” is used to indicate the presence of the immediate byte used to select the fourth source operand.

The VPERMIL2PD and VPERMIL2PS instructions utilize a fifth 2-bit operand which is encoded along with the fourth register select index in an immediate byte. For this special case the immediate byte will be shown in the instruction synopsis as “is5”.

1.2.2 Instruction Format Examples

The following sections provide examples of two-, three-, and four-operand extended instructions. These instructions generally perform *nondestructive-source operations*, meaning that the result of the operation is written to a separately specified destination register rather than overwriting one of the source operands. This preserves the contents of the source registers. Most legacy SSE instructions perform *destructive-source operations*, in which a single register is both source and destination, so source content is lost.

1.2.2.1 XMM Register Destinations

The following general properties apply to YMM/XMM register destination operands.

- For legacy instructions that use XMM registers as a destination: When a result is written to a destination XMM register, bits [255:128] of the corresponding YMM register are not affected.
- For extended instructions that use XMM registers as a destination: When a result is written to a destination XMM register, bits [255:128] of the corresponding YMM register are cleared.

1.2.2.2 Two Operand Instructions

Two-operand instructions use ModRM-based operand assignment. For most instructions, the first operand is the destination, selected by the ModRM.reg field, and the second operand is either a register or a memory source, selected by the ModRM.r/m field.

VCVTDQ2PD is an example of a two-operand AVX instruction.

Mnemonic	Encoding			
	VEX	RXB.map_select	W.vvvv.L.pp	Opcode
VCVTDQ2PD *xmm1*, *xmm2/mem64*	C4	$\overline{\text{RXB}}$.01	0.1111.0.10	E6 /r
VCVTDQ2PD *ymm1*, *xmm2/mem128*	C4	$\overline{\text{RXB}}$.01	0.1111.1.10	E6 /r

The destination register is selected by ModRM.reg. The size of the destination register is determined by VEX.L. The source is either a YMM/XMM register or a memory location specified by ModRM.r/m Because this instruction converts packed doubleword integers to double-precision floating-point values, the source data size is smaller than the destination data size.

VEX.vvvv is not used and must be set to 1111b.

1.2.2.3 Three-Operand Instructions

These extended instructions have two source operands and a destination operand.

VPROTB is an example of a three-operand XOP instruction.

There are versions of the instruction for variable-count rotation and for fixed-count rotation.

VPROTB *dest, src, variable-count*

VPROTB *dest, src, fixed-count*

Mnemonic	Encoding			
	XOP	RXB.map_select	W.vvvv.L.pp	Opcode
VPROTB *xmm1*, *xmm2/mem128, xmm3*	8F	$\overline{\text{RXB}}$.09	0.$\overline{src}$.0.00	90 /r
VPROTB *xmm1*, *xmm2, xmm3/mem128*	8F	$\overline{\text{RXB}}$.09	1.$\overline{src}$.0.00	90 /r
VPROTB *xmm1*, *xmm2/mem128*, *imm8*	8F	$\overline{\text{RXB}}$.08	0.1111.0.00	90 /r ib

For both versions of the instruction, the destination (*dest*) operand is an XMM register specified by ModRM.reg.

The variable-count version of the instruction rotates each byte of the source as specified by the corresponding byte element *variable-count*.

Selection of *src* and *variable-count* is controlled by XOP.W.

- When XOP.W = 0, *src* is either an XMM register or a 128-bit memory location specified by ModRM.r/m, and *variable-count* is an XMM register specified by XOP.vvvv.
- When XOP.W = 1, *src* is an XMM register specified by XOP.vvvv and *variable-count* is either an XMM register or a 128-bit memory location specified by ModRM.r/m.

Table 1-1 summarizes the effect of the XOP.W bit on operand selection.

Table 1-1. Three-Operand Selection

XOP.W	*dest*	*src*	*variable-count*
0	ModRM.reg	ModRM.r/m	XOP.vvvv
1	ModRM.reg	XOP.vvvv	ModRM.r/m

The fixed-count version of the instruction rotates each byte of *src* as specified by the immediate byte operand *fixed-count*. For this version, $\overline{src}$ is either an XMM register or a 128-bit memory location

specified by ModRM.r/m. Because XOP.vvvv is not used to specify the source register, it must be set to 1111b or execution of the instruction will cause an Invalid Opcode (#UD) exception.

1.2.2.4 Four-Operand Instructions

Some extended instructions have three source operands and a destination operand. This is accomplished by using the VEX/XOP.vvvv field, the ModRM.reg and ModRM.r/m fields, and bits [7:4] of an immediate byte to select the operands. The opcode suffix “is4” is used to identify the immediate byte, and the selected operands are shown in the synopsis.

VFMSUBPD is an example of an four-operand FMA4 instruction.

VFMSUBPD *dest, src1, src2, src3* *dest = src1* src2 - src3*

Mnemonic	Encoding			
	VEX	RXB.map_select	W.vvvv.L.pp	Opcode
VFMSUBPD *xmm1, xmm2, xmm3/mem128, xmm4*	C4	$\overline{\text{RXB}}$.03	0.$\overline{src}$.0.01	6D /r is4
VFMSUBPD *ymm1*, *ymm2*, *ymm3/mem256*, *ymm4*	C4	$\overline{\text{RXB}}$.03	0.$\overline{src}$.1.01	6D /r is4
VFMSUBPD *xmm1*, *xmm2, xmm3, xmm4/mem128*	C4	$\overline{\text{RXB}}$.03	1.$\overline{src}$.0.01	6D /r is4
VFMSUBPD *ymm1*, *ymm2, ymm3, ymm4/mem256*	C4	$\overline{\text{RXB}}$.03	1.$\overline{src}$.1.01	6D /r is4

The first operand, the destination (*dest*), is an XMM register or a YMM register (as determined by VEX.L) selected by ModRM.reg. The following three operands (*src1*, *src2*, *src3*) are sources.

The *src1* operand is an XMM or YMM register specified by VEX.vvvv.

VEX.W determines the configuration of the *src2* and *src3* operands.

- When VEX.W = 0, *src2* is either a register or a memory location specified by ModRM.r/m, and *src3* is a register specified by bits [7:4] of the immediate byte.
- When VEX.W = 1, *src2* is a register specified by bits [7:4] of the immediate byte and *src3* is either a register or a memory location specified by ModRM.r/m.

Table 1-1 summarizes the effect of the VEX.W bit on operand selection.

Table 1-2. Four-Operand Selection

VEX.W	*dest*	*src1*	*src2*	*src3*
0	ModRM.reg	VEX.vvvv	ModRM.r/m	is4[7:4]
1	ModRM.reg	VEX.vvvv	is4[7:4]	ModRM.r/m

1.3 VSIB Addressing

Specific AVX2 instructions utilize a vectorized form of indexed register-indirect addressing called vector SIB (VSIB) addressing. In contrast to the standard indexed register-indirect address mode, which generates a single effective address to access a single memory operand, VSIB addressing generates an array of effective addresses which is used to access data from multiple memory locations in a single operation.

VSIB addressing is encoded using three or six bytes following the opcode byte, augmented by the X and B bits from the VEX prefix. The first byte is the ModRM byte with the standard mod, reg, and r/m fields (although allowed values for the mod and r/m fields are restricted). The second is the VSIB byte which replaces the SIB byte in the encoding. The VSIB byte specifies a GPR which serves as a base address register and an XMM/YMM register that contains a packed array of index values. The two-bit scale field specifies a common scaling factor to be applied to all of the index values. A constant displacement value is encoded in the one or four bytes that follow the VSIB byte.

Figure 1-2 shows the format of the VSIB byte.

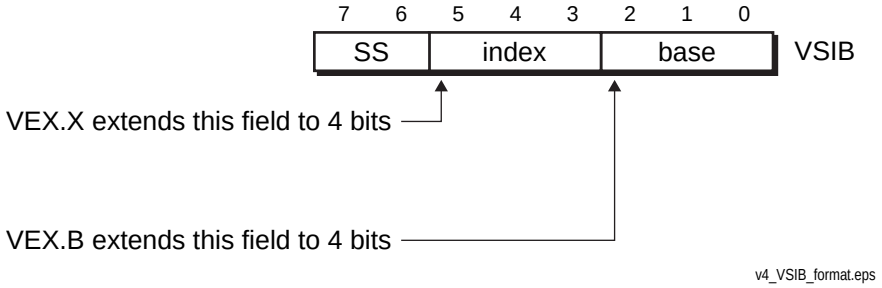

Figure 1-2. VSIB Byte Format

VSIB.SS (Bits [7:6]). The SS field is used to specify the scale factor to be used in the computation of each of the effective addresses. The scale factor *scale* is equal to 2^{SS} (two raised to power of the value of the SS field). Therefore, if SS = 00b, *scale* = 1; if SS = 01b, *scale* = 2; if SS = 10b, *scale* = 4; and if SS = 11b, *scale* = 8.

VSIB.index (Bits [5:3]). This field is concatenated with the complement of the VEX.X bit ({$\overline{X}$, index}) to specify the YMM/XMM register that contains the packed array of index values *index*[*i*] to be used in the computation of the array of effective addresses *effective address*[*i*].

VSIB.base (Bits [5:3]). This field is concatenated with the complement of the VEX.B bit ({$\overline{B}$, base}) to specify the general-purpose register (base GPR) that contains the base address *base* to be used in the computation of each of the effective addresses.

1.3.1 Effective Address Array Computation

Each element *i* of the effective address array is computed using the formula:

effective address[*i*] = *scale* * *index*[*i*] + *base* + *displacement*.

where *index*[*i*] is the *i*th element of the XMM/YMM register specified by {$\overline{X}$,VSIB.index}. An index element is either 32 or 64 bits wide and is treated as a signed integer.

Variants of this mode use either an eight-bit or a 32-bit displacement value. One variant sets the base to zero. The value of the ModRM.mod field specifies the specific variant of VSIB addressing mode, as shown in Table 1. In the table, the notation [XMM*n*/YMM*n*] indicates the XMM/YMM register that contains the packed index array and [base GPR] means the contents of the base GPR selected by {$\overline{B}$, base}.

Table 1: Vectorized Addressing Modes

Index[1]	ModRM.mod		
	00	01	10
0000	scale * [XMM0/YMM0] + Disp32	scale * [XMM0/YMM0] + Disp8 + [base GPR]	scale * [XMM0/YMM0] + Disp32 + [base GPR]
0001	scale * [XMM1/YMM1] + Disp32	scale * [XMM1/YMM1] + Disp8 + [base GPR]	scale * [XMM1/YMM1] + Disp32 + [base GPR]
0010	scale * [XMM2/YMM2] + Disp32	scale * [XMM2/YMM2] + Disp8 + [base GPR]	scale * [XMM2/YMM2] + Disp32 + [base GPR]
0011	scale * [XMM3/YMM3] + Disp32	scale * [XMM3/YMM3] + Disp8 + [base GPR]	scale * [XMM3/YMM3] + Disp32 + [base GPR]
0100	scale * [XMM4/YMM4] + Disp32	scale * [XMM4/YMM4] + Disp8 + [base GPR]	scale * [XMM4/YMM4] + Disp32 + [base GPR]
0101	scale * [XMM5/YMM5] + Disp32	scale * [XMM5/YMM5] + Disp8 + [base GPR]	scale * [XMM5/YMM5] + Disp32 + [base GPR]
0110	scale * [XMM6/YMM6] + Disp32	scale * [XMM6/YMM6] + Disp8 + [base GPR]	scale * [XMM6/YMM6] + Disp32 + [base GPR]
0111	scale * [XMM7/YMM7] + Disp32	scale * [XMM7/YMM7] + Disp8 + [base GPR]	scale * [XMM7/YMM7] + Disp32 + [base GPR]
1000	scale * [XMM8/YMM8] + Disp32	scale * [XMM8/YMM8] + Disp8 + [base GPR]	scale * [XMM8/YMM8] + Disp32 + [base GPR]
1001	scale * [XMM9/YMM9] + Disp32	scale * [XMM9/YMM9] + Disp8 + [base GPR]	scale * [XMM9/YMM9] + Disp32 + [base GPR]
1010	scale * [XMM10/YMM10] + Disp32	scale * [XMM10/YMM10] + Disp8 + [base GPR]	scale * [XMM10/YMM10] + Disp32 + [base GPR]
1011	scale * [XMM11/YMM11] + Disp32	scale * [XMM11/YMM11] + Disp8 + [base GPR]	scale * [XMM11/YMM11] + Disp32 + [base GPR]
1100	scale * [XMM12/YMM12] + Disp32	scale * [XMM12/YMM12] + Disp8 + [base GPR]	scale * [XMM12/YMM12] + Disp32 + [base GPR]
1101	scale * [XMM13/YMM13] + Disp32	scale * [XMM13/YMM13] + Disp8 + [base GPR]	scale * [XMM13/YMM13] + Disp32 + [base GPR]
1110	scale * [XMM14/YMM14] + Disp32	scale * [XMM14/YMM14] + Disp8 + [base GPR]	scale * [XMM14/YMM14] + Disp32 + [base GPR]
1111	scale * [XMM15/YMM15] + Disp32	scale * [XMM15/YMM15] + Disp8 + [base GPR]	scale * [XMM15/YMM15] + Disp32 + [base GPR]

Note *1. Index = {$\overline{VEX.X}$,VSIB.index}. In 32-bit mode, VEX.X = 1.*

1.3.2 Notational Conventions Related to VSIB Addressing Mode

In the instruction descriptions that follow, the notation vm32x indicates a packed array of four 32-bit index values contained in the specified XMM index register and vm32y indicates a packed array of eight 32-bit index values contained in the specified YMM index register. Depending on the instruction, these indices can be used to compute the effective address of up to four (vm32x) or eight (vm32y) memory-based operands.

The notation vm64x indicates a packed array of two 64-bit index values contained in the specified XMM index register and vm64y indicates a packed array of four 64-bit index values contained in the specified YMM index register. Depending on the instruction, these indices can be used to compute the effective address of up to two (vm64x) or four (vm64y) memory-based operands.

In body of the description of the instructions, the notation mem32[vm32x] is used to represent a sparse array of 32-bit memory operands where the packed array of four 32-bit indices used to calculate the effective addresses of the operands is held in an XMM register. The notation mem32[vm32y] refers to a similar array of 32-bit memory operands where the packed array of eight 32-bit indices is held in a YMM register. The notation mem32[vm64x] means a sparse array of 32-bit memory operands where the packed array of two 64-bit indices is held in an XMM register and mem32[vm64y] means a sparse array of 32-bit memory operands where the packed array of four 64-bit indices is held in a YMM register.

The notation mem64[*index_array*], where *index_array* is either vm32x, vm64x, or vm64y, specifies a sparse array of 64-bit memory operands addressed via a packed array of 32-bit or 64-bit indices held in an XMM/YMM register. If an instruction uses either an XMM or a YMM register, depending on operand size, to hold the index array, the notation vm32x/y or vm64x/y is used to represent the array.

In summary, given a maximum operand size of 256-bits, a sparse array of 32-bit memory-based operands can be addressed using a vm32x, vm32y, vm64x, or vm64y index array. A sparse array of 64-bit memory-based operands can be addressed using a vm32x, vm64x, or vm64y index array. Specific instructions may use fewer than the maximum number of memory operands that can be addressed using the specified index array.

VSIB addressing is only valid in 32-bit or 64-bit effective addressing mode and is only supported for instruction encodings using the VEX prefix. The ModRM.mod value of 11b is not valid in VSIB addressing mode and ModRM.r/m must be set to 100b.

1.3.3 Memory Ordering and Exception Behavior

VSIB addressing has some special considerations relative to memory ordering and the signaling of exceptions.

VSIB addressing specifies an array of addresses that allows an instruction to access multiple memory locations. The order in which data is read from or written to memory is not specified. Memory ordering with respect to other instructions follows the memory-ordering model described in Volume 2.

Data may be accessed by the instruction in any order, but access-triggered exceptions are delivered in right-to-left order. That is, if a exception is triggered by the load or store of an element of an XMM/YMM register and delivered, all elements to the right of that element (all the lower indexed elements) have been or will be completed without causing an exception. Elements to the left of the element causing the exception may or may not be completed. If the load or store of a given element triggers multiple exceptions, they are delivered in the conventional order.

Because data can be accessed in any order, elements to the left of the one that triggered the exception may be read or written before the exception is delivered. Although the ordering of accesses is not specified, it is repeatable in a specific processor implementation. Given the same input values and initial architectural state, the same set of elements to the left of the faulting one will be accessed.

VSIB addressing should not be used to access memory mapped I/O as the ordering of the individual loads is implementation-specific and some implementations may access data larger than the data element size or access elements more than once.

1.4 Enabling SSE Instruction Execution

Application software that utilizes the SSE instructions requires support from operating system software.

To enable and support SSE instruction execution, operating system software must:

- enable hardware for supported SSE subsets
- manage the SSE hardware architectural state, saving and restoring it as required during and after task switches
- provide exception handlers for all unmasked SSE exceptions.

See Volume 2, Chapter 11, for details on enabling SSE execution and managing its execution state.

1.5 String Compare Instructions

The legacy SSE instructions PCMPESTRI, PCMPESTRM, PCMPISTRI, and PCMPISTRM and the extended SSE instructions VPCMPESTRI, VPCMPESTRM, VPCMPISTRI, and VPCMPISTRM provide a versatile means of classifying characters of a string by performing one of several different types of comparison operations using a second string as a prototype.

This section describes the operation of the legacy string compare instructions. This discussion applies equally to the extended versions of the instructions. Any difference between the legacy and the extended version of a given instruction is described in the instruction reference entry for the instruction in the following chapter.

A character string is a vector of data elements that is normally used to represent an ordered arrangement of graphemes which may be stored, processed, displayed, or printed. Ordered strings of graphemes are most often used to convey information in a human-readable manner. The string compare instructions, however, do not restrict the use or interpretation of their operands.

The first source operand provides the prototype string and the second operand is the string to be scanned and characterized (referred to herein as the string under test, or SUT). Four string formats and four types of comparisons are supported. The intermediate result of this processing is a bit vector that summarizes the characterization of each character in the SUT. This bit vector is then post-processed based on options specified in the instruction encoding. Instruction variants determine the final result—either an index or a mask.

Instruction execution affects the arithmetic status flags (ZF, CF, SF, OF, AF, PF), but the significance of many of the flags is redefined to provide information tailored to the result of the comparison performed. See Section 1.5.6, “Affect on Flags” on page 19.

The instructions have a defined base function and additional functionality controlled by bit fields in an immediate byte operand (*imm8*). The base function determines whether the source strings have implicitly (PCMPISTRI and PCMPISTRM) or explicitly (PCMPESTRI and PCMPESTRM) defined lengths, and whether the result is an index (PCMPISTRI and PCMPESTRI) or a mask (PCMPISTRM and PCMPESTRM).

PCMPISTRI and PCMPESTRI return their final result (an integer value) via the ECX register, while PCMPISTRM and PCMPESTRM write a bit or character mask, depending on the option selected, to the XMM0 register.

There are a number of different schemes for encoding a set of graphemes, but the most common ones use either an 8-bit code (ASCII) or a 16-bit code (unicode). The string compare instructions support both character sizes.

Bit fields of the immediate operand control the following functions:

- Source data format — character size (byte or word), signed or unsigned values
- Comparison type
- Intermediate result postprocessing
- Output option selection

This overview description covers functions common to all of the string compare instructions and describes some of the differentiated features of specific instructions. Information on instruction encoding and exception behavior are covered in the individual instruction reference pages in the following chapter.

1.5.1 Source Data Format

The character strings that constitute the source operands for the string compare instructions are formatted as either 8-bit or 16-bit integer values packed into a 128-bit data type. The figure below illustrates how a string of byte-wide characters is laid out in memory and how these characters are arranged when loaded into an XMM register.

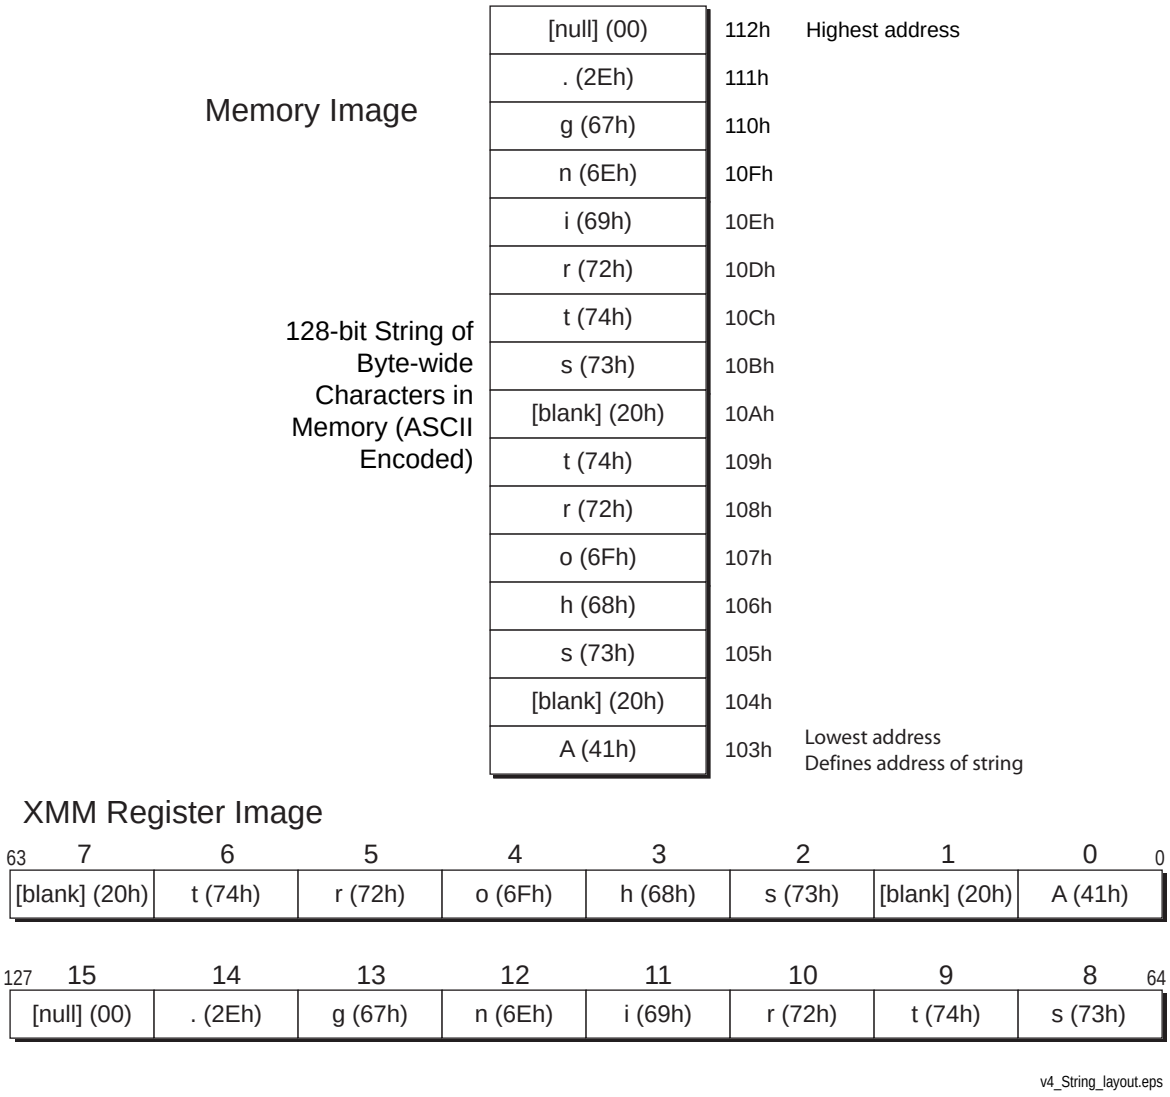

Figure 1-3. Byte-wide Character String – Memory and Register Image

Note from the figure that the longest string that can be packed in a 128-bit data object is either sixteen 8-bit characters (as illustrated) or eight 16-bit characters. When loaded from memory, the character read from the lowest address in memory is placed in the least-significant position of the register and the character read from the highest address is placed in the most-significant position. In other words, for character *i* of width *w*, bits [*w*−1:0] of the character are placed in bits [*iw* + (*w*−1):*iw*] of the register.

Bits [1:0] of the immediate byte operand specify the source string data format, as shown in Table 1-3.

Table 1-3. Source Data Format

Imm8[1:0]	Character Format	Maximum String Length
00b	unsigned bytes	16
01b	unsigned words	8
10b	signed bytes	16
11b	signed words	8

The string compare instructions are defined with the capability of operating on strings of lengths from 0 to the maximum that can be packed into the 128-bit data type as shown in the table above. Because strings being processed may be shorter than the maximum string length, a means is provided to designate the length of each string. As mentioned above, one pair of string compare instructions relies on an explicit method while the other utilizes an implicit method.

For the explicit method, the length of the first operand (the prototype string) is specified by the absolute value of the signed integer contained in rAX and the length of the second operand (the SUT) is specified by the absolute value of the signed integer contained in rDX. If a specified length is greater than the maximum allowed, the maximum value is used. Using the explicit method of length specification, null characters (characters whose numerical value is 0) can be included within a string.

Using the implicit method, a string shorter than the maximum length is terminated by a null character. If no null character is found in the string, its length is implied to be the maximum. For the example illustrated in Figure 1-3 above, the implicit length of the string is 15 because the final character is null. However, using the explicit method, a specified length of 16 would include the null character in the string.

In the following discussion, l_1 is the length of the first operand string (the prototype string), l_2 is the length of the second operand string (the SUT) and m is the maximum string length based on the selected character size.

1.5.2 Comparison Type

Although the string compare instructions can be implemented in many different ways, the instructions are most easily understood as the sequential processing of the SUT using the characters of the prototype string as a template. The template is applied at each character index of SUT, processing the string from the first character (index 0) to the last character (index l_2-1).

The result of each comparison is recorded in successive positions of a summary bit vector *CmprSumm*. When the sequence of comparisons is complete, this bit vector summarizes the results of comparison operations that were performed. The length of the *CmprSumm* bit vector is equal to the maximum input operand string length (*m)*. The rules for the setting of *CmprSumm* bits beyond the end of the SUT (*CmprSumm*[$m-1:l_2$]) are dependent on the comparison type (see Table 1-4 below.)

Bits [3:2] of the immediate byte operand determine the comparison type, as shown in Table 1-4.

Table 1-4. Comparison Type

Imm8[3:2]	Comparison Type	Description
00b	Subset	Tests each character of the SUT to determine if it is within the subset of characters specified by the prototype string. Each set bit of *CmprSumm* indicates that the corresponding character of the SUT is within the subset specified by the prototype. Bits [$m-1:l_2$] are cleared.
01b	Ranges	Tests each character of the SUT to determine if it lies within one or more ranges specified by pairs of values within the prototype string. The ranges are inclusive. Each set bit in *CmprSumm* indicates that the corresponding character of the SUT is within one or more of the inclusive ranges specified. Bits [$m-1:l_2$] are cleared. If the length of the prototype is odd, the last value in the prototype is effectively ignored.
10b	Match	Performs a character-by-character comparison between the SUT and the prototype string. Each set bit of *CmprSumm* indicates that the corresponding characters in the two strings match. If not, the bit is cleared. Bits [$m-1:\max(l_1, l_2)$] of *CmprSumm* are set.
11b	Sub-string	Searches for an exact match between the prototype string and an ordered sequence of characters (a sub-string) in the SUT beginning at the current index *i*. Bit *i* of *CmprSumm* is set for each value of *i* where the sub-string match is made, otherwise the bit is cleared. See discussion below.

In the Sub-string comparison type, any matching sub-string of the SUT must match the prototype string one-for-one, in order, and without gaps. Null characters in the SUT do not match non-null characters in the prototype. If the prototype and the SUT are equal in length and less than the max length, the two strings must be identical for the comparison to be TRUE. In this case, bit 0 of *CmprSumm* is set to one and the remainder are all 0s. If the length of the SUT is less than the prototype string, no match is possible and *CmprSumm* is all 0s.

If the prototype string is shorter than the SUT ($l_1 < l_2$), a sequential search of the SUT is performed. For each *i* from 0 to $l_2 - l_1$, the prototype is compared to characters [$i + l_1 - 1:i$] of the SUT. If the prototype and the sub-string SUT[$i + l_1 - 1:i$] match exactly, then *CmprSumm*[*i*] is set, otherwise the bit is cleared. When the comparison at $i = l_2 - l_1$ is complete, no further testing is required because there are not enough characters remaining in the SUT for a match to be possible. The remaining bits $l_2 - l_1 + 1$ through *m-1* are all set to 0.

For the Match comparison type, the character-by-character comparison is performed on all *m* characters in the 128-bit operand data, which may extend beyond the end of one or both strings. A null character at index *i* within one string is not considered a match when compared with a character beyond the end of the other string. In this case, *CmprSumm*[*i*] is cleared. For index positions beyond the end of both strings, *CmprSumm*[*i*] is set.

The following section provides more detail on the generation of the comparison summary bit vector based on the specified comparison type.

1.5.3 Comparison Summary Bit Vector

The following pseudo code provides more detail on the generation of the comparison summary bit vector *CmprSumm*. The function `CompareStrgs` defined below returns a bit vector of length *m*, the maximum length of the operand data strings.

```
bit vector CompareStrgs(ProtoType, length1, SUT, length2, CmpType, signed, m)
   doubleword vector StrUndTst   // temp vector; holds string under test
   doubleword vector StrProto    // temp vector; holds prototype string
   bit vector[m] Result          // length of vector is m

   StrProto = m{0}         //initialize m elements of StrProto to 0
   StrUndTst = m{0}        //initialize m elements of StrUndTst to 0
   Result = m{0}           //initialize result bit vector

   FOR i = 0 to length1
      StrProto[i] = signed ? SignExtend(ProtoType[i]) : ZeroExtend(ProtoType[i])
   FOR i = 0 to length2
      StrUndTst[i] = signed ? SignExtend(SUT[i]) : ZeroExtend(SUT[i])

   IF CmpType == Subset
      FOR j = 0 to length2 - 1            // j indexes SUT
         FOR i = 0 to length1 - 1         // i indexes prototype
            Result[j] |= (StrProto[i] == StrUndTst[j])

   IF CmpType == Ranges
      FOR j = 0 to length2 - 1                    // j indexes SUT
         FOR i = 0 to length1 - 2, BY 2           // i indexes prototype
            Result[j] |= (StrProto[i] <= StrUndTst[j])
                        && (StrProto[i+1] >= StrUndTst[j])

   IF CmpType == Match
      FOR i = 0 to (min(length1, length2)-1)
         Result[i] = (StrProto[i] == StrUndTst[i])
      FOR i = min(length1, length2) to (max(length1, length2)-1)
         Result[i] = 0
      FOR i = max(length1, length2) to (m-1)
         Result[i] = 1

   IF CmpType == Sub-string
      IF (length2==16)&& (length1==16)
         maxlength=15
      else
          maxlength = length2-length1
   IF length2 >= lenght1
    FOR j = 0 to maxlength             // j indexes result bit vector
         Result[j] = 1
         k = j                         // k scans the SUT
         FOR i = 0 to length1 - 1      // i scans the Prototype
            Result[j] &= (StrProto[i] == StrUndTst[k])// Result[j] is cleared if
any of the comparisons do not match
            k++

Return Result
```

Given the above definition of `CompareStrgs()`, the following pseudo code computes the value of *CmprSumm*:

```
ProtoType = contents of first source operand (xmm1)
SUT = contents of xmm2 or 128-bit value read from the specified memory location
length1 = length of first operand string     //specified implicitly or explicitly
length2 = length of second operand string    //specified implicitly or explicitly
m = Maximum String Length from Table 1-3 above
CmpType = Comparison Type from Table 1-4 above
signed = (imm8[1] == 1) ? TRUE : FALSE
bit vector [m] CmprSumm    // CmprSumm is m bits long

CmprSumm = CompareStrgs(ProtoType, length1, SUT, length2, CmpType, signed, m)
```

The following examples demonstrate the comparison summary bit vector *CmprSumm* for each comparison type. For the sake of illustration, the operand strings are represented as ASCII-encoded strings. Each character value is represented by its ASCII grapheme. Strings are displayed with the lowest indexed character on the left as they would appear when printed or displayed. *CmprSumm* is shown in reverse order with the least significant bit on the left to agree with the string presentation.

Comparison Type = Subset

```
Prototype:  ZCx
SUT:        aCx%xbZreCx
CmprSumm:   0110101001100000
```

Comparison Type = Ranges

```
Prototype:  ACax
SUT:        aCx%xbZreCx
CmprSumm:   1110110111100000
```

Comparison Type = Match

```
Prototype:  ZCx
SUT:        aCx%xbZreCx
CmprSumm:   0110000000011111
```

Comparison Type = Sub-string

```
Prototype:  ZCx
SUT:        aZCx%xCZreZCxCZ
CmprSumm:   0100000000100000
```

1.5.4 Intermediate Result Post-processing

Post-processing of the *CmprSumm* bit vector is controlled by *imm8*[5:4]. The result of this step is designated *pCmprSumm*.

Bit [4] of the immediate operand determines whether a ones' complement (bit-wise inversion) is performed on *CmprSumm*; bit [5] of the immediate operand determines whether the inversion applies to the entire comparison summary bit vector (*CmprSumm*) or just to those bits that correspond to characters within the SUT. See Table 1-5 below for the encoding of the *imm8*[5:4] field.

Table 1-5. Post-processing Options

Imm8[5:4]	Post-processing Applied
x0b	pCmprSumm = CmprSumm
01b	pCmprSumm = NOT CmprSumm
11b	pCmprSumm[*i*] = **!**CmprSumm[*i*] for $i < I_2$, pCmprSumm[*i*] = CmprSumm[*i*], for $I_2 \leq i < m$

1.5.5 Output Option Selection

For PCMPESTRI and PCMPISTRI, *imm8*[6] determines whether the index of the lowest set bit or the highest set bit of *pCmprSumm* is written to ECX, as shown in Table 1-6.

Table 1-6. Indexed Output Option Selection

Imm8[6]	Description
0b	Return the index of the least significant set bit in pCmprSumm.
1b	Return the index of the most significant set bit in pCmprSumm.

For PCMPESTRM and PCMPISTRM, *imm8*[6] specifies whether the output from the instruction is a bit mask or an expanded mask. The bit mask is a copy of *pCmprSumm* zero-extended to 128 bits. The expanded mask is a packed vector of byte or word elements, as determined by the string operand format (as indicated by *imm8*[0]). The expanded mask is generated by copying each bit of *pCmprSumm* to all bits of the element of the same index. Table 1-7 below shows the encoding of *imm8*[6].

Table 1-7. Masked Output Option Selection

Imm8[6]	Description
0b	Return pCmprSumm as the output with zero extension to 128 bits.
1b	Return expanded pCmprSumm byte or word mask.

The PCMPESTRM and PCMPISTRM instructions return their output in register XMM0. For the extended forms of the instructions, bits [127:64] of YMM0 are cleared.

1.5.6 Affect on Flags

The execution of a string compare instruction updates the state of the CF, PF, AF, ZF, SF, and OF flags within the rFLAGs register. All other flags are unaffected. The PF and AF flags are always cleared. The ZF and SF flags are set or cleared based on attributes of the source strings and the CF and OF flags are set or cleared based on attributes of the summary bit vector after post processing.

The CF flag is cleared if the summary bit vector, after post processing, is zero; the flag is set if one or more of the bits in the post-processed bit vector are 1. The OF flag is updated to match the value of the least significant bit of the post-processed summary bit vector.

The ZF flag is set if the length of the second string operand (SUT) is shorter than *m*, the maximum number of 8-bit or 16-bit characters that can be packed into 128 bits. Similarly, the SF flag is set if the length of the first string operand (prototype) is shorter than *m*.

This information is summarized in Table 1-8 below.

Table 1-8. State of Affected Flags After Execution

Unconditional		Source String Length		Post-processed Bit Vector	
PF	**AF**	**SF**	**ZF**	**CF**	**OF**
0	0	($l_1 < m$)	($l_2 < m$)	pCmprSumm ≠ 0	pCmprSumm [0]

2 Instruction Reference

Instructions are listed by mnemonic, in alphabetic order. Each entry describes instruction function, syntax, opcodes, affected flags and exceptions related to the instruction.

Figure 2-1 shows the conventions used in the descriptions. Items that do not pertain to a particular instruction, such as a synopsis of the 256-bit form, may be omitted.

INST **Instruction**
VINST **Mnemonic Expansion**

Brief functional description

INST

Description of legacy version of instruction.

VINST

Description of extended version of instruction.

XMM Encoding

Description of 128-bit extended instruction.

YMM Encoding

Description of 256-bit extended instruction.

Information about CPUID functions related to the instruction set.

Synopsis diagrams for legacy and extended versions of the instruction.

Mnemonic	Opcode	Description
INST *xmm1*, *xmm2*/*mem128*	FF FF /r	Brief summary of legacy operation.

Mnemonic	Encoding			
	VEX	RXB.mmmmm	W.vvvv.L.pp	Opcode
VINST *xmm1*, *xmm2*/*mem128, xmm3*	C4	$\overline{RXB}$.11	0.$\overline{src}$.0.00	FF */r*
VINST *ymm1*, *ymm2*/*mem256, ymm3*	C4	$\overline{RXB}$.11	0.$\overline{src}$.0.00	FF */r*

Exceptions

Exception summary table.

Figure 2-1. Typical Instruction Description

Instruction Exceptions

Under various conditions instructions described below can cause exceptions. The conditions that cause these exceptions can differ based on processor mode and instruction subset. This information is summarized at the end of each instruction reference page in an Exception Table. Rows list the applicable exceptions and the different conditions that trigger each exception for the instruction. For each processor mode (real, virtual, and protected) a symbol in the table indicates whether this exception condition applies.

Each AVX instruction has a legacy form that comes from one of the legacy (SSE1, SSE2, ...) subsets. An “X” at the intersection of a processor mode column and an exception cause row indicates that the causing condition and potential exception applies to both the AVX instruction and the legacy SSE instruction. “A” indicates that the causing condition applies only to the AVX instruction and “S” indicates that the condition applies to the SSE legacy instruction.

Note that XOP and FMA4 instructions do not have corresponding instructions from the SSE legacy subsets. In the exception tables for these instructions, “X” represents the XOP instruction and “F” represents the FMA4 instruction.

ADDPD Add
VADDPD Packed Double-Precision Floating-Point

Adds each packed double-precision floating-point value of the first source operand to the corresponding value of the second source operand and writes the result of each addition into the corresponding quadword of the destination.

There are legacy and extended forms of the instruction:

ADDPD

Adds two pairs of values.

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The first source register is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VADDPD

The extended form of the instruction has both 128-bit and 256-bit encodings:

XMM Encoding

Adds two pairs of values.

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

Adds four pairs of values.

The first source operand is a YMM register and the second source operand is either a YMM register or a 256-bit memory location. The destination is a third YMM register.

Instruction Support

Form	Subset	Feature Flag
ADDPD	SSE2	CPUID Fn0000_0001_EDX[SSE2] (bit 26)
VADDPD	AVX	CPUID Fn0000_0001_ECX[AVX] (bit 28)

For more on using the CPUID instruction to obtain processor feature support information, see Appendix E of Volume 3.

Instruction Encoding

Mnemonic	Opcode	Description
ADDPD *xmm1, xmm2/mem128*	66 0F 58 /r	Adds two packed double-precision floating-point values in *xmm1* to corresponding values in *xmm2* or *mem128*. Writes results to *xmm1*.

Mnemonic	Encoding

A — AVX exception
S — SSE exception

ADDPS Add
VADDPS Packed Single-Precision Floating-Point

Adds each packed single-precision floating-point value of the first source operand to the corresponding value of the second source operand and writes the result of each addition into the corresponding elements of the destination.

There are legacy and extended forms of the instruction:

ADDPS

Adds four pairs of values.

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The first source register is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VADDPS

The extended form of the instruction has both 128-bit and 256-bit encodings:

XMM Encoding

Adds four pairs of values.

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

Adds eight pairs of values.

The first source operand is a YMM register and the second source operand is either a YMM register or a 256-bit memory location. The destination is a third YMM register.

Instruction Support

ADDSD Add
VADDSD Scalar Double-Precision Floating-Point

Adds the double-precision floating-point value in the low-order quadword of the first source operand to the corresponding value in the low-order quadword of the second source operand and writes the result into the low-order quadword of the destination.

There are legacy and extended forms of the instruction:

ADDSD

The first source operand is an XMM register and the second source operand is either an XMM register or a 64-bit memory location. The first source register is also the destination register. Bits [127:64] of the destination and bits [255:128] of the corresponding YMM register are not affected.

VADDSD

The extended form of the instruction has a 128-bit encoding only.

The first source operand is an XMM register and the second source operand is either an XMM register or a 64-bit memory location. The destination is a third XMM register. Bits [127:64] of the first source operand are copied to bits [127:64] of the destination. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

Instruction Support

Form	Subset	Feature Flag
ADDSD	SSE2	CPUID Fn0000_0001_EDX[SSE2] (bit 26)
VADDSD	AVX	CPUID Fn0000_0001_ECX[AVX] (bit 28)

Invalid operation, IE	S	S	X	A source operand was an SNaN value.
	S	S	X	Undefined operation.
Denormalized operand, DE	S	S	X	A source operand was a denormal value.
Overflow, OE	S	S	X	Rounded result too large to fit into the format of the destination operand.
Underflow, UE	S	S	X	Rounded result too small to fit into the format of the destination operand.
Precision, PE	S	S	X	A result could not be represented exactly in the destination format.

X — AVX and SSE exception
A — AVX exception
S — SSE exception

ADDSS Add
VADDSS Scalar Single-Precision Floating-Point

Adds the single-precision floating-point value in the low-order doubleword of the first source operand to the corresponding value in the low-order doubleword of the second source operand and writes the result into the low-order doubleword of the destination.

There are legacy and extended forms of the instruction:

ADDSS

The first source operand is an XMM register and the second source operand is either an XMM register or a 32-bit memory location. The first source register is also the destination. Bits [127:32] of the destination register and bits [255:128] of the corresponding YMM register are not affected.

VADDSS

The extended form of the instruction has a 128-bit encoding only.

The first source operand is an XMM register and the second source operand is either an XMM register or a 32-bit memory location. The destination is a third XMM register. Bits [127:32] of the first source register are copied to bits [127:32] of the of the destination. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

Instruction Support

Form	Subset	Feature Flag
ADDSS	SSE1	CPUID Fn0000_0001_EDX[SSE] (bit 25)
VADDSS	AVX	CPUID Fn0000_0001_ECX[AVX] (bit 28)

For more on using the CPUID instruction to obtain processor feature support information, see Appendix E of Volume 3.

Instruction Encoding

AESDEC AES
VAESDEC Decryption Round

Performs a single round of AES decryption. Transforms a state value specified by the first source operand using a round key value specified by the second source operand, and writes the result to the destination.

See Appendix A on page 975 for more information about the operation of the AES instructions.

Decryption consists of 1, …, $N_r - 1$ iterations of sequences of operations called rounds, terminated by a unique final round, N_r. The AESDEC and VAESDEC instructions perform all the rounds except the last; the AESDECLAST and VAESDECLAST instructions perform the final round.

The 128-bit state and round key vectors are interpreted as 16-byte column-major entries in a 4-by-4 matrix of bytes.The transformed state is written to the destination in column-major order. For both instructions, the destination register is the same as the first source register.

There are legacy and extended forms of the instruction:

AESDEC

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The first source register is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VAESDEC

The extended form of the instruction has both 128-bit and 256-bit encodings:

XMM encoding

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM encoding

The first source operand is a YMM register and the second source operand is either a YMM register or a 256-bit memory location. The destination is a third YMM register.

Instruction Support

AESENC AES
VAESENC Encryption Round

Performs a single round of AES encryption. Transforms a state value specified by the first source operand using a round key value specified by the second source operand, and writes the result to the destination.

See Appendix A on page 975 for more information about the operation of the AES instructions.

Encryption consists of 1, …, $N_r - 1$ iterations of sequences of operations called rounds, terminated by a unique final round, N_r. The AESENC and VAESENC instructions perform all the rounds before the final round; the AESENCLAST and VAESENCLAST instructions perform the final round.

The 128-bit state and round key vectors are interpreted as 16-byte column-major entries in a 4-by-4 matrix of bytes.The transformed state is written to the destination in column-major order. For both instructions, the destination register is the same as the first source register

There are legacy and extended forms of the instruction:

AESENC

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The first source register is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VAESENC

The extended form of the instruction has both 128-bit and 256-bit encodings:

XMM

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM

The first source operand is a YMM register and the second source operand is either a YMM register or a 256-bit memory location. The destination is a third YMM register.

AESENCLAST AES
VAESENCLAST Last Encryption Round

Performs the final round of AES encryption. Completes transformation of a state value specified by the first source operand using a round key value specified by the second source operand, and writes the result to the destination.

See Appendix A on page 975 for more information about the operation of the AES instructions.

Encryption consists of 1, …, $N_r - 1$ iterations of sequences of operations called rounds, terminated by a unique final round, N_r. The AESENC and VAESENC instructions perform all the rounds before the final round; the AESENCLAST and VAESENCLAST instructions perform the final round.

The 128-bit state and round key vectors are interpreted as 16-byte column-major entries in a 4-by-4 matrix of bytes.The transformed state is written to the destination in column-major order. For both instructions, the destination register is the same as the first source register.

There are legacy and extended forms of the instruction:

AESENCLAST

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The first source register is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VAESENCLAST

The extended form of the instruction has both 128-bit and 256-bit encodings:

XMM

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM

The first source operand is a YMM register and the second source operand is either a YMM register or a 256-bit memory location. The destination is a third YMM register.

Instruction Support

Form	Subset	Feature Flag
AESENCLAST	AES	CPUID Fn0000_0001_ECX[AES] (bit 25)
VAESENCLAST 128	AVX	CPUID Fn0000_0001_ECX[AVX] (bit 28)
VAESENCLAST 256	VAES	CPUID Fn0000_0007_ECX[VAES]_x0 (bit 9)

For more on using the CPUID instruction to obtain processor feature support information, see Appendix E of Volume 3.

Instruction Encoding

Mnemonic	Opcode	Description
AESENCLAST *xmm1*, *xmm2/mem128*	66 0F 38 DD /r	Performs the last encryption round on a state value in *xmm1* using the key value in *xmm2* or *mem128*. Writes results to *xmm1*.

AESIMC AES
VAESIMC InvMixColumn Transformation

Applies the AES *InvMixColumns*( ) transformation to expanded round keys in preparation for decryption. Transforms an expanded key specified by the second source operand and writes the result to a destination register.

See Appendix A on page 975 for more information about the operation of the AES instructions.

The 128-bit round key vector is interpreted as 16-byte column-major entries in a 4-by-4 matrix of bytes.The transformed result is written to the destination in column-major order.

AESIMC and VAESIMC are not used to transform the first and last round key in a decryption sequence.

There are legacy and extended forms of the instruction:

AESIMC

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The first source register is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VAESIMC

The extended form of the instruction has a 128-bit encoding only.

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

Instruction Support

Form	Subset	Feature Flag
AESIMC	AES	CPUID Fn0000_0001_ECX[AES] (bit 25)
VAESIMC	AVX	CPUID Fn0000_0001_ECX[AVX] (bit 28)

For more on using the CPUID instruction to obtain processor feature support information, see Appendix E of Volume 3.

Instruction Encoding

Mnemonic	Opcode	Description

AESKEYGENASSIST VAESKEYGENASSIST AES Assist Round Key Generation

Expands a round key for encryption. Transforms a 128-bit round key operand using an 8-bit round constant and writes the result to a destination register.

See Appendix A on page 975 for more information about the operation of the AES instructions.

The round key is provided by the second source operand and the round constant is specified by an immediate operand. The 128-bit round key vector is interpreted as 16-byte column-major entries in a 4-by-4 matrix of bytes. The transformed result is written to the destination in column-major order.

There are legacy and extended forms of the instruction:

AESKEYGENASSIST

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The first source register is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VAESKEYGENASSIST

The extended form of the instruction has a 128-bit encoding only.

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

BLENDPD Blend
VBLENDPD Packed Double-Precision Floating-Point

Copies packed double-precision floating-point values from either of two sources to a destination, as specified by an 8-bit mask operand.

Each mask bit specifies a 64-bit element in a source location and a corresponding 64-bit element in the destination register. When a mask bit = 0, the specified element of the first source is copied to the corresponding position in the destination register. When a mask bit = 1, the specified element of the second source is copied to the corresponding position in the destination register.

There are legacy and extended forms of the instruction:

BLENDPD

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The first source register is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected. Only mask bits [1:0] are used.

VBLENDPD

The extended form of the instruction has both 128-bit and 256-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared. Only mask bits [1:0] are used.

YMM Encoding

The first source operand is a YMM register and the second source operand is either a YMM register or a 256-bit memory location. The destination is a third YMM register. Only mask bits [3:0] are used.

Instruction Support

CMPPD Compare
VCMPPD Packed Double-Precision Floating-Point

Compares each of the two packed double-precision floating-point values of the first source operand to the corresponding values of the second source operand and writes the result of each comparison to the corresponding 64-bit element of the destination. When a comparison is TRUE, all 64 bits of the destination element are set; when a comparison is FALSE, all 64 bits of the destination element are cleared. The type of comparison is specified by an immediate byte operand.

Signed comparisons return TRUE only when both operands are valid numbers and the numbers have the relation specified by the type of comparison operation. Ordered comparison returns TRUE when both operands are valid numbers, or FALSE when either operand is a NaN. Unordered comparison returns TRUE only when one or both operands are NaN and FALSE otherwise.

QNaN operands generate an Invalid Operation Exception (IE) only if the comparison type isn't Equal, Unequal, Ordered, or Unordered. SNaN operands always generate an IE.

There are legacy and extended forms of the instruction:

CMPPD

The first source operand is an XMM register and the second source operand is either an XMM register or a128-bit memory location.The first source register is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected. Comparison type is specified by bits [2:0] of an immediate byte operand.

VCMPPD

The extended form of the instruction has both 128-bit and 256-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared. Comparison type is specified by bits [4:0] of an immediate byte operand.

YMM Encoding

The first source operand is a YMM register and the second source operand is either a YMM register or a 256-bit memory location. The destination operand is a YMM register. Comparison type is specified by bits [4:0] of an immediate byte operand.

Immediate Operand Encoding

CMPPD uses bits [2:0] of the 8-bit immediate operand and VCMPPD uses bits [4:0] of the 8-bit immediate operand. Although VCMPPD supports 20h encoding values, the comparison types echo those of CMPPD on 4-bit boundaries. The following table shows the immediate operand value for CMPPD and each of the VCMPPD echoes.

Some comparison operations that are not directly supported by immediate-byte encodings can be implemented by swapping the contents of the source and destination operands and executing the appropriate comparison of the swapped values. These additional comparison operations are shown with the directly supported comparison operations.

Immediate Operand Value	Compare Operation	Result If NaN Operand	QNaN Operand Causes Invalid Operation Exception
00h, 08h, 10h, 18h	Equal	FALSE	No
01h, 09h, 11h, 19h	Less than	FALSE	Yes
	Greater than (swapped operands)	FALSE	Yes
02h, 0Ah, 12h, 1Ah	Less than or equal	FALSE	Yes
	Greater than or equal (swapped operands)	FALSE	Yes
03h, 0Bh, 13h, 1Bh	Unordered	TRUE	No
04h, 0Ch, 14h, 1Ch	Not equal	TRUE	No
05h, 0Dh, 15h, 1Dh	Not less than	TRUE	Yes
	Not greater than (swapped operands)	TRUE	Yes
06h, 0Eh, 16h, 1Eh	Not less than or equal	TRUE	Yes
	Not greater than or equal (swapped operands)	TRUE	Yes
07h, 0Fh, 17h, 1Fh	Ordered	FALSE	No

The following alias mnemonics for (V)CMPPD with appropriate value of *imm8* are supported.

Mnemonic	Implied Value of *imm8*

X — AVX and SSE exception *A — AVX exception* *S — SSE exception*				

CMPPS Compare
VCMPPS Packed Single-Precision Floating-Point

Compares each of the four packed single-precision floating-point values of the first source operand to the corresponding values of the second source operand and writes the result of each comparison to the corresponding 32-bit element of the destination. When a comparison is TRUE, all 32 bits of the destination element are set; when a comparison is FALSE, all 32 bits of the destination element are cleared. The type of comparison is specified by an immediate byte operand.

Signed comparisons return TRUE only when both operands are valid numbers and the numbers have the relation specified by the type of comparison operation. Ordered comparison returns TRUE when both operands are valid numbers, or FALSE when either operand is a NaN. Unordered comparison returns TRUE only when one or both operands are NaN and FALSE otherwise.

QNaN operands generate an Invalid Operation Exception (IE) only if the comparison type isn't Equal, Unequal, Ordered, or Unordered. SNaN operands always generate an IE.

There are legacy and extended forms of the instruction:

CMPPS

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The first source register is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected. Comparison type is specified by bits [2:0] of an immediate byte operand.

VCMPPS

The extended form of the instruction has both 128-bit and 256-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared. Comparison type is specified by bits [4:0] of an immediate byte operand.

YMM Encoding

The first source operand is a YMM register and the second source operand is either a YMM register or a 256-bit memory location. The destination operand is a YMM register. Comparison type is specified by bits [4:0] of an immediate byte operand.

Immediate Operand Encoding

CMPPS uses bits [2:0] of the 8-bit immediate operand and VCMPPS uses bits [4:0] of the 8-bit immediate operand. Although VCMPPS supports 20h encoding values, the comparison types echo those of CMPPS on 4-bit boundaries. The following table shows the immediate operand value for CMPPS and each of the VCMPPDS echoes.

Some comparison operations that are not directly supported by immediate-byte encodings can be implemented by swapping the contents of the source and destination operands and executing the appropriate comparison of the swapped values. These additional comparison operations are shown in with the directly supported comparison operations.

Immediate Operand Value	Compare Operation	Result If NaN Operand	QNaN Operand Causes Invalid Operation Exception
00h, 08h, 10h, 18h	Equal	FALSE	No
01h, 09h, 11h, 19h	Less than	FALSE	Yes
	Greater than (swapped operands)	FALSE	Yes
02h, 0Ah, 12h, 1Ah	Less than or equal	FALSE	Yes
	Greater than or equal (swapped operands)	FALSE	Yes
03h, 0Bh, 13h, 1Bh	Unordered	TRUE	No
04h, 0Ch, 14h, 1Ch	Not equal	TRUE	No
05h, 0Dh, 15h, 1Dh	Not less than	TRUE	Yes
	Not greater than (swapped operands)	TRUE	Yes
06h, 0Eh, 16h, 1Eh	Not less than or equal	TRUE	Yes
	Not greater than or equal (swapped operands)	TRUE	Yes
07h, 0Fh, 17h, 1Fh	Ordered	FALSE	No

The following alias mnemonics for (V)CMPPS with appropriate value of *imm8* are supported.

Mnemonic	Implied Value of *imm8*
(V)CMPEQPS	00h, 08h, 10h, 18h
(V)CMPLTPS	01h, 09h, 11h, 19h

CMPSD Compare
VCMPSD Scalar Double-Precision Floating-Point

Compares a double-precision floating-point value in the low-order 64 bits of the first source operand with a double-precision floating-point value in the low-order 64 bits of the second source operand and writes the result to the low-order 64 bits of the destination. When a comparison is TRUE, all 64 bits of the destination element are set; when a comparison is FALSE, all 64 bits of the destination element are cleared. Comparison type is specified by an immediate byte operand.

Signed comparisons return TRUE only when both operands are valid numbers and the numbers have the relation specified by the type of comparison operation. Ordered comparison returns TRUE when both operands are valid numbers, or FALSE when either operand is a NaN. Unordered comparison returns TRUE only when one or both operands are NaN and FALSE otherwise.

QNaN operands generate an Invalid Operation Exception (IE) only when the comparison type is not Equal, Unequal, Ordered, or Unordered. SNaN operands always generate an IE.

There are legacy and extended forms of the instruction:

CMPSD

The first source operand is an XMM register. The second source operand is either an XMM register or a 64-bit memory location. The first source register is also the destination. Bits [127:64] of the destination are not affected. Bits [255:128] of the YMM register that corresponds to the destination are not affected. Comparison type is specified by bits [2:0] of an immediate byte operand.

This CMPSD instruction must not be confused with the same-mnemonic CMPSD (compare strings by doubleword) instruction in the general-purpose instruction set. Assemblers can distinguish the instructions by the number and type of operands.

VCMPSD

The extended form of the instruction has a 128-bit encoding only.

The first source operand is an XMM register. The second source operand is either an XMM register or a 64-bit memory location. The destination is a third XMM register. Bits [127:64] of the destination are copied from bits [127:64] of the first source. Bits [255:128] of the YMM register that corresponds to the destination are cleared. Comparison type is specified by bits [4:0] of an immediate byte operand.

Immediate Operand Encoding

CMPSD uses bits [2:0] of the 8-bit immediate operand and VCMPSD uses bits [4:0] of the 8-bit immediate operand. Although VCMPSD supports 20h encoding values, the comparison types echo those of CMPSD on 4-bit boundaries. The following table shows the immediate operand value for CMPSD and each of the VCMPSD echoes.

Some comparison operations that are not directly supported by immediate-byte encodings can be implemented by swapping the contents of the source and destination operands and executing the appropriate comparison of the swapped values. These additional comparison operations are shown with the directly supported comparison operations. When operands are swapped, the first source XMM register is overwritten by the result.

Immediate Operand Value	Compare Operation	Result If NaN Operand	QNaN Operand Causes Invalid Operation Exception
00h, 08h, 10h, 18h	Equal	FALSE	No
01h, 09h, 11h, 19h	Less than	FALSE	Yes
	Greater than (swapped operands)	FALSE	Yes
02h, 0Ah, 12h, 1Ah	Less than or equal	FALSE	Yes
	Greater than or equal (swapped operands)	FALSE	Yes
03h, 0Bh, 13h, 1Bh	Unordered	TRUE	No
04h, 0Ch, 14h, 1Ch	Not equal	TRUE	No
05h, 0Dh, 15h, 1Dh	Not less than	TRUE	Yes
	Not greater than (swapped operands)	TRUE	Yes
06h, 0Eh, 16h, 1Eh	Not less than or equal	TRUE	Yes
	Not greater than or equal (swapped operands)	TRUE	Yes
07h, 0Fh, 17h, 1Fh	Ordered	FALSE	No

The following alias mnemonics for (V)CMPSD with appropriate value of *imm8* are supported.

Mnemonic	Implied Value of *imm8*

CMPSS Compare
VCMPSS Scalar Single-Precision Floating-Point

Compares a single-precision floating-point value in the low-order 32 bits of the first source operand with a single-precision floating-point value in the low-order 32 bits of the second source operand and writes the result to the low-order 32 bits of the destination. When a comparison is TRUE, all 32 bits of the destination element are set; when a comparison is FALSE, all 32 bits of the destination element are cleared. Comparison type is specified by an immediate byte operand.

Signed comparisons return TRUE only when both operands are valid numbers and the numbers have the relation specified by the type of comparison operation. Ordered comparison returns TRUE when both operands are valid numbers, or FALSE when either operand is a NaN. Unordered comparison returns TRUE only when one or both operands are NaN and FALSE otherwise.

QNaN operands generate an Invalid Operation Exception (IE) only if the comparison type isn't Equal, Unequal, Ordered, or Unordered. SNaN operands always generate an IE.

There are legacy and extended forms of the instruction:

CMPSS

The first source operand is an XMM register. The second source operand is either an XMM register or a 32-bit memory location. The first source register is also the destination. Bits [127:32] of the destination are not affected. Bits [255:128] of the YMM register that corresponds to the destination are not affected. Comparison type is specified by bits [2:0] of an immediate byte operand.

VCMPSS

The extended form of the instruction has a 128-bit encoding only.

The first source operand is an XMM register. The second source operand is either an XMM register or a 32-bit memory location. The destination is a third XMM register. Bits [127:32] of the destination are copied from bits [127L32] of the first source. Bits [255:128] of the YMM register that corresponds to the destination are cleared. Comparison type is specified by bits [4:0] of an immediate byte operand.

Immediate Operand Encoding

CMPSS uses bits [2:0] of the 8-bit immediate operand and VCMPSS uses bits [4:0] of the 8-bit immediate operand. Although VCMPSS supports 20h encoding values, the comparison types echo those of CMPSS on 4-bit boundaries. The following table shows the immediate operand value for CMPSS and each of the VCMPSS echoes.

Some comparison operations that are not directly supported by immediate-byte encodings can be implemented by swapping the contents of the source and destination operands and executing the appropriate comparison of the swapped values. These additional comparison operations are shown below with the directly supported comparison operations. When operands are swapped, the first source XMM register is overwritten by the result.

Immediate Operand Value	Compare Operation	Result If NaN Operand	QNaN Operand Causes Invalid Operation Exception
00h, 08h, 10h, 18h	Equal	FALSE	No
01h, 09h, 11h, 19h	Less than	FALSE	Yes
	Greater than (swapped operands)	FALSE	Yes
02h, 0Ah, 12h, 1Ah	Less than or equal	FALSE	Yes
	Greater than or equal (swapped operands)	FALSE	Yes
03h, 0Bh, 13h, 1Bh	Unordered	TRUE	No
04h, 0Ch, 14h, 1Ch	Not equal	TRUE	No
05h, 0Dh, 15h, 1Dh	Not less than	TRUE	Yes
	Not greater than (swapped operands)	TRUE	Yes
06h, 0Eh, 16h, 1Eh	Not less than or equal	TRUE	Yes
	Not greater than or equal (swapped operands)	TRUE	Yes
07h, 0Fh, 17h, 1Fh	Ordered	FALSE	No

The following alias mnemonics for (V)CMPSS with appropriate value of *imm8* are supported.

Mnemonic	Implied Value of *imm8*
(V)CMPEQSS	00h, 08h, 10h, 18h

COMISD Compare Ordered
VCOMISD Scalar Double-Precision Floating-Point

Compares a double-precision floating-point value in the low-order 64 bits of the first operand with a double-precision floating-point value in the low-order 64 bits of the second operand and sets rFLAGS.ZF, PF, and CF to show the result of the comparison:

Comparison	ZF	PF	CF
NaN input	1	1	1
operand 1 > operand 2	0	0	0
operand 1 < operand 2	0	0	1
operand 1 == operand 2	1	0	0

The result is unordered if one or both of the operand values is a NaN. The rFLAGS.OF, AF, and SF bits are cleared. If an #XF SIMD floating-point exception occurs the rFLAGS bits are not updated.

There are legacy and extended forms of the instruction:

COMISD

The first source operand is an XMM register and the second source operand is an XMM register or a 64-bit memory location.

VCOMISD

The extended form of the instruction has a 128-bit encoding only.

The first source operand is an XMM register and the second source operand is either an XMM register or a 64-bit memory location.

Instruction Support

CVTDQ2PD VCVTDQ2PD Convert Packed Doubleword Integers to Packed Double-Precision Floating-Point

Converts packed 32-bit signed integer values to packed double-precision floating-point values and writes the converted values to the destination.

There are legacy and extended forms of the instruction:

CVTDQ2PD

Converts two packed 32-bit signed integer values in the low-order 64 bits of an XMM register or in a 64-bit memory location to two packed double-precision floating-point values and writes the converted values to an XMM register. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VCVTDQ2PD

The extended form of the instruction has both 128-bit and 256-bit encodings:

XMM Encoding

Converts two packed 32-bit signed integer values in the low-order 64 bits of an XMM register or in a 64-bit memory location to two packed double-precision floating-point values and writes the converted values to an XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

Converts four packed 32-bit signed integer values in the low-order 128 bits of a YMM register or a 256-bit memory location to four packed double-precision floating-point values and writes the converted values to a YMM register.

Instruction Support

Form	Subset	Feature Flag
CVTDQ2PD	SSE2	CPUID Fn0000_0001_EDX[SSE2] (bit 26)
VCVTDQ2PD	AVX	CPUID Fn0000_0001_ECX[AVX] (bit 28)

For more on using the CPUID instruction to obtain processor feature support information, see Appendix E of Volume 3.

Instruction Encoding

Mnemonic	Opcode	Description
CVTDQ2PD *xmm1*, *xmm2/mem64*	F3 0F E6 /r	Converts packed doubleword signed integers in *xmm2* or *mem64* to double-precision floating-point values in *xmm1*.

CVTDQ2PS VCVTDQ2PS Convert Packed Doubleword Integers to Packed Single-Precision Floating-Point

Converts packed 32-bit signed integer values to packed single-precision floating-point values and writes the converted values to the destination. When the result is an inexact value, it is rounded as specified by MXCSR.RC.

There are legacy and extended forms of the instruction:

CVTDQ2PS

Converts four packed 32-bit signed integer values in an XMM register or a 128-bit memory location to four packed single-precision floating-point values and writes the converted values to an XMM register. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VCVTDQ2PS

The extended form of the instruction has both 128-bit and 256-bit encodings:

XMM Encoding

Converts four packed 32-bit signed integer values in an XMM register or a 128-bit memory location to four packed single-precision floating-point values and writes the converted values to an XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

Converts eight packed 32-bit signed integer values in a YMM register or a 256-bit memory location to eight packed single-precision floating-point values and writes the converted values to a YMM register.

Instruction Support

CVTPD2DQ VCVTPD2DQ Convert Packed Double-Precision Floating-Point to Packed Doubleword Integer

Converts packed double-precision floating-point values to packed signed doubleword integers and writes the converted values to the destination.

When the result is an inexact value, it is rounded as specified by MXCSR.RC. When the floating-point value is a NaN, infinity, or the result of the conversion is larger than the maximum signed doubleword (-2^{31} to $+2^{31} - 1$), the instruction returns the 32-bit indefinite integer value (8000_0000h) when the invalid-operation exception (IE) is masked.

There are legacy and extended forms of the instruction:

CVTPD2DQ

Converts two packed double-precision floating-point values in an XMM register or a 128-bit memory location to two packed signed doubleword integers and writes the converted values to the two low-order doublewords of the destination XMM register. Bits [127:64] of the destination are cleared. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VCVTPD2DQ

The extended form of the instruction has both 128-bit and 256-bit encodings:

XMM Encoding

Converts two packed double-precision floating-point values in an XMM register or a 128-bit memory location to two signed doubleword values and writes the converted values to the lower two doubleword elements of the destination XMM register. Bits [127:64] of the destination are cleared. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

Converts four packed double-precision floating-point values in a YMM register or a 256-bit memory location to four signed doubleword values and writes the converted values to an XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

CVTPS2DQ VCVTPS2DQ Convert Packed Single-Precision Floating-Point to Packed Doubleword Integers

Converts packed single-precision floating-point values to packed signed doubleword integer values and writes the converted values to the destination.

When the result is an inexact value, it is rounded as specified by MXCSR.RC. When the floating-point value is a NaN, infinity, or the result of the conversion is larger than the maximum signed doubleword (-2^{31} to $+2^{31} - 1$), the instruction returns the 32-bit indefinite integer value (8000_0000h) when the invalid-operation exception (IE) is masked.

There are legacy and extended forms of the instruction:

CVTPS2DQ

Converts four packed single-precision floating-point values in an XMM register or a 128-bit memory location to four packed signed doubleword integer values and writes the converted values to an XMM register. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VCVTPS2DQ

The extended form of the instruction has both 128-bit and 256-bit encodings:

XMM Encoding

Converts four packed single-precision floating-point values in an XMM register or a 128-bit memory location to four packed signed doubleword integer values and writes the converted values to an XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

Converts eight packed single-precision floating-point values in a YMM register or a 256-bit memory location to eight packed signed doubleword integer values and writes the converted values to a YMM register.

Instruction Support

CVTPS2PD VCVTPS2PD Convert Packed Single-Precision Floating-Point to Packed Double-Precision Floating-Point

Converts packed single-precision floating-point values to packed double-precision floating-point values and writes the converted values to the destination.

There are legacy and extended forms of the instruction:

CVTPS2PD

Converts two packed single-precision floating-point values in the two low order doubleword elements of an XMM register or a 64-bit memory location to two double-precision floating-point values and writes the converted values to an XMM register. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VCVTPS2PD

The extended form of the instruction has both 128-bit and 256-bit encodings:

XMM Encoding

Converts two packed single-precision floating-point values in the two low order doubleword elements of an XMM register or a 64-bit memory location to two double-precision floating-point values and writes the converted values to an XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

Converts four packed single-precision floating-point values in a YMM register or a 128-bit memory location to four double-precision floating-point values and writes the converted values to a YMM register.

Instruction Support

Form	Subset	Feature Flag
CVTPS2PD	SSE2	CPUID Fn0000_0001_EDX[SSE2] (bit 26)
VCVTPS2PD	AVX	CPUID Fn0000_0001_ECX[AVX] (bit 28)

For more on using the CPUID instruction to obtain processor feature support information, see Appendix E of Volume 3.

Instruction Encoding

CVTSD2SI VCVTSD2SI Convert Scalar Double-Precision Floating-Point to Signed Doubleword or Quadword Integer

Converts a scalar double-precision floating-point value to a 32-bit or 64-bit signed integer value and writes the converted value to a general-purpose register.

When the result is an inexact value, it is rounded as specified by MXCSR.RC. When the floating-point value is a NaN, infinity, or the result of the conversion is larger than the maximum signed doubleword (-2^{31} to $+2^{31} - 1$) or quadword value (-2^{63} to $+2^{63} - 1$), the instruction returns the indefinite integer value (8000_0000h for 32-bit integers, 8000_0000_0000_0000h for 64-bit integers) when the invalid-operation exception (IE) is masked.

There are legacy and extended forms of the instruction:

CVTSD2SI

The legacy form has two encodings:

- When REX.W = 0, converts a scalar double-precision floating-point value in the low-order 64 bits of an XMM register or a 64-bit memory location to a 32-bit signed integer and writes the converted value to a 32-bit general purpose register.
- When REX.W = 1, converts a scalar double-precision floating-point value in the low-order 64 bits of an XMM register or a 64-bit memory location to a 64-bit sign-extended integer and writes the converted value to a 64-bit general purpose register.

VCVTSD2SI

The extended form of the instruction has two 128-bit encodings:

- When VEX.W = 0, converts a scalar double-precision floating-point value in the low-order 64 bits of an XMM register or a 64-bit memory location to a 32-bit signed integer and writes the converted value to a 32-bit general purpose register.
- When VEX.W = 1, converts a scalar double-precision floating-point value in the low-order 64 bits of an XMM register or a 64-bit memory location to a 64-bit sign-extended integer and writes the converted value to a 64-bit general purpose register.

Instruction Support

Form	Subset	Feature Flag

CVTSI2SD VCVTSI2SD Convert Signed Doubleword or Quadword Integer to Scalar Double-Precision Floating-Point

Converts a signed integer value to a double-precision floating-point value and writes the converted value to a destination register. When the result of the conversion is an inexact value, the value is rounded as specified by MXCSR.RC.

There are legacy and extended forms of the instruction:

CVTSI2SD

The legacy form as two encodings:

- When REX.W = 0, converts a signed doubleword integer value from a 32-bit source general-purpose register or a 32-bit memory location to a double-precision floating-point value and writes the converted value to the low-order 64 bits of an XMM register. Bits [127:64] of the destination XMM register and bits [255:128] of the corresponding YMM register are not affected.
- When REX.W = 1, converts a a signed quadword integer value from a 64-bit source general-purpose register or a 64-bit memory location to a 64-bit double-precision floating-point value and writes the converted value to the low-order 64 bits of an XMM register. Bits [127:64] of the destination XMM register and bits [255:128] of the corresponding YMM register are not affected.

VCVTSI2SD

The extended form of the instruction has two 128-bit encodings:

- When VEX.W = 0, converts a signed doubleword integer value from a 32-bit source general-purpose register or a 32-bit memory location to a double-precision floating-point value and writes the converted value to the low-order 64 bits of the destination XMM register. Bits [127:64] of the first source XMM register are copied to the destination XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.
- When VEX.W = 1, converts a signed quadword integer value from a 64-bit source general-purpose register or a 64-bit memory location to a double-precision floating-point value and writes the converted value to the low-order 64 bits of the destination XMM register. Bits [127:64] of the first source XMM register are copied to the destination XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

CVTSI2SS VCVTSI2SS Convert Signed Doubleword or Quadword Integer to Scalar Single-Precision Floating-Point

Converts a signed integer value to a single-precision floating-point value and writes the converted value to an XMM register. When the result of the conversion is an inexact value, the value is rounded as specified by MXCSR.RC.

There are legacy and extended forms of the instruction:

CVTSI2SS

The legacy form has two encodings:

- When REX.W = 0, converts a signed doubleword integer value from a 32-bit source general-purpose register or a 32-bit memory location to a single-precision floating-point value and writes the converted value to the low-order 32 bits of an XMM register. Bits [127:32] of the destination XMM register and bits [255:128] of the corresponding YMM register are not affected.
- When REX.W = 1, converts a a signed quadword integer value from a 64-bit source general-purpose register or a 64-bit memory location to a single-precision floating-point value and writes the converted value to the low-order 32 bits of an XMM register. Bits [127:32] of the destination XMM register and bits [255:128] of the corresponding YMM register are not affected.

VCVTSI2SS

The extended form of the instruction has two 128-bit encodings:

- When VEX.W = 0, converts a signed doubleword integer value from a 32-bit source general-purpose register or a 32-bit memory location to a single-precision floating-point value and writes the converted value to the low-order 32 bits of the destination XMM register. Bits [127:32] of the first source XMM register are copied to the destination XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.
- When VEX.W = 1, converts a signed quadword integer value from a 64-bit source general-purpose register or a 64-bit memory location to a single-precision floating-point value and writes the converted value to the low-order 32 bits of the destination XMM register. Bits [127:32] of the first source XMM register are copied to the destination XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

CVTSS2SD VCVTSS2SD Convert Scalar Single-Precision Floating-Point to Scalar Double-Precision Floating-Point

Converts a scalar single-precision floating-point value to a scalar double-precision floating-point value and writes the converted value to the low-order 64 bits of the destination.

There are legacy and extended forms of the instruction:

CVTSS2SD

Converts a scalar single-precision floating-point value in the low-order 32 bits of a source XMM register or a 32-bit memory location to a scalar double-precision floating-point value and writes the converted value to the low-order 64 bits of a destination XMM register. Bits [127:64] of the destination and bits [255:128] of the corresponding YMM register are not affected.

VCVTSS2SD

The extended form of the instruction has a 128-bit encoding only.

Converts a scalar single-precision floating-point value in the low-order 32 bits of the second source XMM register or 32-bit memory location to a scalar double-precision floating-point value and writes the converted value to the low-order 64 bits of the destination XMM register. Bits [127:64] of the destination are copied from the first source XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

Instruction Support

S — SSE exception

CVTSS2SI VCVTSS2SI Convert Scalar Single-Precision Floating-Point to Signed Doubleword or Quadword Integer

Converts a single-precision floating-point value to a signed integer value and writes the converted value to a general-purpose register.

When the result of the conversion is an inexact value, the value is rounded as specified by MXCSR.RC. When the floating-point value is a NaN, infinity, or the result of the conversion is larger than the maximum signed doubleword (-2^{31} to $+2^{31} - 1$) or quadword value (-2^{63} to $+2^{63} - 1$), the indefinite integer value (8000_0000h for 32-bit integers, 8000_0000_0000_0000h for 64-bit integers) is returned when the invalid-operation exception (IE) is masked.

There are legacy and extended forms of the instruction:

CVTSS2SI

The legacy form has two encodings:

- When REX.W = 0, converts a single-precision floating-point value in the low-order 32 bits of an XMM register or a 32-bit memory location to a 32-bit signed integer value and writes the converted value to a 32-bit general-purpose register.
- When REX.W = 1, converts a single-precision floating-point value in the low-order 32 bits of an XMM register or a 32-bit memory location to a 64-bit signed integer value and writes the converted value to a 64-bit general-purpose register.

VCVTSS2SI

The extended form of the instruction has two 128-bit encodings:

- When VEX.W = 0, converts a single-precision floating-point value in the low-order 32 bits of an XMM register or a 32-bit memory location to a 32-bit signed integer value and writes the converted value to a 32-bit general-purpose register.
- When VEX.W = 1, converts a single-precision floating-point value in the low-order 32 bits of an XMM register or a 32-bit memory location to a 64-bit signed integer value and writes the converted value to a 64-bit general-purpose register.

Instruction Support

Form	Subset	Feature Flag

CVTTPD2DQ Convert Packed Double-Precision Floating-Point VCVTTPD2DQ to Packed Doubleword Integer, Truncated

Converts packed double-precision floating-point values to packed signed doubleword integer values and writes the converted values to the destination.

When the result is an inexact value, it is truncated (rounded toward zero). When the floating-point value is a NaN, infinity, or the result of the conversion is larger than the maximum signed doubleword (-2^{31} to $+2^{31} - 1$), the instruction returns the 32-bit indefinite integer value (8000_0000h) when the invalid-operation exception (IE) is masked.

There are legacy and extended forms of the instruction:

CVTTPD2DQ

Converts two packed double-precision floating-point values in an XMM register or a 128-bit memory location to two packed signed doubleword integers and writes the converted values to the two low-order doublewords of the destination XMM register. Bits [127:64] of the destination are cleared. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VCVTTPD2DQ

The extended form of the instruction has both 128-bit and 256-bit encodings:

XMM Encoding

Converts two packed double-precision floating-point values in an XMM register or a 128-bit memory location to two signed doubleword values and writes the converted values to the lower two doubleword elements of the destination XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

Converts four packed double-precision floating-point values in a YMM register or a 256-bit memory location to four signed doubleword integer values and writes the converted values to an XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

Instruction Support

Form	Subset	Feature Flag
CVTTPD2DQ	SSE2	CPUID Fn0000_0001_EDX[SSE2] (bit 26)
VCVTTPD2DQ	AVX	CPUID Fn0000_0001_ECX[AVX] (bit 28)

CVTTPS2DQ Convert Packed Single-Precision Floating-Point VCVTTPS2DQ to Packed Doubleword Integers, Truncated

Converts packed single-precision floating-point values to packed signed doubleword integer values and writes the converted values to the destination.

When the result of the conversion is an inexact value, the value is truncated (rounded toward zero). When the floating-point value is a NaN, infinity, or the result of the conversion is larger than the maximum signed doubleword (-2^{31} to $+2^{31} - 1$), the instruction returns the 32-bit indefinite integer value (8000_0000h) when the invalid-operation exception (IE) is masked.

There are legacy and extended forms of the instruction:

CVTTPS2DQ

Converts four packed single-precision floating-point values in an XMM register or a 128-bit memory location to four packed signed doubleword integer values and writes the converted values to an XMM register. The high-order 128-bits of the corresponding YMM register are not affected.

VCVTTPS2DQ

The extended form of the instruction has both 128-bit and 256-bit encodings:

XMM Encoding

Converts four packed single-precision floating-point values in an XMM register or a 128-bit memory location to four packed signed doubleword integer values and writes the converted values to an XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

Converts eight packed single-precision floating-point values in a YMM register or a 256-bit memory location to eight packed signed doubleword integer values and writes the converted values to a YMM register.

Instruction Support

CVTTSD2SI Convert Scalar Double-Precision Floating-Point VCVTTSD2SI to Signed Double- or Quadword Integer, Truncated

Converts a scalar double-precision floating-point value to a signed integer value and writes the converted value to a general-purpose register.

When the result of the conversion is an inexact value, the value is truncated (rounded toward zero). When the floating-point value is a NaN, infinity, or the result of the conversion is larger than the maximum signed doubleword (-2^{31} to $+2^{31} - 1$) or quadword value (-2^{63} to $+2^{63} - 1$), the instruction returns the indefinite integer value (8000_0000h for 32-bit integers, 8000_0000_0000_0000h for 64-bit integers) when the invalid-operation exception (IE) is masked.

There are legacy and extended forms of the instruction:

CVTTSD2SI

The legacy form of the instruction has two encodings:

- When REX.W = 0, converts a scalar double-precision floating-point value in the low-order 64 bits of an XMM register or a 64-bit memory location to a 32-bit signed integer and writes the converted value to a 32-bit general purpose register.
- When REX.W = 1, converts a scalar double-precision floating-point value in the low-order 64 bits of an XMM register or a 64-bit memory location to a 64-bit sign-extended integer and writes the converted value to a 64-bit general purpose register.

VCVTTSD2SI

The extended form of the instruction has two 128-bit encodings.

- When VEX.W = 0, converts a scalar double-precision floating-point value in the low-order 64 bits of an XMM register or a 64-bit memory location to a 32-bit signed integer and writes the converted value to a 32-bit general purpose register.
- When VEX.W = 1, converts a scalar double-precision floating-point value in the low-order 64 bits of an XMM register or a 64-bit memory location to a 64-bit sign-extended integer and writes the converted value to a 64-bit general purpose register.

DIVPD Divide
VDIVPD Packed Double-Precision Floating-Point

Divides each of the packed double-precision floating-point values of the first source operand by the corresponding packed double-precision floating-point values of the second source operand and writes the quotients to the destination.

There are legacy and extended forms of the instruction:

DIVPD

Divides two packed double-precision floating-point values in the first source XMM register by the corresponding packed double-precision floating-point values in either a second source XMM register or a 128-bit memory location. The first source register is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VDIVPD

The extended form of the instruction has both 128-bit and 256-bit encodings:

XMM Encoding

Divides two packed double-precision floating-point values in the first source XMM register by the corresponding packed double-precision floating-point values in either a second source XMM register or a 128-bit memory location and writes the two results a destination XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

Divides four packed double-precision floating-point values in the first source YMM register by the corresponding packed double-precision floating-point values in either a second source YMM register or a 256-bit memory location and writes the two results a destination YMM register.

Instruction Support

DIVPS VDIVPS — Divide Packed Single-Precision Floating-Point

Divides each of the packed single-precision floating-point values of the first source operand by the corresponding packed single-precision floating-point values of the second source operand and writes the quotients to the destination.

There are legacy and extended forms of the instruction:

DIVPS

Divides four packed single-precision floating-point values in the first source XMM register by the corresponding packed single-precision floating-point values in either a second source XMM register or a 128-bit memory location. The first source register is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VDIVPS

The extended form of the instruction has both 128-bit and 256-bit encodings:

XMM Encoding

Divides four packed single-precision floating-point values in the first source XMM register by the corresponding packed single-precision floating-point values in either a second source XMM register or a 128-bit memory location and writes two results to a third destination XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

Divides eight packed single-precision floating-point values in the first source YMM register by the corresponding packed single-precision floating-point values in either a second source YMM register or a 256-bit memory location and writes the two results a destination YMM register.

Instruction Support

DIVSD Divide
VDIVSD Scalar Double-Precision Floating-Point

Divides the double-precision floating-point value in the low-order quadword of the first source operand by the double-precision floating-point value in the low-order quadword of the second source operand and writes the quotient to the low-order quadword of the destination.

There are legacy and extended forms of the instruction:

DIVSD

The first source operand is an XMM register and the second source operand is either an XMM register or a 64-bit memory location. The first source register is also the destination register. Bits [127:64] of the destination are not affected. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VDIVSD

The extended form of the instruction has a 128-bit encoding only.

The first source operand is an XMM register and the second source operand is either an XMM register or a 64-bit memory location. Bits [127:64] of the first source operand are copied to bits [127:64] of the destination. The destination is a third XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

Instruction Support

Form	Subset	Feature Flag
DIVSD	SSE2	CPUID Fn0000_0001_EDX[SSE2] (bit 26)

DPPD Dot Product
VDPPD Packed Double-Precision Floating-Point

Computes the dot-product of the input operands. An immediate operand specifies both the input values and the destination locations to which the products are written.

Selectively multiplies packed double-precision values in a source operand by the corresponding values in a second source operand, writes the results to a temporary location, adds the results, writes the sum to a second temporary location and selectively writes the sum to a destination.

Mask bits [5:4] of an 8-bit immediate operand perform multiplicative selection. Bit 5 selects bits [127:64] of the source operands; bit 4 selects bits [63:0] of the source operands. When a mask bit = 1, the corresponding packed double-precision floating point values are multiplied and the product is written to the corresponding position of a 128-bit temporary location. When a mask bit = 0, the corresponding position of the temporary location is cleared.

After the two 64-bit values in the first temporary location are added and written to the 64-bit second temporary location, mask bits [1:0] of the same 8-bit immediate operand perform write selection. Bit 1 selects bits [127:64] of the destination; bit 0 selects bits [63:0] of the destination. When a mask bit = 1, the 64-bit value of the second temporary location is written to the corresponding position of the destination. When a mask bit = 0, the corresponding position of the destination is cleared.

When the operation produces a NaN, its value is determined as follows.

Source Operands (in either order)		NaN Result[1]
QNaN	Any non-NaN floating-point value (or single-operand instruction)	Value of QNaN
SNaN	Any non-NaN floating-point value (or single-operand instruction)	Value of SNaN, converted to a QNaN[2]
QNaN	QNaN	First operand
QNaN	SNaN	First operand (converted to QNaN if SNaN
SNaN	SNaN	First operand converted to a QNaN[2]

Note: *1. A NaN result produced when the floating-point invalid-operation exception is masked.*
2. The conversion is done by changing the most-significant fraction bit to 1.

For each addition occurring in either the second or third step, for the purpose of NaN propagation, the addend of lower bit index is considered to be the first of the two operands. For example, when both multiplications produce NaNs, the one that corresponds to bits [64:0] is written to all indicated fields of the destination, regardless of how those NaNs were generated from the sources. When the high-order multiplication produces NaNs and the low-order multiplication produces infinities of opposite signs, the real indefinite QNaN (produced as the sum of the infinities) is written to the destination.

NaNs in source operands or in computational results result in at least one NaN in the destination. For the 256-bit version, NaNs are propagated within the two independent dot product operations only to their respective 128-bit results.

There are legacy and extended forms of the instruction:

DPPD

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The first source register is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VDPPD

The extended form of the instruction has a single 128-bit encoding.

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

Instruction Support

DPPS Dot Product
VDPPS Packed Single-Precision Floating-Point

Computes the dot-product of the input operands. An immediate operand specifies both the input values and the destination locations to which the products are written.

Selectively multiplies packed single-precision values in a source operand by corresponding values in a second source operand, writes results to a temporary location, adds pairs of results, writes the sums to additional temporary locations, and selectively writes a cumulative sum to a destination.

Mask bits [7:4] of an 8-bit immediate operand perform multiplicative selection. Each bit selects a 32-bit segment of the source operands; bit 7 selects bits [127:96], bit 6 selects bits [95:64], bit 5 selects bits [63:32], and bit 4 selects bits [31:0]. When a mask bit = 1, the corresponding packed single-precision floating point values are multiplied and the product is written to the corresponding position of a 128-bit temporary location. When a mask bit = 0, the corresponding position of the temporary location is cleared.

After multiplication, three pairs of 32-bit values are added and written to temporary locations. Bits [63:32] and [31:0] of temporary location 1 are added and written to 32-bit temporary location 2; bits [127:96] and [95:64] of temporary location 1 are added and written to 32-bit temporary location 3; then the contents of temporary locations 2 and 3 are added and written to 32-bit temporary location 4.

After addition, mask bits [3:0] of the same 8-bit immediate operand perform write selection. Each bit selects a 32-bit segment of the source operands; bit 3 selects bits [127:96], bit 2 selects bits [95:64], bit 1 selects bits [63:32], and bit 0 selects bits [31:0] of the destination. When a mask bit = 1, the 64-bit value of the fourth temporary location is written to the corresponding position of the destination. When a mask bit = 0, the corresponding position of the destination is cleared.

For the 256-bit extended encoding, this process is performed on the upper and lower 128 bits of the affected YMM registers.

When the operation produces a NaN, its value is determined as follows.

Source Operands (in either order)		NaN Result[1]
QNaN	Any non-NaN floating-point value (or single-operand instruction)	Value of QNaN
SNaN	Any non-NaN floating-point value (or single-operand instruction)	Value of SNaN, converted to a QNaN[2]
QNaN	QNaN	First operand
QNaN	SNaN	First operand (converted to QNaN if SNaN
SNaN	SNaN	First operand converted to a QNaN[2]

Note: *1. A NaN result produced when the floating-point invalid-operation exception is masked.*
2. The conversion is done by changing the most-significant fraction bit to 1.

For each addition occurring in either the second or third step, for the purpose of NaN propagation, the addend of lower bit index is considered to be the first of the two operands. For example, when all four multiplications produce NaNs, the one that corresponds to bits [31:0] is written to all indicated fields

of the destination, regardless of how those NaNs were generated from the sources. When the two highest-order multiplication produce NaNs and the two lowest-low-order multiplications produce infinities of opposite signs, the real indefinite QNaN (produced as the sum of the infinities) is written to the destination.

NaNs in source operands or in computational results result in at least one NaN in the destination. For the 256-bit version, NaNs are propagated within the two independent dot product operations only to their respective 128-bit results.

There are legacy and extended forms of the instruction:

DPPS

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The first source register is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VDPPS

The extended form of the instruction has both 128-bit and 256-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register and the second source operand is either a YMM register or a 256-bit memory location. The destination is a third YMM register.

EXTRACTPS Extract
VEXTRACTPS Packed Single-Precision Floating-Point

Copies one of four packed single-precision floating-point values from a source XMM register to a general purpose register or a 32-bit memory location.

Bits [1:0] of an immediate byte operand specify the location of the 32-bit value that is copied. 00b corresponds to the low word of the source register and 11b corresponds to the high word of the source register. Bits [7:2] of the immediate operand are ignored.

There are legacy and extended forms of the instruction:

EXTRACTPS

The source operand is an XMM register. The destination can be a general purpose register or a 32-bit memory location. A 32-bit single-precision value extracted to a general purpose register is zero-extended to 64-bits.

VEXTRACTPS

The extended form of the instruction has a single 128-bit encoding.

The source operand is an XMM register. The destination can be a general purpose register or a 32-bit memory location.

Instruction Support

EXTRQ Extract Field From Register

Extracts specified bits from the lower 64 bits of the first operand (the destination XMM register). The extracted bits are saved in the least-significant bit positions of the lower quadword of the destination; the remaining bits in the lower quadword of the destination register are cleared to 0. The upper quadword of the destination register is undefined.

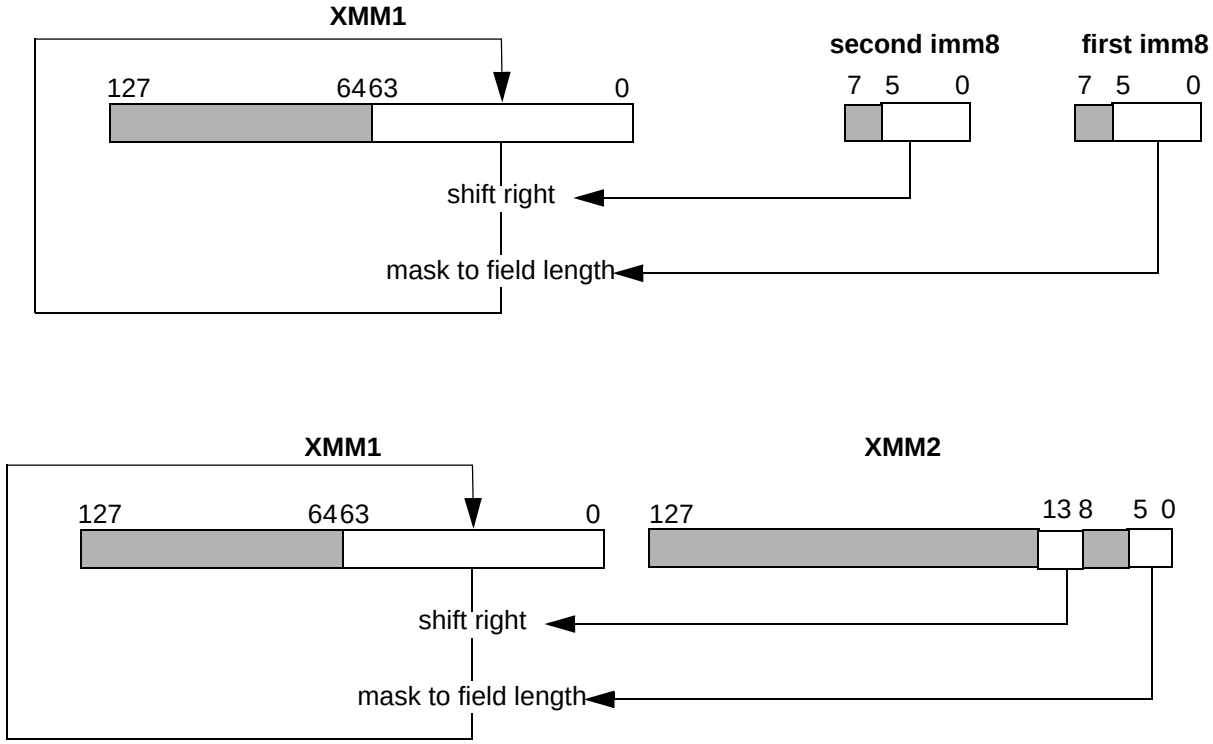
The portion of the source data being extracted is defined by the bit index and the field length. The bit index defines the least-significant bit of the source operand being extracted. Bits [*bit index* + *length field* – 1]:[*bit index*] are extracted. If the sum of the *bit index* + *length field* is greater than 64, the results are undefined.

For example, if the bit index is 32 (20h) and the field length is 16 (10h), then the result in the destination register will be source [47:32] in bits 15:0, with zeros in bits 63:16.

A value of zero in the field length is defined as a length of 64. If the *length field* is 0 and the *bit index* is 0, bits 63:0 of the source are extracted. For any other value of the *bit index*, the results are undefined.

The *bit index* and *field length* can be specified as immediate values (second and first immediate operands, respectively, in the case of the three argument version of the instruction), or they can both be specified by fields in an XMM source operand. In the latter case, bits [5:0] of the XMM register specify the number of bits to extract (the *field length*) and bits [13:8] of the XMM register specify the index of the first bit in the field to extract. The *bit index* and *field length* are each six bits in length; other bits of the field are ignored.

The diagram below illustrates the operation of this instruction.



Instruction Support

Form	Subset	Feature Flag
EXTRQ	SSE4A	CPUID Fn8000_0001_ECX[SSE4A] (bit 6)

Software *must* check the CPUID bit once per program or library initialization before using the instruction, or inconsistent behavior may result. For more on using the CPUID instruction to obtain processor feature support information, see Appendix E of Volume 3.

Instruction Encoding

Mnemonic	Opcode	Description
EXTRQ *xmm1*, *imm8*, *imm8*	66 0F 78 /0 ib ib	Extract field from *xmm1*, with the least significant bit of the extracted data starting at the bit index specified by [5:0] of the second immediate byte, with the length specified by [5:0] of the first immediate byte.
EXTRQ *xmm1*, *xmm2*	66 0F 79 /r	Extract field from *xmm1*, with the least significant bit of the extracted data starting at the bit index specified by xmm2[13:8], with the length specified by xmm2[5:0].

HADDPD Horizontal Add
VHADDPD Packed Double-Precision Floating-Point

Adds adjacent pairs of double-precision floating-point values in two source operands and writes the sums to a destination.

There are legacy and extended forms of the instruction:

HADDPD

Adds the packed double-precision values in bits [127:64] and bits [63:0] of the first source XMM register and writes the sum to bits [63:0] of the destination; adds the corresponding doublewords of the second source XMM register or a 128-bit memory location and writes the sum to bits [127:64] of the destination. The first source register is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VHADDPD

The extended form of the instruction has both 128-bit and 256-bit encodings:

XMM Encoding

Adds the packed double-precision values in bits [127:64] and bits [63:0] of the first source XMM register and writes the sum to bits [63:0] of the destination XMM register; adds the corresponding doublewords of the second source XMM register or a 128-bit memory location and writes the sum to bits [127:64] of the destination. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

Adds the packed double-precision values in bits [127:64] and bits [63:0] of the of the first source YMM register and writes the sum to bits [63:0] of the destination YMM register; adds the corresponding doublewords of the second source YMM register or a 256-bit memory location and writes the sum to bits [127:64] of the destination. Performs the same process for the upper 128 bits of the sources and destination.

HSUBPD Horizontal Subtract
VHSUBPD Packed Double-Precision

Subtracts adjacent pairs of double-precision floating-point values in two source operands and writes the sums to a destination.

There are legacy and extended forms of the instruction:

HSUBPD

The first source register is also the destination.

Subtracts the packed double-precision value in bits [127:64] from the value in bits [63:0] of the first source XMM register and writes the difference to bits [63:0] of the destination; subtracts the corresponding values of the second source XMM register or a 128-bit memory location and writes the difference to bits [127:64] of the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VHSUBPD

The extended form of the instruction has both 128-bit and 256-bit encodings:

XMM Encoding

Subtracts the packed double-precision values in bits [127:64] from the value in bits [63:0] of the first source XMM register and writes the difference to bits [63:0] of the destination XMM register; subtracts the corresponding values of the second source XMM register or a 128-bit memory location and writes the difference to bits [127:64] of the destination. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

Subtracts the packed double-precision values in bits [127:64] from the value in bits [63:0] of the of the first source YMM register and writes the difference to bits [63:0] of the destination YMM register; subtracts the corresponding values of the second source YMM register or a 256-bit memory location and writes the difference to bits [127:64] of the destination. Performs the same process for the upper 128 bits of the sources and destination.

Instruction Support

HSUBPS Horizontal Subtract Packed Single
VHSUBPS

Subtracts adjacent pairs of single-precision floating-point values in two source operands and writes the differences to a destination.

There are legacy and extended forms of the instruction:

HSUBPS

Subtracts the packed single-precision values in bits [63:32] from the values in bits [31:0] of the first source XMM register and writes the difference to bits [31:0] of the destination; subtracts the packed single-precision values in bits [127:96] from the value in bits [95:64] of the first source register and writes the difference to bits [63:32] of the destination. Subtracts the corresponding values of the second source XMM register or a 128-bit memory location and writes the differences to bits [95:64] and [127:96] of the destination. The first source register is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VHSUBPS

The extended form of the instruction has both 128-bit and 256-bit encodings:

XMM Encoding

Subtracts the packed single-precision values in bits [63:32] from the value in bits [31:0] of the first source XMM register and writes the difference to bits [31:0] of the destination XMM register; subtracts the packed single-precision values in bits [127:96] from the value bits [95:64] of the first source register and writes the sum to bits [63:32] of the destination. Subtracts the corresponding values of the second source XMM register or a 128-bit memory location and writes the differences to bits [95:64] and [127:96] of the destination. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

Subtracts the packed single-precision values in bits [63:32] from the value in bits [31:0] of the first source YMM register and writes the difference to bits [31:0] of the destination YMM register; subtracts the packed single-precision values in bits [127:96] from the value in bits [95:64] of the first source register and writes the difference to bits [63:32] of the destination. Subtracts the corresponding values of the second source YMM register or a 256-bit memory location and writes the differences to bits [95:64] and [127:96] of the destination. Performs the same process for the upper 128 bits of the sources and destination.

INSERTPS Insert
VINSERTPS Packed Single-Precision Floating-Point

Copies a selected single-precision floating-point value from a source operand to a selected location in a destination register and optionally clears selected elements of the destination. The legacy and extended forms of the instruction treat the remaining elements of the destination in different ways.

Selections are specified by three fields of an immediate 8-bit operand:

7	6	5	4	3	2	1	0
COUNT_S		COUNT_D		ZMASK			

COUNT_S — The binary value of the field specifies a 32-bit element of a source register, counting upward from the low-order doubleword. COUNT_S is used only for register source; when the source is a memory operand, COUNT_S = 0.

COUNT_D — The binary value of the field specifies a 32-bit destination element, counting upward from the low-order doubleword.

ZMASK — Set a bit to clear a 32-bit element of the destination.

There are legacy and extended forms of the instruction:

INSERTPS

The source operand is either an XMM register or a 32-bit memory location. The destination is an XMM register. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

When the source operand is a register, the instruction copies the 32-bit element of the source specified by Count_S to the location in the destination specified by Count_D, and clears destination elements as specified by ZMask. Elements of the destination that are not cleared are not affected.

When the source operand is a memory location, the instruction copies a 32-bit value from memory, to the location in the destination specified by Count_D, and clears destination elements as specified by ZMask. Elements of the destination that are not cleared are not affected.

VINSERTPS

The extended form of the instruction has a 128-bit encoding only.

The first source operand is an XMM register and the second source operand is either an XMM register or a 32-bit memory location. The destination is an XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

When the second source operand is a register, the instruction copies the 32-bit element of the source specified by Count_S to the location in the destination specified by Count_D. The other elements of the destination are either copied from the first source operand or cleared as specified by ZMask.

When the second source operand is a memory location, the instruction copies a 32-bit value from the source to the location in the destination specified by Count_D. The other elements of the destination are either copied from the first source operand or cleared as specified by ZMask.

INSERTQ Insert Field

Inserts bits from the lower 64 bits of the source operand into the lower 64 bits of the destination operand. No other bits in the lower 64 bits of the destination are modified. The upper 64 bits of the destination are undefined.

The least-significant *l* bits of the source operand are inserted into the destination, with the least-significant bit of the source operand inserted at bit position *n*, where *l* and *n* are defined as the *field length* and *bit index*, respectively.

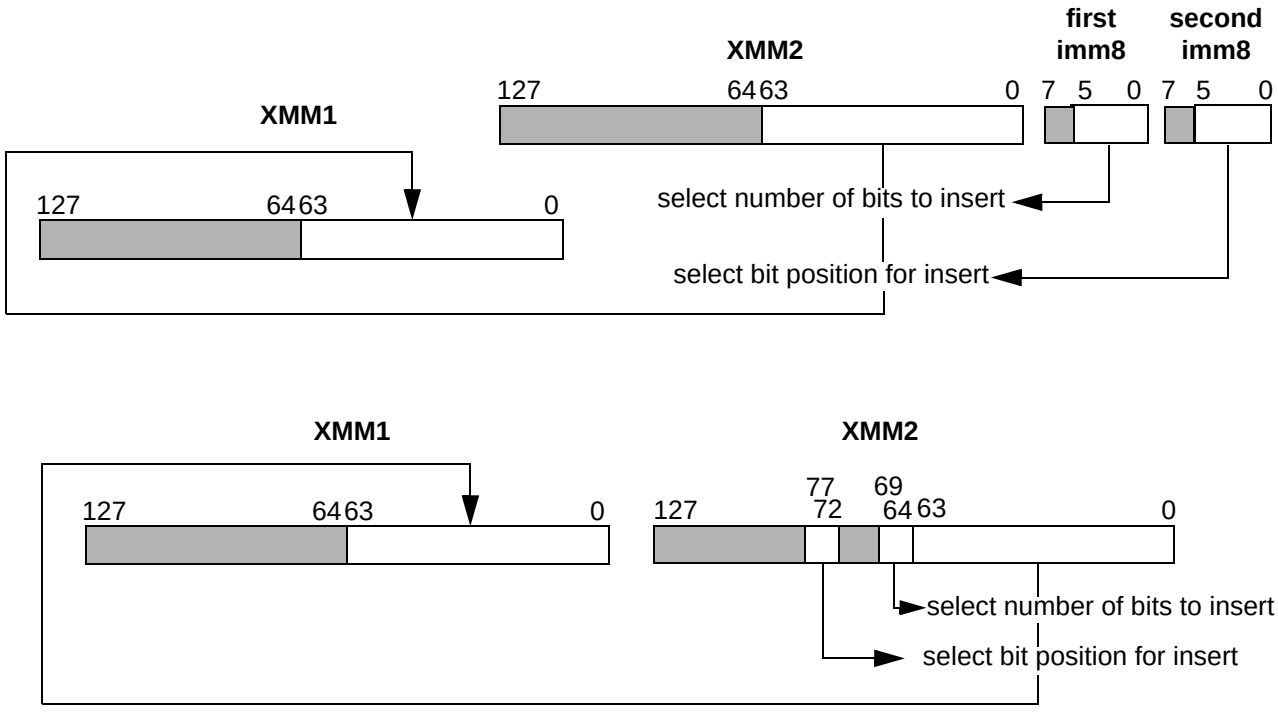
Bits (*field length* – 1):0 of the source operand are inserted into bits (*bit index* + *field length* – 1):(*bit index*) of the destination. If the sum of the *bit index* + *length field* is greater than 64, the results are undefined.

For example, if the *bit index* is 32 (20h) and the field length is 16 (10h), then the result in the destination register will be *source operand*[15:0] in bits 47:32. Bits 63:48 and bits 31:0 are not modified.

A value of zero in the *field length* is defined as a length of 64. If the *length field* is 0 and the *bit index* is 0, bits 63:0 of the source operand are inserted. For any other value of the *bit index*, the results are undefined.

The bits to insert are located in the XMM2 source operand. The *bit index* and *field length* can be specified as immediate values or can be specified in the XMM source operand. In the immediate form, the *bit index* and the *field length* are specified by the fourth (second immediate byte) and third operands (first immediate byte), respectively. In the register form, the *bit index* and *field length* are specified in bits [77:72] and bits [69:64] of the source XMM register, respectively. The *bit index* and *field length* are each six bits in length; other bits in the field are ignored.

The diagram below illustrates the operation of this instruction.



Instruction Support

Form	Subset	Feature Flag
INSERTQ	SSE4A	CPUID Fn8000_0001_ECX[SSE4A] (bit 6)

Software *must* check the CPUID bit once per program or library initialization before using the instruction, or inconsistent behavior may result. For more on using the CPUID instruction to obtain processor feature support information, see Appendix E of Volume 3.

Instruction Encoding

Mnemonic	Opcode	Description
INSERTQ *xmm1*, *xmm2*, *imm8*, *imm8*	F2 0F 78 /r ib ib	Insert field starting at bit 0 of xmm2 with the length specified by [5:0] of the first immediate byte. This field is inserted into xmm1 starting at the bit position specified by [5:0] of the second immediate byte.
INSERTQ *xmm1*, *xmm2*	F2 0F 79 /r	Insert field starting at bit 0 of xmm2 with the length specified by xmm2[69:64]. This field is inserted into xmm1 starting at the bit position specified by xmm2[77:72].

Device not available, #NM	X	X	X	The task-switch bit (TS) of CR0 was set to 1.

LDDQU Load
VLDDQU Unaligned Double Quadword

Loads unaligned double quadwords from a memory location to a destination register.

Like the (V)MOVUPD instructions, (V)LDDQU loads a 128-bit or 256-bit operand from an unaligned memory location. However, to improve performance when the memory operand is actually misaligned, (V)LDDQU may read an aligned 16 or 32 bytes to get the first part of the operand, and an aligned 16 or 32 bytes to get the second part of the operand. This behavior is implementation-specific, and (V)LDDQU may only read the exact 16 or 32 bytes needed for the memory operand. If the memory operand is in a memory range where reading extra bytes can cause performance or functional issues, use (V)MOVUPD instead of (V)LDDQU.

Memory operands that are not aligned on 16-byte or 32-byte boundaries do not cause general-protection exceptions.

There are legacy and extended forms of the instruction:

LDDQU

The source operand is an unaligned 128-bit memory location. The destination operand is an XMM register. Bits [255:128] of the YMM register that corresponds to the destination register are not affected.

VLDDQU

The extended form of the instruction has both 128-bit and 256-bit encodings:

XMM Encoding

The source operand is an unaligned 128-bit memory location. The destination operand is an XMM register. Bits [255:128] of the YMM register that corresponds to the destination register are cleared.

YMM Encoding

The source operand is an unaligned 256-bit memory location. The destination operand is a YMM register.

LDMXCSR Load
VLDMXCSR MXCSR Control/Status Register

Loads the MXCSR register with a 32-bit value from memory.

For both legacy LDMXCSR and extended VLDMXCSR forms of the instruction, the source operand is a 32-bit memory location and the destination operand is the MXCSR.

If an MXCSR load clears a SIMD floating-point exception mask bit and sets the corresponding exception flag bit, a SIMD floating-point exception is not generated immediately. An exception is generated only when the next instruction that operates on an XMM or YMM register operand and causes that particular SIMD floating-point exception to be reported executes.

A general protection exception occurs if the instruction attempts to load non-zero values into reserved MXCSR bits. Software can use MXCSR_MASK to determine which bits are reserved. For details, see “128-Bit, 64-Bit, and x87 Programming” in Volume 2.

The MXCSR register is described in “Registers” in Volume 1.

MASKMOVDQU Masked Move
VMASKMOVDQU Double Quadword Unaligned

Moves bytes from the first source operand to a memory location specified by the DS:rDI register. Bytes are selected by mask bits in the second source operand. The memory location may be unaligned.

The mask consists of the most significant bit of each byte of the second source register. When a mask bit = 1, the corresponding byte of the first source register is written to the destination; when a mask bit = 0, the corresponding byte is not written.

Exception and trap behavior for elements not selected for storage to memory is implementation dependent. For instance, a given implementation may signal a data breakpoint or a page fault for bytes that are zero-masked and not actually written.

The instruction implicitly uses weakly-ordered, write-combining buffering for the data, as described in “Buffering and Combining Memory Writes” in Volume 2. For data that is shared by multiple processors, this instruction should be used together with a fence instruction in order to ensure data coherency (see “Cache and TLB Management” in Volume 2).

There are legacy and extended forms of the instruction:

MASKMOVDQU

The first source operand is an XMM register and the second source operand is an XMM register. The destination is a 128-bit memory location.

VMASKMOVDQU

The extended form of the instruction has a 128-bit encoding only.

The first source operand is an XMM register and the second source operand is an XMM register. The destination is a 128-bit memory location.

Instruction Support

X — AVX and SSE exception
A — AVX exception
S — SSE exception

MAXPD Maximum
VMAXPD Packed Double-Precision Floating-Point

Compares each packed double-precision floating-point value of the first source operand to the corresponding value of the second source operand and writes the numerically greater value into the corresponding location of the destination.

If both source operands are equal to zero, the value of the second source operand is returned. If either operand is a NaN (SNaN or QNaN), and invalid-operation exceptions are masked, the second source operand is written to the destination.

There are legacy and extended forms of the instruction:

MAXPD

Compares two pairs of packed double-precision floating-point values.

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The first source operand is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VMAXPD

The extended form of the instruction has both 128-bit and 256-bit encodings:

XMM Encoding

Compares two pairs of packed double-precision floating-point values.

The first source operand is an XMM register and the second source operand is either an XMM register or a 128-bit memory location. The destination is an XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

Compares four pairs of packed double-precision floating-point values.

The first source operand is a YMM register and the second source operand is either a YMM register or a 256-bit memory location. The destination is a YMM register.

Instruction Support

Form	Subset	Feature Flag
MAXPD	SSE2	CPUID Fn0000_0001_EDX[SSE2] (bit 26)
VMAXPD	AVX	CPUID Fn0000_0001_ECX[AVX] (bit 28)

For more on using the CPUID instruction to obtain processor feature support information, see Appendix E of Volume 3.

Denormalized operand, DE	S	S	X	A source operand was a denormal value.
X — AVX and SSE exception *A — AVX exception* *S — SSE exception*				

MINSD Minimum
VMINSD Scalar Double-Precision Floating-Point

Compares the scalar double-precision floating-point value in the low-order 64 bits of the first source operand to a corresponding value in the second source operand and writes the numerically lesser value into the low-order 64 bits of the destination.

If both source operands are equal to zero, the value of the second source operand is returned. If either operand is a NaN (SNaN or QNaN), and invalid-operation exceptions are masked, the second source operand is written to the destination.

There are legacy and extended forms of the instruction:

MINSD

The first source operand is an XMM register. The second source operand is either an XMM register or a 64-bit memory location. The first source register is also the destination. Bits [127:64] of the destination are not affected. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VMINSD

The extended form of the instruction has a 128-bit encoding only.

The first source operand is an XMM register and the second source operand is either an XMM register or a 64-bit memory location. The destination is an XMM register. Bits [127:64] of the destination are copied from the first source operand. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

MOVAPD Move Aligned
VMOVAPD Packed Double-Precision Floating-Point

Moves packed double-precision floating-point values. Values can be moved from a register or memory location to a register; or from a register to a register or memory location.

A memory operand that is not aligned causes a general-protection exception.

There are legacy and extended forms of the instruction:

MOVAPD

Moves two double-precision floating-point values. There are encodings for each type of move.

- The source operand is either an XMM register or a 128-bit memory location. The destination operand is an XMM register.
- The source operand is an XMM register. The destination operand is either an XMM register or a 128-bit memory location.

Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VMOVAPD

The extended form of the instruction has both 128-bit and 256-bit encodings:

XMM Encoding

Moves two double-precision floating-point values. There are encodings for each type of move:

- The source operand is either an XMM register or a 128-bit memory location. The destination operand is an XMM register.
- The source operand is an XMM register. The destination operand is either an XMM register or a 128-bit memory location.

Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

Moves four double-precision floating-point values. There are encodings for each type of move:

- The source operand is either a YMM register or a 256-bit memory location. The destination operand is a YMM register.
- The source operand is a YMM register. The destination operand is either a YMM register or a 256-bit memory location.

Instruction Support

MOVAPS Move Aligned
VMOVAPS Packed Single-Precision Floating-Point

Moves packed single-precision floating-point values. Values can be moved from a register or memory location to a register; or from a register to a register or memory location.

A memory operand that is not aligned causes a general-protection exception.

There are legacy and extended forms of the instruction:

MOVAPS

Moves four single-precision floating-point values.

There are encodings for each type of move.

- The source operand is either an XMM register or a 128-bit memory location. The destination operand is an XMM register.
- The source operand is an XMM register. The destination operand is either an XMM register or a 128-bit memory location.

Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VMOVAPS

The extended form of the instruction has both 128-bit and 256-bit encodings:

XMM Encoding

Moves four single-precision floating-point values. There are encodings for each type of move.

- The source operand is either an XMM register or a 128-bit memory location. The destination operand is an XMM register.
- The source operand is an XMM register. The destination operand is either an XMM register or a 128-bit memory location.

Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

Moves eight single-precision floating-point values. There are encodings for each type of move.

- The source operand is either a YMM register or a 256-bit memory location. The destination operand is a YMM register.
- The source operand is a YMM register. The destination operand is either a YMM register or a 256-bit memory location.

Instruction Support

X — AVX and SSE exception *A — AVX exception* *S — SSE exception*				

MOVD Move
VMOVD Doubleword or Quadword

Moves 32-bit and 64-bit values. A value can be moved from a general-purpose register or memory location to the corresponding low-order bits of an XMM register, with zero-extension to 128 bits; or from the low-order bits of an XMM register to a general-purpose register or memory location.

The quadword form of this instruction is distinct from the differently-encoded (V)MOVQ instruction.

There are legacy and extended forms of the instruction:

MOVD

There are two encodings for 32-bit moves, characterized by REX.W = 0.

- The source operand is either a 32-bit general-purpose register or a 32-bit memory location. The destination is an XMM register. The 32-bit value is zero-extended to 128 bits.
- The source operand is an XMM register. The destination is either a 32-bit general-purpose register or a 32-bit memory location.

There are two encodings for 64-bit moves, characterized by REX.W = 1.

- The source operand is either a 64-bit general-purpose register or a 64-bit memory location. The destination is an XMM register. The 64-bit value is zero-extended to 128 bits.
- The source operand is an XMM register. The destination is either a 64-bit general-purpose register or a 64-bit memory location.

Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VMOVD

The extended form of the instruction has four 128-bit encodings:

There are two encodings for 32-bit moves, characterized by VEX.W = 0.

- The source operand is either a 32-bit general-purpose register or a 32-bit memory location. The destination is an XMM register. The 32-bit value is zero-extended to 128 bits.
- The source operand is an XMM register. The destination is either a 32-bit general-purpose register or a 32-bit memory location.

There are two encodings for 64-bit moves, characterized by VEX.W = 1.

- The source operand is either a 64-bit general-purpose register or a 64-bit memory location. The destination is an XMM register. The 64-bit value is zero-extended to 128 bits.
- The source operand is an XMM register. The destination is either a 64-bit general-purpose register or a 64-bit memory location.

Bits [255:128] of the YMM register that corresponds to the destination are cleared.

Instruction Support

MOVDDUP VMOVDDUP — Move and Duplicate Double-Precision Floating-Point

Moves and duplicates double-precision floating-point values.

There are legacy and extended forms of the instruction:

MOVDDUP

Moves and duplicates one quadword value.

The source operand is either the low 64 bits of an XMM register or the address of the least-significant byte of 64 bits of data in memory. The destination is an XMM register. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VMOVDDUP

The extended form of the instruction has both 128-bit and 256-bit encodings:

XMM Encoding

Moves and duplicates one quadword value.

The source operand is either the low 64 bits of an XMM register or the address of the least-significant byte of 64 bits of data in memory. The destination is an XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

Moves and duplicates two even-indexed quadword values.

The source operand is either a YMM register or the address of the least-significant byte of 256 bits of data in memory. The destination is a YMM register.Bits [63:0] of the source are written to bits [127:64] and [63:0] of the destination; bits [191:128] of the source are written to bits [255:192] and [191:128] of the destination.

Instruction Support

MOVDQA
VMOVDQA

Move Aligned Double Quadword

Moves aligned packed integer values. Values can be moved from a register or a memory location to a register, or from a register to a register or a memory location.

A memory operand that is not aligned causes a general-protection exception.

There are legacy and extended forms of the instruction:

MOVDQA

Moves two aligned quadwords (128-bit move). There are two encodings.

- The source operand is an XMM register. The destination is either an XMM register or a 128-bit memory location.
- The source operand is either an XMM register or a 128-bit memory location. The destination is an XMM register.

Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VMOVDQA

The extended form of the instruction has both 128-bit and 256-bit encodings:

XMM Encoding

Moves two aligned quadwords (128-bit move). There are two encodings.

- The source operand is an XMM register. The destination is either an XMM register or a 128-bit memory location.
- The source operand is either an XMM register or a 128-bit memory location. The destination is an XMM register.

Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

Moves four aligned quadwords (256-bit move). There are two encodings.

- The source operand is a YMM register. The destination is either a YMM register or a 256-bit memory location.
- The source operand is either a YMM register or a 256-bit memory location. The destination is a YMM register.

Instruction Support

MOVDQU Move
VMOVDQU Unaligned Double Quadword

Moves unaligned packed integer values. Values can be moved from a register or a memory location to a register, or from a register to a register or a memory location.

There are legacy and extended forms of the instruction:

MOVDQU

Moves two unaligned quadwords (128-bit move). There are two encodings.

- The source operand is an XMM register. The destination is either an XMM register or a 128-bit memory location.
- The source operand is either an XMM register or a 128-bit memory location. The destination is an XMM register.

Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VMOVDQU

The extended form of the instruction has both 128-bit and 256-bit encodings:

XMM Encoding

Moves two unaligned quadwords (128-bit move). There are two encodings:

- The source operand is an XMM register. The destination is either an XMM register or a 128-bit memory location.
- The source operand is either an XMM register or a 128-bit memory location. The destination is an XMM register.

Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

Moves four unaligned quadwords (256-bit move). There are two encodings:

- The source operand is a YMM register. The destination is either a YMM register or a 256-bit memory location.
- The source operand is either a YMM register or a 256-bit memory location. The destination is a YMM register.

MOVHLPS Move High to Low
VMOVHLPS Packed Single-Precision Floating-Point

Moves two packed single-precision floating-point values from the high quadword of an XMM register to the low quadword of an XMM register.

There are legacy and extended forms of the instruction:

MOVHLPS

The source operand is bits [127:64] of an XMM register. The destination is bits [63:0] of an XMM register. Bits [127:64] of the destination are not affected. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VMOVHLPS

The extended form of the instruction has a 128-bit encoding only.

The source operands are bits [127:64] of two XMM registers. The destination is a third XMM register. Bits [127:64] of the first source are moved to bits [127:64] of the destination; bits [127:64] of the second source are moved to bits [63:0] of the destination. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

MOVHPD Move High
VMOVHPD Packed Double-Precision Floating-Point

Moves a packed double-precision floating-point value. Values can be moved from a 64-bit memory location to the high-order quadword of an XMM register, or from the high-order quadword of an XMM register to a 64-bit memory location.

There are legacy and extended forms of the instruction:

MOVHPD

There are two encodings.

- The source operand is a 64-bit memory location. The destination is bits [127:64] of an XMM register.
- The source operand is bits [127:64] of an XMM register. The destination is a 64-bit memory location.

Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VMOVHPD

The extended form of the instruction has two 128-bit encodings:

- There are two source operands. The first source is an XMM register. The second source is a 64-bit memory location. The destination is an XMM register. Bits [63:0] of the source register are written to bits [63:0] of the destination; bits [63:0] of the source memory location are written to bits [127:64] of the destination.
- The source operand is bits [127:64] of an XMM register. The destination is a 64-bit memory location.

Bits [255:128] of the YMM register that corresponds to the destination are cleared.

MOVLPS VMOVLPS — Move Low Packed Single-Precision Floating-Point

Moves two packed single-precision floating-point values. Values can be moved from a 64-bit memory location to the low-order quadword of an XMM register, or from the low-order quadword of an XMM register to a 64-bit memory location.

There are legacy and extended forms of the instruction:

MOVLPS

There are two encodings.

- The source operand is a 64-bit memory location. The destination is bits [63:0] of an XMM register. Bits [255:128] of the YMM register that corresponds to the destination are not affected.
- The source operand is bits [63:0] of an XMM register. The destination is a 64-bit memory location.

VMOVLPS

The extended form of the instruction has two 128-bit encodings.

- There are two source operands. The first source is an XMM register. The second source is a 64-bit memory location. The destination is an XMM register. Bits [127:64] of the source register are written to bits [127:64] of the destination; bits [63:0] of the source memory location are written to bits [63:0] of the destination. Bits [255:128] of the YMM register that corresponds to the destination are cleared.
- The source operand is bits [63:0] of an XMM register. The destination is a 64-bit memory location.

Instruction Support

Form	Subset	Feature Flag
MOVLPS	SSE1	CPUID Fn0000_0001_EDX[SSE] (bit 25)
VMOVLPS	AVX	CPUID Fn0000_0001_ECX[AVX] (bit 28)

For more on using the CPUID instruction to obtain processor feature support information, see Appendix E of Volume 3.

Instruction Encoding

Mnemonic	Opcode	Description
MOVLPS *xmm1*, *mem64*	0F 12 /r	Moves two packed single-precision floating-point value from *mem64* to *xmm1[63:0].*
MOVLPS *mem64*, *xmm1*	0F 13 /r	Moves two packed single-precision floating-point value from *xmm1[63:0]* to *mem64*.

MOVMSKPD Extract Sign Mask
VMOVMSKPD Packed Double-Precision Floating-Point

Extracts the sign bits of packed double-precision floating-point values from an XMM register, zero-extends the value, and writes it to the low-order bits of a general-purpose register.

There are legacy and extended forms of the instruction:

MOVMSKPD

Extracts two mask bits.

The source operand is an XMM register. The destination can be either a 64-bit or a 32-bit general purpose register. Writes the extracted bits to positions [1:0] of the destination and clears the remaining bits. Bits [255:128] of the YMM register that corresponds to the source are not affected.

MOVMSKPD

The extended form of the instruction has both 128-bit and 256-bit encodings:

XMM Encoding

Extracts two mask bits.

The source operand is an XMM register. The destination can be either a 64-bit or a 32-bit general purpose register. Writes the extracted bits to positions [1:0] of the destination and clears the remaining bits. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

Extracts four mask bits.

The source operand is a YMM register. The destination can be either a 64-bit or a 32-bit general purpose register. Writes the extracted bits to positions [3:0] of the destination and clears the remaining bits.

Instruction Support

MOVNTDQ
VMOVNTDQ

Move Non-Temporal Double Quadword

Moves double quadword values from a register to a memory location.

Indicates to the processor that the data is non-temporal, and is unlikely to be used again soon. The processor treats the store as a write-combining (WC) memory write, which minimizes cache pollution. The method of minimization depends on the hardware implementation of the instruction. For further information, see “Memory Optimization” in Volume 1.

The instruction is weakly-ordered with respect to other instructions that operate on memory. Software should use an SFENCE or MFENCE instruction to force strong memory ordering of MOVNTDQ with respect to other stores.

An attempted store to a non-aligned memory location results in a #GP exception.

There are legacy and extended forms of the instruction:

MOVNTDQ

Moves one 128-bit value.

The source operand is an XMM register. The destination is a 128-bit memory location.

VMOVNTDQ

The extended form of the instruction has both 128-bit and 256-bit encodings:

XMM Encoding

Moves one 128-bit value.

The source operand is an XMM register. The destination is a 128-bit memory location.

YMM Encoding

Moves two 128-bit values.

The source operand is a YMM register. The destination is a 256-bit memory location.

MOVNTDQA Move Non-Temporal
VMOVNTDQA Double Quadword Aligned

Loads an XMM/YMM register from a naturally-aligned 128-bit or 256-bit memory location.

Indicates to the processor that the data is non-temporal, and is unlikely to be used again soon. The processor treats the load as a write-combining (WC) memory read, which minimizes cache pollution. The method of minimization depends on the hardware implementation of the instruction. For further information, see “Memory Optimization” in Volume 1.

The instruction is weakly-ordered with respect to other instructions that operate on memory. Software should use an MFENCE instruction to force strong memory ordering of MOVNTDQA with respect to other reads.

An attempted load from a non-aligned memory location results in a #GP exception.

There are legacy and extended forms of the instruction:

MOVNTDQA

Loads a 128-bit value into the specified XMM register from a 16-byte aligned memory location.

VMOVNTDQA

The extended form of the instruction has both 128-bit and 256-bit encodings:

XMM Encoding

Loads a 128-bit value into the specified XMM register from a 16-byte aligned memory location.

YMM Encoding

Loads a 256-bit value into the specified YMM register from a 32-byte aligned memory location.

MOVNTPS VMOVNTPS — Move Non-Temporal Packed Single-Precision Floating-Point

Moves packed single-precision floating-point values from a register to a memory location.

Indicates to the processor that the data is non-temporal, and is unlikely to be used again soon. The processor treats the store as a write-combining (WC) memory write, which minimizes cache pollution. The method of minimization depends on the hardware implementation of the instruction. For further information, see “Memory Optimization” in Volume 1.

The instruction is weakly-ordered with respect to other instructions that operate on memory. Software should use an SFENCE or MFENCE instruction to force strong memory ordering of MOVNTDQ with respect to other stores.

An attempted store to a non-aligned memory location results in a #GP exception.

There are legacy and extended forms of the instruction:

MOVNTPS

Moves four values.

The source operand is an XMM register. The destination is a 128-bit memory location.

MOVNTPS

The extended form of the instruction has both 128-bit and 256-bit encodings:

XMM Encoding

Moves four values.

The source operand is an XMM register. The destination is a 128-bit memory location.

YMM Encoding

Moves eight values.

The source operand is a YMM register. The destination is a 256-bit memory location.

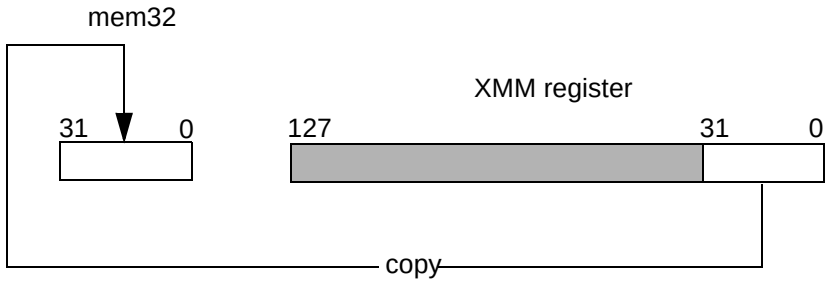
MOVNTSS Move Non-Temporal Scalar Single-Precision Floating-Point

Stores one single-precision floating-point value from an XMM register to a 32-bit memory location. This instruction indicates to the processor that the data is non-temporal, and is unlikely to be used again soon. The processor treats the store as a write-combining memory write, which minimizes cache pollution.

The diagram below illustrates the operation of this instruction:



Instruction Support

Form	Subset	Feature Flag
MOVNTSS	SSE4A	CPUID Fn8000_0001_ECX[SSE4A] (bit 6)

Software *must* check the CPUID bit once per program or library initialization before using the instruction, or inconsistent behavior may result. For more on using the CPUID instruction to obtain processor feature support information, see Appendix E of Volume 3.

Instruction Encoding

Mnemonic		Opcode	Description
MOVNTSS	*mem32*, *xmm*	F3 0F 2B /r	Stores one single-precision floating-point XMM register value into a 32-bit memory location. Treat as a non-temporal store.

Related Instructions

MOVNTDQ, MOVNTI, MOVNTOPD, MOVNTPS, MOVNTQ, MOVNTSD

rFLAGS Affected

Exceptions

Exception	Real	Virtual 8086	Protected	Cause of Exception
Invalid opcode, #UD	X	X	X	The SSE4A instructions are not supported, as indicated by CPUID Fn8000_0001_ECX[SSE4A] = 0.
	X	X	X	The emulate bit (CR0.EM) was set to 1.
	X	X	X	The operating-system FXSAVE/FXRSTOR support bit (CR4.OSFXSR) was cleared to 0.
Device not available, #NM	X	X	X	The task-switch bit (CR0.TS) was set to 1.
Stack, #SS	X	X	X	A memory address exceeded the stack segment limit or was non-canonical.
General protection, #GP	X	X	X	A memory address exceeded a data segment limit or was non-canonical.
			X	A null data segment was used to reference memory.
			X	The destination operand was in a non-writable segment.
Page fault, #PF		X	X	A page fault resulted from executing the instruction.
Alignment check, #AC		X	X	An unaligned memory reference was performed while alignment checking was enabled.

MOVQ VMOVQ Move Quadword

Moves 64-bit values. The source is either the low-order quadword of an XMM register or a 64-bit memory location. The destination is either the low-order quadword of an XMM register or a 64-bit memory location. When the destination is a register, the 64-bit value is zero-extended to 128 bits.

There are legacy and extended forms of the instruction:

MOVQ

There are two encodings:

- The source operand is either an XMM register or a 64-bit memory location. The destination is an XMM register. The 64-bit value is zero-extended to 128 bits.
- The source operand is an XMM register. The destination is either an XMM register or a 64-bit memory location. When the destination is a register, the 64-bit value is zero-extended to 128 bits.

Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VMOVQ

The extended form of the instruction has three 128-bit encodings:

- The source operand is an XMM register. The destination is an XMM register. The 64-bit value is zero-extended to 128 bits.
- The source operand is a 64-bit memory location. The destination is an XMM register. The 64-bit value is zero-extended to 128 bits.
- The source operand is an XMM register. The destination is either an XMM register or a 64-bit memory location. When the destination is a register, the 64-bit value is zero-extended to 128 bits.

Bits [255:128] of the YMM register that corresponds to the destination are cleared.

Instruction Support

Form	Subset	Feature Flag
MOVQ	SSE2	CPUID Fn0000_0001_EDX[SSE2] (bit 26)
VMOVQ	AVX	CPUID Fn0000_0001_ECX[AVX] (bit 28)

For more on using the CPUID instruction to obtain processor feature support information, see Appendix E of Volume 3.

Instruction Encoding

Mnemonic	Opcode	Description
MOVQ *xmm1, xmm2/mem64*	F3 0F 7E /r	Move a zero-extended 64-bit value from *xmm2* or *mem64* to *xmm1*.
MOVQ *xmm1/mem64*, *xmm2*	66 0F D6 /r	Move a 64-bit value from *xmm2* to *xmm1* or *mem64*. Zero-extends for register destination.

Mnemonic	Encoding

X — AVX and SSE exception
A — AVX exception
S — SSE exception

MOVSD Move
VMOVSD Scalar Double-Precision Floating-Point

Moves scalar double-precision floating point values. The source is either a low-order quadword of an XMM register or a 64-bit memory location. The destination is either a low-order quadword of an XMM register or a 64-bit memory location.

There are legacy and extended forms of the instruction:

MOVSD

There are two encodings.

- The source operand is either an XMM register or a 64-bit memory location. The destination is an XMM register. If the source operand is a register, bits [127:64] of the destination are not affected. If the source operand is a 64-bit memory location, the upper 64 bits of the destination are cleared.
- The source operand is an XMM register. The destination is either an XMM register or a 64-bit memory location. When the destination is a register, bits [127:64] of the destination are not affected.

Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VMOVSD

The extended form of the instruction has four 128-bit encodings. Two of the encodings are functionally equivalent.

- The source operand is a 64-bit memory location. The destination is an XMM register. The 64-bit value is zero-extended to 128 bits.
- The source operand is an XMM register. The destination is a 64-bit memory location.
- Two functionally-equivalent encodings:
  There are two source XMM registers. The destination is an XMM register. Bits [127:64] of the first source register are copied to bits [127:64] of the destination; the 64-bit value in bits [63:0] of the second source register is written to bits [63:0] of the destination.

Bits [255:128] of the YMM register that corresponds to the destination are cleared.

This instruction must not be confused with the MOVSD (move string doubleword) instruction of the general-purpose instruction set. Assemblers can distinguish the instructions by the number and type of operands.

Instruction Support

Form	Subset	Feature Flag
MOVSD	SSE2	CPUID Fn0000_0001_EDX[SSE2] (bit 26)
VMOVSD	AVX	CPUID Fn0000_0001_ECX[AVX] (bit 28)

For more on using the CPUID instruction to obtain processor feature support information, see Appendix E of Volume 3.

Instruction Encoding

Mnemonic	Opcode	Description
MOVSD *xmm1, xmm2/mem64*	F2 0F 10 /r	Moves a 64-bit value from *xmm2 or mem64* to *xmm1*. Zero extends to 128 bits when source operand is memory.
MOVSD *xmm1/mem64*, *xmm2*	F2 0F 11 /r	Moves a 64-bit value from *xmm2* to *xmm1* or *mem64*.

	Encoding [1]			
Mnemonic	**VEX**	**RXB.map_select**	**W.vvvv.L.pp**	**Opcode**
VMOVSD *xmm1*, *mem64*	C4	$\overline{\text{RXB}}$.00001	X.1111.X.11	10 /r
VMOVSD *mem64*, *xmm1*	C4	$\overline{\text{RXB}}$.00001	X.1111.X.11	11 /r
VMOVSD *xmm1, xmm2*, *xmm3* [2]	C4	$\overline{\text{RXB}}$.00001	X.$\overline{src}$.X.11	10 /r
VMOVSD *xmm1, xmm2*, *xmm3* [2]	C4	$\overline{\text{RXB}}$.00001	X.$\overline{src}$.X.11	11 /r

Note 1: The addressing mode differentiates between the two operand form (where one operand is a memory location) and the three operand form (where all operands are held in registers).

Note 2: These two encodings are functionally equivalent.

MOVSHDUP VMOVSHDUP — Move High and Duplicate Single-Precision

Moves and duplicates odd-indexed single-precision floating-point values.

There are legacy and extended forms of the instruction:

MOVSHDUP

Moves and duplicates two odd-indexed single-precision floating-point values.

The source operand is an XMM register or a 128-bit memory location. The destination is an XMM register. Bits [127:96] of the source are duplicated and written to bits [127:96] and [95:64] of the destination. Bits [63:32] of the source are duplicated and written to bits [63:32] and [31:0] of the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VMOVSHDUP

The extended form of the instruction has both 128-bit and 256-bit encodings:

XMM Encoding

Moves and duplicates two odd-indexed single-precision floating-point values.

The source operand is an XMM register or a 128-bit memory location. The destination is an XMM register. Bits [127:96] of the source are duplicated and written to bits [127:96] and [95:64] of the destination. Bits [63:32] of the source are duplicated and written to bits [63:32] and [31:0] of the destination. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

Moves and duplicates four odd-indexed single-precision floating-point values.

The source operand is a YMM register or a 256-bit memory location. The destination is a YMM register. Bits [255:224] of the source are duplicated and written to bits [255:224] and [223:192] of the destination. Bits [191:160] of the source are duplicated and written to bits [191:160] and [159:128] of the destination. Bits [127:96] of the source are duplicated and written to bits [127:96] and [95:64] of the destination. Bits [63:32] of the source are duplicated and written to bits [63:32] and [31:0] of the destination.

MOVUPD Move Unaligned
VMOVUPD Packed Double-Precision Floating-Point

Moves packed double-precision floating-point values. Values can be moved from a register or memory location to a register; or from a register to a register or memory location.

A memory operand that is not aligned does not cause a general-protection exception.

There are legacy and extended forms of the instruction:

MOVUPD

Moves two double-precision floating-point values. There are encodings for each type of move.

- The source operand is either an XMM register or a 128-bit memory location. The destination operand is an XMM register.
- The source operand is an XMM register. The destination operand is either an XMM register or a 128-bit memory location.

Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VMOVUPD

The extended form of the instruction has both 128-bit and 256-bit encodings:

XMM Encoding

Moves two double-precision floating-point values. There are encodings for each type of move.

- The source operand is either an XMM register or a 128-bit memory location. The destination operand is an XMM register.
- The source operand is an XMM register. The destination operand is either an XMM register or a 128-bit memory location.

Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

Moves four double-precision floating-point values. There are encodings for each type of move.

- The source operand is either a YMM register or a 256-bit memory location. The destination operand is a YMM register.
- The source operand is a YMM register. The destination operand is either a YMM register or a 256-bit memory location.

Instruction Support

MOVUPS VMOVUPS Move Unaligned Packed Single-Precision Floating-Point

Moves packed single-precision floating-point values. Values can be moved from a register or memory location to a register; or from a register to a register or memory location.

A memory operand that is not aligned does not cause a general-protection exception.

There are legacy and extended forms of the instruction:

MOVUPS

Moves four single-precision floating-point values. There are encodings for each type of move.

- The source operand is either an XMM register or a 128-bit memory location. The destination operand is an XMM register.
- The source operand is an XMM register. The destination operand is either an XMM register or a 128-bit memory location.

Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VMOVUPS

The extended form of the instruction has both 128-bit and 256-bit encodings:

XMM Encoding

Moves four single-precision floating-point values. There are encodings for each type of move.

- The source operand is either an XMM register or a 128-bit memory location. The destination operand is an XMM register.
- The source operand is an XMM register. The destination operand is either an XMM register or a 128-bit memory location.

Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

Moves eight single-precision floating-point values. There are encodings for each type of move.

- The source operand is either a YMM register or a 256-bit memory location. The destination operand is a YMM register.
- The source operand is a YMM register. The destination operand is either a YMM register or a 256-bit memory location.

Instruction Support

MPSADBW VMPSADBW Multiple Sum of Absolute Differences

Calculates 8 or 16 sums of absolute differences of sequentially selected groups of four contiguous unsigned byte integers in the first source operand and a selected group of four contiguous unsigned byte integers in a second source operand and writes the eight or sixteen 16-bit unsigned integer sums to sequential words of the destination register. The 256-bit form of the instruction additionally performs a similar but independent calculation using the upper 128 bits of the source operands.

Figure 2-2 on page 238 provides a graphical representation of the operation of the instruction. The following description accompanies it.

The computation uses as inputs 11 bytes from the first source operand and 4 bytes in the second source operand. Bit fields in the imm8 operand specify the index of the right-most byte of each group.

Bits [1:0] of the immediate operand determine the index of the right-most byte of four contiguous bytes within the second source operand used in the operation that produces the result (or, in the case of the 256-bit form of the instruction, the lower 128 bits of the result). Bit 2 of the immediate operand determines the right-most index of the 11contiguous bytes in the first source operand used in the same calculation. In the 128-bit form of the instruction, bits [7:3] of the immediate operand are ignored.

Bits [4:3] of the immediate operand determine the index of the right-most byte of four contiguous bytes within the second source operand used in the operation that produces the upper 128 bits of the result in the 256-bit form of the instruction. Bit 5 of the immediate operand determines the right-most index of the 11 contiguous bytes within in the upper half of the first 256-bit source operand used in the same calculation. In the 256-bit form of the instruction, bits [7:6] of the immediate operand are ignored.

Each word of the destination register receives the result of a separate computation of the sum of absolute differences function applied to a specific pair of four-element vectors derived from the source operands. The sum of absolute differences function SumAbsDiff (A, B) takes as input two 4-element unsigned 8-bit integer vectors and produces a single unsigned 16-bit integer result. The function is defined as:

SumAbsDiff(A, B) = | A[0]-B[0] | + | A[1]-B[1] | + | A[2]-B[2] | + | A[3]-B[3] |

The sum of absolute differences function produces a quantitative measure of the difference between two 4-element vectors. Each of the calculations that generates a result uses this metric to assess the difference between the selected 4-byte vector from operand 2 (B in the above equation) with each of eight overlapping 4-byte vectors (A in the equation) selected sequentially from the first source operand.

The right-most word (Word 0) of the destination receives the result of the comparison of the right-most 4 bytes of the selected group of 11 from operand 1 (src1[i1+3 : i1], as shown in the figure) to the selected 4 bytes from operand 2 (src2[j1+3:j1], in the figure). Word 1 of the destination receives the result of the comparison of the four bytes starting at an offset of 1 from the right-most byte of the group of 11 (src1[i1+4 : i1+1] in the figure) to the 4 bytes from operand 2. Word 2 of the destination receives the result of the comparison of the four bytes starting at an offset of 2 from the right-most byte of the group of 11 (src1[i1+5 : i1+2], in the figure) to the selected 4 bytes from operand 2. This continues in like manner until the left-most four bytes of the 11 are compared to the 4 bytes from operand 2 with the result being written to Word 7. This completes the generation of the lower 128 bits of the result.

The generation of the upper 128 bits of the result for the 256-bit form of the instruction is performed in like manner using separately selected groups of bytes from the upper half of the 256-bit operands, as described above.

The following is a more formal description of the operation of the (V)MPSADBW instruction:

For both the 128-bit and 256-bit form of the instruction, the following set of operations is performed:

```
src1 and src2 are byte vectors that overlay the first and second source operand respectively.
dest is a word vector that overlays the destination register.
tmp1[ ] is an array of 4-element vectors derived from the first source operand.
tmp2 and tmp3 are 4-element vectors derived from the second source operand.

i1 = imm8[2] * 4
j1= imm8[1:0] * 4

tmp1[0] = {src1[i1+3], src1[i1+2], src1[i1+1], src1[i1]}
tmp1[1] = {src1[i1+4], src1[i1+3], src1[i1+2], src1[i1+1]}
tmp1[2] = {src1[i1+5], src1[i1+4], src1[i1+3], src1[i1+2]}
tmp1[3] = {src1[i1+6], src1[i1+5], src1[i1+4], src1[i1+3]}
tmp1[4] = {src1[i1+7], src1[i1+6], src1[i1+5], src1[i1+4]}
tmp1[5] = {src1[i1+8], src1[i1+7], src1[i1+6], src1[i1+5]}
tmp1[6] = {src1[i1+9], src1[i1+8], src1[i1+7], src1[i1+6]}
tmp1[7] = {src1[i1+10], src1[i1+9], src1[i1+8], src1[i1+7]}
tmp2 = {src2[j1+3], src2[j1+2], src2[j1+1], src2[j1]}

dest[0] = SumAbsDiff(tmp1[0], tmp2)
dest[1] = SumAbsDiff(tmp1[1], tmp2)
dest[2] = SumAbsDiff(tmp1[2], tmp2)
dest[3] = SumAbsDiff(tmp1[3], tmp2)
dest[4] = SumAbsDiff(tmp1[4], tmp2)
dest[5] = SumAbsDiff(tmp1[5], tmp2)
dest[6] = SumAbsDiff(tmp1[6], tmp2)
dest[7] = SumAbsDiff(tmp1[7], tmp2)
```

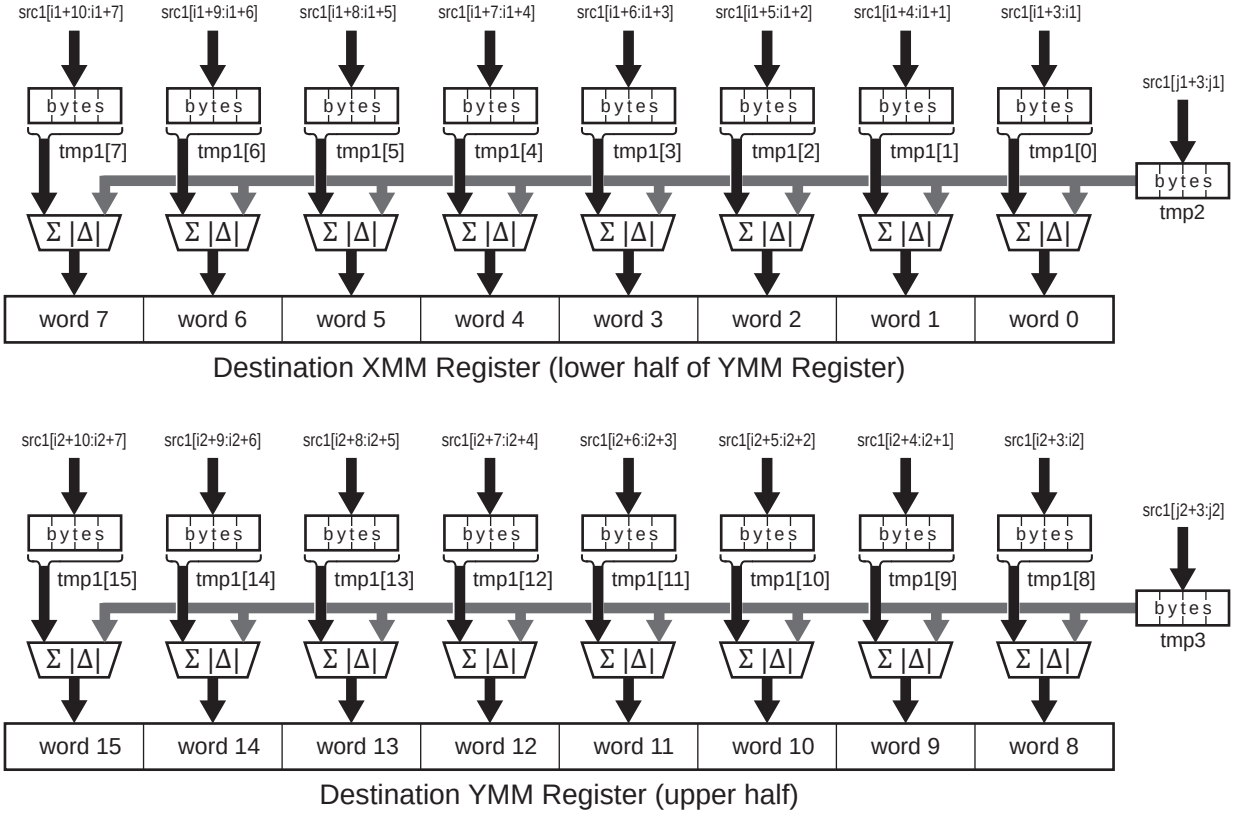
Additionally, for the 256-bit form of the instruction, the following set of operations is performed:

```
i2 = imm8[5] * 4 + 16
j2= imm8[4:3] * 4 +16

tmp1[8] = {src1[i2+3], src1[i2+2], src1[i2+1], src1[i2]}
tmp1[9] = {src1[i2+4], src1[i2+3], src1[i2+2], src1[i2+1]}
tmp1[10] = {src1[i2+5], src1[i2+4], src1[i2+3], src1[i2+2]}
tmp1[11] = {src1[i2+6], src1[i2+5], src1[i2+4], src1[i2+3]}
tmp1[12] = {src1[i2+7], src1[i2+6], src1[i2+5], src1[i2+4]}
tmp1[13] = {src1[i2+8], src1[i2+7], src1[i2+6], src1[i2+5]}
tmp1[14] = {src1[i2+9], src1[i2+8], src1[i2+7], src1[i2+6]}
tmp1[15] = {src1[i2+10], src1[i2+9], src1[i2+8], src1[i2+7]}
tmp3 = {src2[j2+3], src2[j2+2], src2[j2+1], src2[j2]}

dest[8] = SumAbsDiff(tmp1[8], tmp3)
dest[9] = SumAbsDiff(tmp1[9], tmp3)
dest[10] = SumAbsDiff(tmp1[10], tmp3)
dest[11] = SumAbsDiff(tmp1[11], tmp3)
```

dest[12] = SumAbsDiff(tmp1[12], tmp3)
dest[13] = SumAbsDiff(tmp1[13], tmp3)
dest[14] = SumAbsDiff(tmp1[14], tmp3)
dest[15] = SumAbsDiff(tmp1[15], tmp3)



Notes:
- i1 is a byte offset into source operand 1 (i1 = imm8[2] * 4).
- j1 is a byte offset into source operand 2 (j1 = imm8[1:0] * 4)
- i2 is a second byte offset into source operand 1 (i2 = imm8[5] * 4 + 16)
- j2 is a second byte offset into source operand 2 (j2 = imm8[4:3] * 4 + 16)
- Σ |Δ| represents the sum of absolute differences function which operates on two 4-element unsigned packed byte values and produces an unsigned 16-bit integer.

MPSADBW_instruct2.eps

Figure 2-2. (V)MPSADBW Instruction

There are legacy and extended forms of the instruction:

MPSADBW

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The first source register is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VMPSADBW

The extended form of the instruction has 128-bit and 256-bit encodings:

XMM Encoding

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is either a YMM register or a 256-bit memory location. The destination is a third YMM register. Bits [127:0] of the destination receive the results of the first 8 sums of absolute differences calculation using the selected bytes of the lower halves of the two source operands. Bits [255:128] of the destination receive the results of the second 8 sums of absolute differences calculation using selected bytes of the upper halves of the two source operands.

MULSD VMULSD Multiply Scalar Double-Precision Floating-Point

Multiplies the double-precision floating-point value in the low-order quadword of the first source operand by the double-precision floating-point value in the low-order quadword of the second source operand and writes the product into the low-order quadword of the destination.

There are legacy and extended forms of the instruction:

MULSD

The first source operand is an XMM register and the second source operand is either an XMM register or a 64-bit memory location. The first source register is also the destination register. Bits [127:64] of the destination and bits [255:128] of the corresponding YMM register are not affected.

VMULSD

The extended form of the instruction has a 128-bit encoding only.

The first source operand is an XMM register and the second source operand is either an XMM register or a 64-bit memory location. The destination is a third XMM register. Bits [127:64] of the first source operand are copied to bits [127:64] of the destination. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

Instruction Support

Form	Subset	Feature Flag
MULSD	SSE2	CPUID Fn0000_0001_EDX[SSE2] (bit 26)
VMULSD	AVX	CPUID Fn0000_0001_ECX[AVX] (bit 28)

For more on using the CPUID instruction to obtain processor feature support information, see Appendix E of Volume 3.

Instruction Encoding

PABSB VPABSB — Packed Absolute Value Signed Byte

Computes the absolute value of 16 or 32 packed 8-bit signed integers in the source operand. Each byte of the destination receives an unsigned 8-bit integer that is the absolute value of the signed 8-bit integer in the corresponding byte of the source operand.

There are legacy and extended forms of the instruction:

PABSB

The source operand is an XMM register or a 128-bit memory location. The destination is an XMM register. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VPABSB

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

The source operand is an XMM register or a 128-bit memory location. The destination is an XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

The source operand is a YMM register or a 256-bit memory location. The destination is a YMM register. All 32 bytes of the destination are written.

Instruction Support

PABSD
VPABSD

Packed Absolute Value Signed Doubleword

Computes the absolute value of four or eight packed 32-bit signed integers in the source operand. Each doubleword of the destination receives an unsigned 32-bit integer that is the absolute value of the signed 32-bit integer in the corresponding doubleword of the source operand.

There are legacy and extended forms of the instruction:

PABSD

The source operand is an XMM register or a 128-bit memory location. The destination is an XMM register. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VPABSD

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

The source operand is an XMM register or a 128-bit memory location. The destination is an XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

The source operand is a YMM register or a 256-bit memory location. The destination is a YMM register. All four doublewords of the destination are written.

PABSW VPABSW Packed Absolute Value Signed Word

Computes the absolute value of eight or sixteen packed 16-bit signed integers in the source operand. Each word of the destination receives an unsigned 16-bit integer that is the absolute value of the signed 16-bit integer in the corresponding word of the source operand.

There are legacy and extended forms of the instruction:

PABSW

The source operand is an XMM register or a 128-bit memory location. The destination is an XMM register. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VPABSW

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

The source operand is an XMM register or a 128-bit memory location. The destination is an XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

The source operand is a YMM register or a 256-bit memory location. The destination is a YMM register. All 16 words of the destination are written.

Instruction Support

Form	Subset	Feature Flag

S — SSE exception

PACKSSDW VPACKSSDW — Pack with Signed Saturation Doubleword to Word

Converts four or eight 32-bit signed integers from the first source operand and the second source operand into 16-bit signed integers and packs the results into the destination.

Positive source value greater than 7FFFh are saturated to 7FFFh; negative source values less than 8000h are saturated to 8000h.

Converted values from the first source operand are packed into the low-order words of the destination; converted values from the second source operand are packed into the high-order words of the destination.

There are legacy and extended forms of the instruction:

PACKSSDW

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The first source register is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VPACKSSDW

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is either a YMM register or a 256-bit memory location. The destination is a third YMM register.

Instruction Support

PADDB VPADDB — Packed Add Bytes

Adds 16 or 32 packed 8-bit integer values in the first source operand to corresponding values in the second source operand and writes the integer sums to the corresponding bytes of the destination.

This instruction operates on both signed and unsigned integers. When a result overflows, the carry is ignored (neither the overflow nor carry bit in rFLAGS is set), and only the low-order 8 bits of each result are written to the destination.

There are legacy and extended forms of the instruction:

PADDB

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The first source register is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VPADDB

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is either a YMM register or a 256-bit memory location. The destination is a third YMM register.

PADDSB VPADDSB — Packed Add with Signed Saturation Bytes

Adds 16 or 32 packed 8-bit signed integer values in the first source operand to the corresponding values in the second source operand and writes the signed integer sums to corresponding bytes of the destination.

Positive sums greater than 7Fh are saturated to 7Fh; negative sums less than 80h are saturated to 80h.

There are legacy and extended forms of the instruction:

PADDSB

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The first source register is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VPADDSB

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is either a YMM register or a 256-bit memory location. The destination is a third YMM register.

PADDW VPADDW — Packed Add Words

Adds or 16 packed 16-bit integer value in the first source operand to the corresponding values in the second source operand and writes the integer sums to the corresponding word of the destination.

This instruction operates on both signed and unsigned integers. When a result overflows, the carry is ignored (neither the overflow nor carry bit in rFLAGS is set), and only the low-order 16 bits of each result are written to the destination.

There are legacy and extended forms of the instruction:

PADDW

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The first source register is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VPADDW

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is either a YMM register or a 256-bit memory location. The destination is a third YMM register.

Instruction Support

PALIGNR Packed Align Right
VPALIGNR

Concatenates one or two pairs of 16-byte values from the first and second source operands and right-shifts the concatenated values the number of bytes specified by the unsigned immediate operand. Writes the least-significant 16 bytes of the shifted result to the destination or writes the least-significant 16 bytes of the two shifted results to the upper and lower halves of the destination.

For the 128-bit form of the instruction, the first and second 128-bit source operands are concatenated to form a temporary 256-bit value with the first source operand occupying the most-significant half of the temporary value. After the right-shift operation, the lower 128 bits of the result are written to the destination.

For the 256-bit form of the instruction, the lower 16 bytes of the first and second source operands are concatenated to form a first temporary 256-bit value with the bytes from the first source operand occupying the most-significant half of the temporary value. The upper 16 bytes of the first and second source operands are concatenated to form a second temporary 256-bit value with the bytes from the first source operand occupying the most-significant half of the second temporary value. Both temporary values are right-shifted the number of bytes specified by the immediate operand. After the right-shift operation, the lower 16 bytes of the first temporary value are written to the lower 128 bits of the destination and the lower 16 bytes of the second temporary value are written to the upper 128 bits of the destination.

The binary value of the immediate operand determines the byte shift value. On each shift the most-significant byte is set to zero. When the byte shift value is greater than 31, the destination is zeroed.

There are two forms of the instruction.

PALIGNR

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The first source register is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VPALIGNR

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is either a YMM register or a 256-bit memory location. The destination is a third YMM register.

PAND Packed AND
VPAND

Performs a bitwise AND of the packed values in the first and second source operands and writes the result to the destination.

There are legacy and extended forms of the instruction:

PAND

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The first source register is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VPAND

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is either a YMM register or a 256-bit memory location. The destination is a third YMM register.

PANDN Packed AND NOT
VPANDN

Generates the ones' complement of the value in the first source operand and performs a bitwise AND of the complement and the value in the second source operand. Writes the result to the destination.

There are legacy and extended forms of the instruction:

PANDN

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The first source register is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VPANDN

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is either a YMM register or a 256-bit memory location. The destination is a third YMM register.

PAVGB
VPAVGB

Packed Average Unsigned Bytes

Computes the rounded averages of 16 or 32 packed unsigned 8-bit integer values in the first source operand and the corresponding values of the second source operand. Writes each average to the corresponding byte of the destination.

An average is computed by adding pairs of 8-bit integer values in corresponding positions in the two operands, adding 1 to a 9-bit temporary sum, and right-shifting the temporary sum by one bit position.

There are legacy and extended forms of the instruction:

PAVGB

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The first source register is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VPAVGB

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is either a YMM register or a 256-bit memory location. The destination is a third YMM register.

PBLENDVB Variable Blend
VPBLENDVB Packed Bytes

Copies packed bytes from either of two sources to a destination, as specified by a mask operand.

The mask is defined by the most significant bit of each byte of the mask operand. The position of a mask bit corresponds to the position of the most significant bit of a copied value.

- When a mask bit = 0, the specified element of the first source is copied to the corresponding position in the destination.
- When a mask bit = 1, the specified element of the second source is copied to the corresponding position in the destination.

There are legacy and extended forms of the instruction:

PBLENDVB

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The first source register is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected. The mask operand is the implicit register XMM0.

VPBLENDVB

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared. The mask operand is a fourth XMM register selected by bits [7:4] of an immediate byte.

YMM Encoding

The first source operand is a YMM register. The second source operand is either a YMM register or a 256-bit memory location. The destination is a third YMM register. The mask operand is a fourth YMM register selected by bits [7:4] of an immediate byte.

Instruction Support

S — SSE exception

PBLENDW VPBLENDW — Blend Packed Words

Copies packed words from either of two sources to a destination, as specified by an immediate 8-bit mask operand. For the 256-bit form, the same 8-bit mask is applied twice; once to select words to be written to the lower 128 bits of the destination and again to select words to be written to the upper 128 bits of the destination.

Each bit of the mask selects a word from one of the source operands based on the position of the word within the operand. Bit 0 of the mask selects the least-significant word (word 0) to be copied, bit 1 selects the next-most significant word (word 1), and so forth. Bit 7 selects word 7 (the most-significant word for 128-bit operands).

For the 256-bit operands, the mask is reused to select words in the upper 128-bits of the source operands to be copied. Bit 0 of the mask selects word 8, bit 1 selects word 9, and so forth. Finally, bit 7 of the mask selects the word from position 15.

- When a mask bit = 0, the specified element of the first source is copied to the corresponding position in the destination.
- When a mask bit = 1, the specified element of the second source is copied to the corresponding position in the destination.

There are legacy and extended forms of the instruction:

PBLENDW

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The first source register is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VPBLENDW

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is either a YMM register or a 256-bit memory location. The destination is a third YMM register.

Instruction Support

PCLMULQDQ Carry-less Multiply Quadwords
VPCLMULQDQ

Performs a carry-less multiplication of a selected quadword element of the first source operand by a selected quadword element of the second source operand and writes the product to the destination.

Carry-less multiplication, also known as *binary polynomial multiplication*, is the mathematical operation of computing the product of two operands without generating or propagating carries. It is an essential component of cryptographic processing, and typically requires a large number of cycles.

The instruction provides an efficient means of performing the operation and is particularly useful in implementing the Galois counter mode used in the Advanced Encryption Standard (AES). See Appendix A on page 975 for additional information.

Bits 4 and 0 of an 8-bit immediate byte operand specify which quadword of each source operand to multiply, as follows.

Mnemonic	Imm[0]	Imm[4]	Quadword Operands Selected
(V)PCLMULLQLQDQ	0	0	SRC1[63:0], SRC2[63:0]
(V)PCLMULHQLQDQ	1	0	SRC1[127:64], SRC2[63:0]
(V)PCLMULLQHQDQ	0	1	SRC1[63:0], SRC2[127:64]
(V)PCLMULHQHQDQ	1	1	SRC1[127:64], SRC2[127:64]

Alias mnemonics are provided for the various immediate byte combinations.

There are legacy and extended forms of the instruction:

PCLMULQDQ

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The first source register is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VPCLMULQDQ

The extended form of the instruction has both 128-bit and 256-bit encodings:

XMM

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM

The first source operand is a YMM register and the second source operand is either a YMM register or a 256-bit memory location. The destination is a third YMM register.

Instruction Support

PCMPEQB VPCMPEQB — Packed Compare Equal Bytes

Compares packed byte values in the first source operand to corresponding values in the second source operand and writes a comparison result to the corresponding byte of the destination.

When values are equal, the result is FFh; when values are not equal, the result is 00h.

There are legacy and extended forms of the instruction:

PCMPEQB

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The first source register is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VPCMPEQB

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is either a YMM register or a 256-bit memory location. The destination is a third YMM register.

PCMPESTRI Packed Compare
VPCMPESTRI Explicit Length Strings Return Index

Compares character string data in the first and second source operands. Comparison operations are carried out as specified by values encoded in the immediate operand. Writes an index to the ECX register.

Source operands are formatted as a packed characters in one of two supported widths: 8 or 16 bits. Characters may be treated as either signed or unsigned values. Each operand has associated with it a separate integer value specifying the length of the string.

The absolute value of the data in the EAX/RAX register represents the length of the character string in the first source operand; the absolute value of the data in the EDX/RDX register represents the length of the character string in the second source operand.

If the absolute value of the data in either register is greater than the maximum string length that fits in 128 bits, the length is set to the maximum: 8, for 16-bit characters, or 16, for 8-bit characters.

The comparison operations between the two operand strings are summarized in an intermediate result—a comparison summary bit vector that is post-processed to produce the final output. Data fields within the immediate byte specify the source data format, comparison type, comparison summary bit vector post-processing, and output option selection.

The index of either the most significant or least significant set bit of the post-processed comparison summary bit vector is returned in ECX. If no bits are set in the post-processed comparison summary bit vector, ECX is set to 16 for source operand strings composed of 8-bit characters or 8 for 16-bit character strings.

See Section 1.5, “String Compare Instructions” for information about source string data format, comparison operations, comparison summary bit vector generation, post-processing, and output selection options.

The rFLAGS are set to indicate the following conditions:

Flag	Condition
CF	Cleared if the comparison summary bit vector is zero; otherwise set.
PF	cleared.
AF	cleared.
ZF	Set if the specified length of the second string is less than the maximum; otherwise cleared.
SF	Set if the specified length of the first string is less than the maximum; otherwise cleared.
OF	Equal to the value of the lsb of the post-processed comparison summary bit vector.

There are legacy and extended forms of the instruction:

PCMPESTRI

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. A result index is written to the ECX register.

VPCMPESTRI

The extended form of the instruction has a 128-bit encoding only.

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. A result index is written to the ECX register.

Instruction Support

PCMPESTRM Packed Compare
VPCMPESTRM Explicit Length Strings Return Mask

Compares character string data in the first and second source operands. Comparison operations are carried out as specified by values encoded in the immediate operand. Writes a mask value to the YMM0/XMM0 register.

Source operands are formatted as a packed characters in one of two supported widths: 8 or 16 bits. Characters may be treated as either signed or unsigned values. Each operand has associated with it a separate integer value specifying the length of the string.

The absolute value of the data in the EAX/RAX register represents the length of the character string in the first source operand; the absolute value of the data in the EDX/RDX register represents the length of the character string in the second source operand.

If the absolute value of the data in either register is greater than the maximum string length that fits in 128 bits, the length is set to the maximum: 8, for 16-bit characters, or 16, for 8-bit characters.

The comparison operations between the two operand strings are summarized in an intermediate result—a comparison summary bit vector that is post-processed to produce the final output. Data fields within the immediate byte specify the source data format, comparison type, comparison summary bit vector post-processing, and output option selection.

Depending on the output option selected, the post-processed comparison summary bit vector is either zero-extended to 128 bits or expanded into a byte/word-mask and then written to XMM0.

See Section 1.5, “String Compare Instructions” for information about source string data format, comparison operations, comparison summary bit vector generation, post-processing, and output selection options.

The rFLAGS are set to indicate the following conditions:

Flag	Condition
CF	Cleared if the comparison summary bit vector is zero; otherwise set.
PF	cleared.
AF	cleared.
ZF	Set if the specified length of the second string is less than the maximum; otherwise cleared.
SF	Set if the specified length of the first string is less than the maximum; otherwise cleared.
OF	Equal to the value of the lsb of the post-processed summary bit vector.

There are legacy and extended forms of the instruction:

PCMPESTRM

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The mask result is written to the XMM0 register.

VPCMPESTRM

The extended form of the instruction has a 128-bit encoding only.

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The mask result is written to the XMM0 register. Bits [255:128] of the YMM0 register are cleared.

Instruction Support

VPCMPGTB
Packed Compare Greater Than Signed Bytes

Compares packed signed byte values in the first source operand to corresponding values in the second source operand and writes a comparison result to the corresponding byte of the destination.

When a value in the first operand is greater than a value in the second source operand, the result is FFh; when a value in the first operand is less than or equal to a value in the second operand, the result is 00h.

There are legacy and extended forms of the instruction:

PCMPGTB

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The first source register is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VPCMPGTB

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is either a YMM register or a 256-bit memory location. The destination is a third YMM register.

Instruction Support

Form	Subset	Feature Flag
PCMPGTB	SSE2	CPUID Fn0000_0001_EDX[SSE2] (bit 26)
VPCMPGTB 128-bit	AVX	CPUID Fn0000_0001_ECX[AVX] (bit 28)
VPCMPGTB 256-bit	AVX2	CPUID Fn0000_0007_EBX[AVX2]_x0 (bit 5)

For more on using the CPUID instruction to obtain processor feature support information, see Appendix E of Volume 3.

Instruction Encoding

Mnemonic	Opcode	Description
PCMPGTB *xmm1*, *xmm2/mem128*	66 0F 64 /r	Compares packed bytes in *xmm1* to packed bytes in *xmm2* or *mem128*. Writes results to *xmm1.*

PCMPISTRI Packed Compare
VPCMPISTRI Implicit Length Strings Return Index

Compares character string data in the first and second source operands. Comparison operations are carried out as specified by values encoded in the immediate operand. Writes an index to the ECX register.

Source operands are formatted as a packed characters in one of two supported widths: 8 or 16 bits. Characters may be treated as either signed or unsigned values.

Source operand strings shorter than the maximum that can be packed into a 128-bit value are terminated by a null character (value of 0). The characters prior to the null character constitute the string. If the first (lowest indexed) character is null, the string length is 0.

The comparison operations between the two operand strings are summarized in an intermediate result—a comparison summary bit vector that is post-processed to produce the final output. Data fields within the immediate byte specify the source data format, comparison type, comparison summary bit vector post-processing, and output option selection.

The index of either the most significant or least significant set bit of the post-processed comparison summary bit vector is returned in ECX. If no bits are set in the post-processed comparison summary bit vector, ECX is set to 16 for source operand strings composed of 8-bit characters or 8 for 16-bit character strings.

See Section 1.5, “String Compare Instructions” for information about source string data format, comparison operations, comparison summary bit vector generation, post-processing, and output selection options.

The rFLAGS are set to indicate the following conditions:

Flag	Condition
CF	Cleared if the comparison summary bit vector is zero; otherwise set.
PF	cleared.
AF	cleared.
ZF	Set if any byte (word) in the second operand is null; otherwise cleared.
SF	Set if any byte (word) in the first operand is null; otherwise cleared
OF	Equal to the value of the lsb of the post-processed summary bit vector.

There are legacy and extended forms of the instruction:

PCMPISTRI

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. A result index is written to the ECX register.

VPCMPISTRI

The extended form of the instruction has a 128-bit encoding only.

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. A result index is written to the ECX register.

Instruction Support

PCMPISTRM VPCMPISTRM — Packed Compare Implicit Length Strings Return Mask

Compares character string data in the first and second source operands. Comparison operations are carried out as specified by values encoded in the immediate operand. Writes a mask value to the YMM0/XMM0 register

Source operands are formatted as a packed characters in one of two supported widths: 8 or 16 bits. Characters may be treated as either signed or unsigned values.

Source operand strings shorter than the maximum that can be packed into a 128-bit value are terminated by a null character (value of 0). The characters prior to the null character constitute the string. If the first (lowest indexed) character is null, the string length is 0.

The comparison operations between the two operand strings are summarized in an intermediate result—a comparison summary bit vector that is post-processed to produce the final output. Data fields within the immediate byte specify the source data format, comparison type, comparison summary bit vector post-processing, and output option selection.

Depending on the output option selected, the post-processed comparison summary bit vector is either zero-extended to 128 bits or expanded into a byte/word-mask and then written to XMM0.

See Section 1.5, “String Compare Instructions” for information about source string data format, comparison operations, comparison summary bit vector generation, post-processing, and output selection options.

The rFLAGS are set to indicate the following conditions:

Flag	Condition
CF	Cleared if the comparison summary bit vector is zero; otherwise set.
PF	cleared.
AF	cleared.
ZF	Set if any byte (word) in the second operand is null; otherwise cleared.
SF	Set if any byte (word) in the first operand is null; otherwise cleared.
OF	Equal to the value of the lsb of the post-processed summary bit vector.

There are legacy and extended forms of the instruction:

PCMPISTRM

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The mask result is written to the XMM0 register.

VPCMPISTRM

The extended form of the instruction has a 128-bit encoding only.

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The mask result is written to the XMM0 register. Bits [255:128] of the YMM0 register are cleared.

Instruction Support

Form	Subset	Feature Flag
PCMPISTRM	SSE4.2	CPUID Fn0000_0001_ECX[SSE42] (bit 20)
VPCMPISTRM	AVX	CPUID Fn0000_0001_ECX[AVX] (bit 28)

PEXTRB Extract
VPEXTRB Packed Byte

Extracts a byte from a source register and writes it to an 8-bit memory location or to the low-order byte of a general-purpose register, with zero-extension to 32 or 64 bits. Bits [3:0] of an immediate byte operand select the byte to be extracted:

Value of imm8 [3:0]	Source Bits Extracted
0000	[7:0]
0001	[15:8]
0010	[23:16]
0011	[31:24]
0100	[39:32]
0101	[47:40]
0110	[55:48]
0111	[63:56]
1000	[71:64]
1001	[79:72]
1010	[87:80]
1011	[95:88]
1100	[103:96]
1101	[111:104]
1110	[119:112]
1111	[127:120]

There are legacy and extended forms of the instruction:

PEXTRB

The source operand is an XMM register and the destination is either an 8-bit memory location or the low-order byte of a general-purpose register. When the destination is a general-purpose register, the extracted byte is zero-extended to 32 or 64 bits.

VPEXTRB

The extended form of the instruction has a 128-bit encoding only.

The source operand is an XMM register and the destination is either an 8-bit memory location or the low-order byte of a general-purpose register. When the destination is a general-purpose register, the extracted byte is zero-extended to 32 or 64 bits.

Instruction Support

Form	Subset	Feature Flag
PEXTRB	SSE4.1	CPUID Fn0000_0001_ECX[SSE41] (bit 19)
VPEXTRB	AVX	CPUID Fn0000_0001_ECX[AVX] (bit 28)

For more on using the CPUID instruction to obtain processor feature support information, see Appendix E of Volume 3.

Instruction Encoding

Mnemonic	Opcode	Description
PEXTRB *reg/m8*, *xmm*, *imm8*	66 0F 3A 14 /r ib	Extracts an 8-bit value specified by *imm8* from *xmm* and writes it to *m8* or the low-order byte of a general-purpose register, with zero-extension.

Mnemonic	Encoding			
	VEX	RXB.map_select	W.vvvv.L.pp	Opcode
VPEXTRB *reg/mem8*, *xmm, imm8*	C4	$\overline{\text{RXB}}$.03	X.1111.0.01	14 /r ib

PEXTRD Extract
VPEXTRD Packed Doubleword

Extracts a doubleword from a source register and writes it to an 32-bit memory location or a 32-bit general-purpose register. Bits [1:0] of an immediate byte operand select the doubleword to be extracted:

Value of imm8 [1:0]	Source Bits Extracted
00	[31:0]
01	[63:32]
10	[95:64]
11	[127:96]

There are legacy and extended forms of the instruction:

PEXTRD

The encoding is the same as PEXTRQ, with REX.W = 0.

The source operand is an XMM register and the destination is either an 32-bit memory location or a 32-bit general-purpose register.

VPEXTRD

The extended form of the instruction has a 128-bit encoding only.

The encoding is the same as VPEXTRQ, with VEX.W = 0.

The source operand is an XMM register and the destination is either an 32-bit memory location or a 32-bit general-purpose register.

Instruction Support

Form	Subset	Feature Flag
PEXTRD	SSE4.1	CPUID Fn0000_0001_ECX[SSE41] (bit 19)
VPEXTRD	AVX	CPUID Fn0000_0001_ECX[AVX] (bit 28)

For more on using the CPUID instruction to obtain processor feature support information, see Appendix E of Volume 3.

Instruction Encoding

Mnemonic	Opcode	Description
PEXTRD *reg32/mem32*, *xmm*, *imm8*	66 (W0) 0F 3A 16 /r ib	Extracts a 32-bit value specified by *imm8* from *xmm* and writes it to *mem32* or *reg32*.

Mnemonic	Encoding			
	VEX	RXB.map_select	W.vvvv.L.pp	Opcode

PEXTRQ Extract
VPEXTRQ Packed Quadword

Extracts a quadword from a source register and writes it to an 64-bit memory location or to a 64-bit general-purpose register. Bit [0] of an immediate byte operand selects the quadword to be extracted:

Value of imm8 [0]	Source Bits Extracted
0	[63:0]
1	[127:64]

There are legacy and extended forms of the instruction:

PEXTRQ

The encoding is the same as PEXTRD, with REX.W = 1.

The source operand is an XMM register and the destination is either an 64-bit memory location or a 64-bit general-purpose register.

VPEXTRQ

The extended form of the instruction has a 128-bit encoding only.

The encoding is the same as VPEXTRD, with VEX.W = 1.

The source operand is an XMM register and the destination is either an 64-bit memory location or a 64-bit general-purpose register.

Instruction Support

Form	Subset	Feature Flag
PEXTRD	SSE4.1	CPUID Fn0000_0001_ECX[SSE41] (bit 19)
VPEXTRD	AVX	CPUID Fn0000_0001_ECX[AVX] (bit 28)

For more on using the CPUID instruction to obtain processor feature support information, see Appendix E of Volume 3.

Instruction Encoding

Mnemonic	Opcode	Description
PEXTRQ *reg64/mem64*, *xmm*, *imm8*	66 (W1) 0F 3A 16 /r ib	Extracts a 64-bit value specified by *imm8* from *xmm* and writes it to *mem64* or *reg64*.

PEXTRW
VPEXTRW
Extract Packed Word

Extracts a word from a source register and writes it to a 16-bit memory location or to the low-order word of a general-purpose register, with zero-extension to 32 or 64 bits. Bits [3:0] of an immediate byte operand select the word to be extracted:

Value of imm8 [2:0]	Source Bits Extracted
000	[15:0]
001	[31:16]
010	[47:32
011	[63:48]
100	[79:64]
101	[95:80]
110	[111:96]
111	[127:112]

There are legacy and extended forms of the instruction:

PEXTRW

The legacy form of the instruction has SSE2 and SSE4.1 encodings.

The source operand is an XMM register and the destination is the low-order word of a general-purpose register. The extracted word is zero-extended to 32 or 64 bits.

The source operand is an XMM register and the destination is either an 16-bit memory location or the low-order word of a general-purpose register. When the destination is a general-purpose register, the extracted word is zero-extended to 32 or 64 bits.

VPEXTRW

The extended form of the instruction has two 128-bit encodings that correspond to the two legacy encodings.

The source operand is an XMM register and the destination is the low-order word of a general-purpose register. The extracted word is zero-extended to 32 or 64 bits.

The source operand is an XMM register and the destination is either an 16-bit memory location or the low-order word of a general-purpose register. When the destination is a general-purpose register, the extracted word is zero-extended to 32 or 64 bits.

Instruction Support

PHADDD Packed Horizontal Add
VPHADDD Doubleword

Adds adjacent 32-bit signed integers in each of two source operands and packs the sums into the destination. If a sum overflows, the carry is ignored (neither the overflow nor carry bit in rFLAGS is set) and only the low-order 32 bits of the sum are written in the destination.

Adds the 32-bit signed integer values in bits [63:32] and bits [31:0] of the first source operand and packs the sum into bits [31:0] of the destination; adds the 32-bit signed integer values in bits [127:96] and bits [95:64] of the first source operand and packs the sum into bits [63:32] of the destination. Adds the corresponding values in the second source operand and packs the sums into bits [95:64] and [127:96] of the destination.

Additionally, for the 256-bit form, adds the 32-bit signed integer values in bits [191:160] and bits [159:128] of the first source operand and packs the sum into bits [159:128] of the destination; adds the 32-bit signed integer values in bits [255:224] and bits [223:192] of the first source operand and packs the sum into bits [191:160] of the destination. Adds the corresponding values in the second source operand and packs the sums into bits [223:192] and [255:224] of the destination.

There are legacy and extended forms of the instruction:

PHADDD

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The first source register is also the destination register. Bits [255:128] of the YMM register that corresponds to the destination not affected.

VPHADDD

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is either a YMM register or a 256-bit memory location. The destination is a third YMM register.

PHADDSW VPHADDSW Packed Horizontal Add with Saturation Word

Adds adjacent 16-bit signed integers in each of two source operands, with saturation, and packs the 16-bit signed sums into the destination.

Positive sums greater than 7FFFh are saturated to 7FFFh; negative sums less than 8000h are saturated to 8000h.

For the 128-bit form of the instruction, the following operations are performed:

```
dest is the destination register – either an XMM register or the corresponding YMM register.
src1 is the first source operand. src2 is the second source operand.
Ssum() is a function that returns the saturated 16-bit signed sum of its arguments.

dest[15:0] = Ssum(src1[31:16], src1[15:0])
dest[31:16] = Ssum(src1[63:48], src1[47:32])
dest[47:32] = Ssum(src1[95:80], src1[79:64])
dest[63:48] = Ssum(src1[127:112], src1[111:96])
dest[79:64] = Ssum(src2[31:16], src2[15:0])
dest[95:80] = Ssum(src2[63:48], src2[47:32])
dest[111:96] = Ssum(src2[95:80], src2[79:64])
dest[127:112] = Ssum(src2[127:112], src2[111:96])
```

Additionally, for the 256-bit form of the instruction, the following operations are performed:

```
dest[143:128] = Ssum(src1[159:144], src1[143:128])
dest[159:144] = Ssum(src1[191:176], src1[175:160])
dest[175:160] = Ssum(src1[223:208], src1[207:192])
dest[191:176] = Ssum(src1[255:240], src1[239:224])
dest[207:192] = Ssum(src2[159:144], src2[143:128])
dest[223:208] = Ssum(src2[191:176], src2[175:160])
dest[239:224] = Ssum(src2[223:208], src2[207:192])
dest[255:240] = Ssum(src2[255:240], src2[239:224])
```

There are legacy and extended forms of the instruction:

PHADDSW

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The first source register is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VPHADDSW

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is either a YMM register or a 256-bit memory location. The destination is a third YMM register.

PHADDW VPHADDW — Packed Horizontal Add Word

Adds adjacent 16-bit signed integers in each of two source operands and packs the 16-bit sums into the destination. If a sum overflows, the carry is ignored (neither the overflow nor carry bit in rFLAGS is set).

For the 128-bit form of the instruction, the following operations are performed:

dest is the destination register – either an XMM register or the corresponding YMM register.
src1 is the first source operand. src2 is the second source operand.

```
dest[15:0] = src1[31:16] + src1[15:0]
dest[31:16] = src1[63:48] + src1[47:32]
dest[47:32] = src1[95:80] + src1[79:64]
dest[63:48] = src1[127:112] + src1[111:96]
dest[79:64] = src2[31:16] + src2[15:0]
dest[95:80] = src2[63:48] + src2[47:32]
dest[111:96] = src2[95:80] + src2[79:64]
dest[127:112] = src2[127:112] + src2[111:96]
```

Additionally, for the 256-bit form of the instruction, the following operations are performed:

```
dest[143:128] = src1[159:144] + src1[143:128]
dest[159:144] = src1[191:176] + src1[175:160]
dest[175:160] = src1[223:208] + src1[207:192]
dest[191:176] = src1[255:240] + src1[239:224]
dest[207:192] = src2[159:144] + src2[143:128]
dest[223:208] = src2[191:176] + src2[175:160]

PHSUBD VPHSUBD Packed Horizontal Subtract Doubleword

Subtracts adjacent 32-bit signed integers in each of two source operands and packs the differences into the destination. The higher-order doubleword of each pair is subtracted from the lower-order doubleword.

Subtracts the 32-bit signed integer value in bits [63:32] of the first source operand from the 32-bit signed integer value in bits [31:0] of the first source operand and packs the difference into bits [31:0] of the destination; subtracts the 32-bit signed integer value in bits [127:96] of the first source operand from the 32-bit signed integer value in bits [95:64] of the first source operand and packs the difference into bits [63:32] of the destination. Performs the corresponding operations on pairs of 32-bit signed integer values in the second source operand and packs the differences into bits [95:64] and [127:96] of the destination.

Additionally, for the 256-bit form, subtracts the 32-bit signed integer value in bits [191:160] of the first source operand from the 32-bit signed integer value in bits [159:128] of the first source operand and packs the difference into bits [159:128] of the destination; subtracts the 32-bit signed integer value in bits [255:224] of the first source operand from the 32-bit integer value in bits [223:192] of the first source operand and packs the difference into bits [191:160] of the destination. Performs the corresponding operations on pairs of 32-bit signed integer values in the second source operand and packs the differences into bits [223:192] and [255:224] of the destination.

There are legacy and extended forms of the instruction:

PHSUBD

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The first source register is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VPHSUBD

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is either a YMM register or a 256-bit memory location. The destination is a third YMM register.

PHSUBSW VPHSUBSW Packed Horizontal Subtract with Saturation Word

Subtracts adjacent 16-bit signed integers in each of two source operands, with saturation, and packs the differences into the destination. The higher-order word of each pair is subtracted from the lower-order word.

Positive differences greater than 7FFFh are saturated to 7FFFh; negative differences less than 8000h are saturated to 8000h.

For the 128-bit form of the instruction, the following operations are performed:

dest is the destination register – either an XMM register or the corresponding YMM register.
src1 is the first source operand. src2 is the second source operand.
Sdiff(A,B) is a function that returns the saturated 16-bit signed difference A − B.

```
dest[15:0] = Sdiff(src1[15:0], src1[31:16])
dest[31:16] = Sdiff(src1[47:32], src1[63:48])
dest[47:32] = Sdiff(src1[79:64], src1[95:80])
dest[63:48] = Sdiff(src1[111:96], src1[127:112])
dest[79:64] = Sdiff(src2[15:0], src2[31:16])
dest[95:80] = Sdiff(src2[47:32], src2[63:48])
dest[111:96] = Sdiff(src2[79:64], src2[95:80])
dest[127:112] = Sdiff(src2[111:96], src2[127:112])
```

Additionally, for the 256-bit form of the instruction, the following operations are performed:

```
dest[143:128] = Sdiff(src1[143:128], src1[159:144])
dest[159:144] = Sdiff(src1[175:160], src1[191:176])
dest[175:160] = Sdiff(src1[207:192], src1[223:208])
dest[191:176] = Sdiff(src1[239:224], src1[255:240])
dest[207:192] = Sdiff(src2[143:128], src2[159:144])
dest[223:208] = Sdiff(src2[175:160], src2[191:176])
dest[239:224] = Sdiff(src2[207:192], src2[223:208])
dest[255:240] = Sdiff(src2[239:224], src2[255:240])
```

There are legacy and extended forms of the instruction:

PHSUBSW

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The first source register is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VPHSUBSW

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is either a YMM register or a 256-bit memory location. The destination is a third YMM register.

PHSUBW VPHSUBW — Packed Horizontal Subtract Word

Subtracts adjacent 16-bit signed integers in each of two source operands and packs the differences into a destination. The higher-order word of each pair is subtracted from the lower-order word.

For the 128-bit form of the instruction, the following operations are performed:

dest is the destination register – either an XMM register or the corresponding YMM register.
src1 is the first source operand. src2 is the second source operand.

```
dest[15:0] = src1[15:0] − src1[31:16
dest[31:16] = src1[47:32] − src1[63:48]
dest[47:32] = src1[79:64] − src1[95:80]
dest[63:48] = src1[111:96] − src1[127:112]
dest[79:64] = src2[15:0] − src2[31:16]
dest[95:80] = src2[47:32] − src2[63:48]
dest[111:96] = src2[79:64] − src2[95:80]
dest[127:112] = src2[111:96] − src2[127:112]
```

Additionally, for the 256-bit form of the instruction, the following operations are performed:

```
dest[143:128] = src1[143:128] − src1[159:144]
dest[159:144] = src1[175:160] − src1[191:176]
dest[175:160] = src1[207:192] − src1[223:208]
dest[191:176] = src1[239:224] − src1[255:240]
dest[207:192] = src2[143:128] − src2[159:144]
dest[223:208] = src2[175:160] − src2[191:176]
dest[239:224] = src2[207:192] − src2[223:208]
dest[255:240] = src2[239:224] − src2[255:240]
```

There are legacy and extended forms of the instruction:

PHSUBW

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The first source register is also the destination register. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VPHSUBW

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

PINSRB VPINSRB Packed Insert Byte

Inserts a byte from an 8-bit memory location or the low-order byte of a 32-bit general-purpose register into a destination register. Bits [3:0] of an immediate byte operand select the location where the byte is to be inserted:

Value of imm8 [3:0]	Insertion Location
0000	[7:0]
0001	[15:8]
0010	[23:16]
0011	[31:24]
0100	[39:32]
0101	[47:40]
0110	[55:48]
0111	[63:56]
1000	[71:64]
1001	[79:72]
1010	[87:80]
1011	[95:88]
1100	[103:96]
1101	[111:104]
1110	[119:112]
1111	[127:120]

There are legacy and extended forms of the instruction:

PINSRB

The source operand is either an 8-bit memory location or the low-order byte of a 32-bit general-purpose register and the destination an XMM register. The other bytes of the destination are not affected. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VPINSRB

The extended form of the instruction has a 128-bit encoding only.

There are two source operands. The first source operand is either an 8-bit memory location or the low-order byte of a 32-bit general-purpose register and the second source operand is an XMM register. The destination is a second XMM register. All the bytes of the second source other than the byte that corresponds to the location of the inserted byte are copied to the destination. Bits [255:128] of the YMM register that corresponds to destination are cleared.

Instruction Support

Form	Subset	Feature Flag
PINSRB	SSE4.1	CPUID Fn0000_0001_ECX[SSE41] (bit 19)
VPINSRB	AVX	CPUID Fn0000_0001_ECX[AVX] (bit 28)

For more on using the CPUID instruction to obtain processor feature support information, see Appendix E of Volume 3.

PINSRD VPINSRD — Packed Insert Doubleword

Inserts a doubleword from a 32-bit memory location or a 32-bit general-purpose register into a destination register. Bits [1:0] of an immediate byte operand select the location where the doubleword is to be inserted:

Value of imm8 [1:0]	Insertion Location
00	[31:0]
01	[63:32]
10	[95:64]
11	[127:96]

There are legacy and extended forms of the instruction:

PINSRD

The encoding is the same as PINSRQ, with REX.W = 0.

The source operand is either a 32-bit memory location or a 32-bit general-purpose register and the destination an XMM register. The other doublewords of the destination are not affected. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VPINSRD

The extended form of the instruction has a 128-bit encoding only.

The encoding is the same as VPINSRQ, with VEX.W = 0.

There are two source operands. The first source operand is either a 32-bit memory location or a 32-bit general-purpose register and the second source operand is an XMM register. The destination is a second XMM register. All the doublewords of the second source other than the doubleword that corresponds to the location of the inserted doubleword are copied to the destination. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

Instruction Support

Form	Subset	Feature Flag
PINSRD	SSE4.1	CPUID Fn0000_0001_ECX[SSE41] (bit 19)
VPINSRD	AVX	CPUID Fn0000_0001_ECX[AVX] (bit 28)

For more on using the CPUID instruction to obtain processor feature support information, see Appendix E of Volume 3.

PINSRQ VPINSRQ — Packed Insert Quadword

Inserts a quadword from a 64-bit memory location or a 64-bit general-purpose register into a destination register. Bit [0] of an immediate byte operand selects the location where the doubleword is to be inserted:

Value of imm8 [0]	Insertion Location
0	[63:0]
1	[127:64]

There are legacy and extended forms of the instruction:

PINSRQ

The encoding is the same as PINSRD, with REX.W = 1.

The source operand is either a 64-bit memory location or a 64-bit general-purpose register and the destination an XMM register. The other quadwords of the destination are not affected. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VPINSRQ

The extended form of the instruction has a 128-bit encoding only.

The encoding is the same as VPINSRD, with VEX.W = 1.

There are two source operands. The first source operand is either a 64-bit memory location or a 64-bit general-purpose register and the second source operand is an XMM register. The destination is a second XMM register. All the quadwords of the second source other than the quadword that corresponds to the location of the inserted quadword are copied to the destination. Bits [255:128] of the YMM register that corresponds to the destination XMM registers are cleared.

Instruction Support

PMADDUBSW VPMADDUBSW — Packed Multiply and Add Unsigned Byte to Signed Word

Multiplies and adds sets of two packed 8-bit unsigned values from the first source operand and two packed 8-bit signed values from the second source operand, with signed saturation; writes eight 16-bit sums to the destination.

For the 128-bit form of the instruction, the following operations are performed:

```
dest is the destination register – either an XMM register or the corresponding YMM register.
src1 is the first source operand. src2 is the second source operand.
Ssum() is a function that returns the saturated 16-bit signed sum of its arguments.

dest[15:0] = Ssum(src1[7:0] * src2[7:0], src1[15:8] * src2[15:8])
dest[31:16] = Ssum(src1[23:16] * src2[23:16], src1[31:24] * src2[31:24])
dest[47:32] = Ssum(src1[39:32] * src2[39:32], src1[47:40] * src2[47:40])
dest[63:48] = Ssum(src1[55:48] * src2[55:48], src1[63:56] * src2[63:56])
dest[79:64] = Ssum(src1[71:64] * src2[71:64], src1[79:72] * src2[79:72])
dest[95:80] = Ssum(src1[87:80] * src2[87:80], src1[95:88] * src2[95:88])
dest[111:96] = Ssum(src1[103:96] * src2[103:96]], src1[111:104] * src2[111:104])
dest[127:112] = Ssum(src1[119:112] * src2[119:112], src1[127:120] * src2[127:120])
```

Additionally, for the 256-bit form of the instruction, the following operations are performed:

```
dest[143:128] = Ssum(src1[135:128] * src2[135:128], src1[143:136] * src2[143:136])
dest[159:144] = Ssum(src1[151:144] * src2[151:144], src1[159:152] * src2[159:152])
dest[175:160] = Ssum(src1[167:160] * src2[167:160], src1[175:168] * src2[175:168])
dest[191:176] = Ssum(src1[183:176] * src2[183:176], src1[191:184] * src2[191:184])
dest[207:192] = Ssum(src1[199:192] * src2[199:192], src1[207:200] * src2[207:200])
dest[223:208] = Ssum(src1[215:208] * src2[215:208], src1[223:216] * src2[223:216])
dest[239:224] = Ssum(src1[231:224] * src2[231:224], src1[239:232] * src2[239:232])
dest[255:240] = Ssum(src1[247:240] * src2[247:240], src1[255:248] * src2[255:248])
```

There are legacy and extended forms of the instruction:

PMADDUBSW

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The first source register is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VPMADDUBSW

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is either a YMM register or a 256-bit memory location. The destination is a third YMM register.

PMADDWD VPMADDWD Packed Multiply and Add Word to Doubleword

Multiplies and adds sets of four packed 16-bit signed values from two source registers; writes four 32-bit sums to the destination.

For the 128-bit form of the instruction, the following operations are performed:

dest is the destination register – either an XMM register or the corresponding YMM register.
src1 is the first source operand. src2 is the second source operand.

```
dest[31:0] = (src1[15:0] * src2[15:0]) + (src1[31:16] * src2[31:16])
dest[63:32] = (src1[47:32] * src2[47:32]) + (src1[63:48] * src2[63:48])
dest[95:64] = (src1[79:64] * src2[79:64]) + (src1[95:80] * src2[95:80])
dest[127:96] = (src1[111:96] * src2[111:96]) + (src1[127:112] * src2[127:112])
```

Additionally, for the 256-bit form of the instruction, the following operations are performed:

```
dest[159:128] = (src1[143:128] * src2[143:128]) + (src1[159:144] * src2[159:144])
dest[191:160] = (src1[175:160] * src2[175:160]) + (src1[191:176] * src2[191:176])
dest[223:192] = (src1[207:192] * src2[207:192]) + (src1[223:208] * src2[223:208])
dest[255:224] = (src1[239:224] * src2[239:224]) + (src1[255:240] * src2[255:240])
```

When all four of the signed 16-bit source operands in a set have the value 8000h, the 32-bit overflow wraps around to 8000_0000h. There are no other overflow cases.

There are legacy and extended forms of the instruction:

PMADDWD

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The first source register is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VPMADDWD

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is either a YMM register or a 256-bit memory location. The destination is a third YMM register.

PMAXSB
VPMAXSB

Packed Maximum Signed Bytes

Compares each packed 8-bit signed integer value of the first source operand to the corresponding value of the second source operand and writes the numerically greater value into the corresponding byte of the destination.

The 128-bit form of the instruction compares 16 pairs of 8-bit signed integer values; the 256-bit form compares 32 pairs.

There are legacy and extended forms of the instruction:

PMAXSB

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The first source operand is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VPMAXSB

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

The first source operand is an XMM register and the second source operand is either an XMM register or a 128-bit memory location. The destination is an XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is either a YMM register or a 256-bit memory location. The destination is a third YMM register.

PMINSD VPMINSD — Packed Minimum Signed Doublewords

Compares each packed 32-bit signed integer value of the first source operand to the corresponding value of the second source operand and writes the numerically lesser value into the corresponding doubleword of the destination.

The 128-bit form of the instruction compares four pairs of 32-bit signed integer values; the 256-bit form compares eight.

There are legacy and extended forms of the instruction:

PMINSD

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The first source operand is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VPMINSD

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

The first source operand is an XMM register and the second source operand is either an XMM register or a 128-bit memory location. The destination is an XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

The first source operand is a YMM register. The second source operand is either a YMM register or a 256-bit memory location. The destination is a third YMM register.

PMOVSXBD VPMOVSXBD — Packed Move with Sign-Extension Byte to Doubleword

Sign-extends four or eight packed 8-bit signed integers in the source operand to 32 bits and writes the packed doubleword signed integers to the destination.

If the source operand is a register, the 8-bit signed integers are taken from the least-significant bytes of the register.

There are legacy and extended forms of the instruction:

PMOVSXBD

The source operand is either an XMM register or a 32-bit memory location. The destination is an XMM register. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VPMOVSXBD

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

The source operand is either an XMM register or a 32-bit memory location. The destination is an XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

The source operand is either an XMM register or a 64-bit memory location. The destination is a YMM register.

Instruction Support

Form	Subset	Feature Flag
PMOVSXBD	SSE4.1	CPUID Fn0000_0001_ECX[SSE41] (bit 19)

PMOVSXBQ VPMOVSXBQ — Packed Move with Sign Extension Byte to Quadword

Sign-extends two or four packed 8-bit signed integers in the source operand to 64 bits and writes the packed quadword signed integers to the destination.

If the source operand is a register, the 8-bit signed integers are taken from the least-significant bytes of the register.

There are legacy and extended forms of the instruction:

PMOVSXBQ

The source operand is either an XMM register or a 16-bit memory location. The destination is an XMM register. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VPMOVSXBQ

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

The source operand is either an XMM register or a 16-bit memory location. The destination is an XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

The source operand is either an XMM register or a 32-bit memory location. The destination is a YMM register.

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

The source operand is either an XMM register or a 64-bit memory location. The destination is an XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

The source operand is either an XMM register or a 128-bit memory location. The destination is a YMM register.

PMOVZXDQ VPMOVZXDQ Packed Move with Zero-Extension Doubleword to Quadword

Zero-extends two or four packed 32-bit unsigned integers in the source operand to 64 bits and writes the packed quadword positive-signed integers to the destination.

If the source operand is a register, the two 32-bit signed integers are taken from the lower half of the register.

There are legacy and extended forms of the instruction:

PMOVZXDQ

The source operand is either an XMM register or a 64-bit memory location. The destination is an XMM register. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VPMOVZXDQ

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

The source operand is either an XMM register or a 64-bit memory location. The destination is an XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

The source operand is either an XMM register or a 128-bit memory location. The destination is a YMM register.

PMOVZXWD VPMOVZXWD — Packed Move Word to Doubleword with Zero-Extension

Zero-extends four or eight packed 16-bit unsigned integers in the source operand to 32 bits and writes the packed doubleword positive-signed integers to the destination.

If the source operand is a register, the four 16-bit signed integers are taken from the lower half of the register.

There are legacy and extended forms of the instruction:

PMOVZXWD

The source operand is either an XMM register or a 64-bit memory location. The destination is an XMM register. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VPMOVZXWD

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

The source operand is either an XMM register or a 64-bit memory location. The destination is an XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

The source operand is either an XMM register or a 128-bit memory location. The destination is a YMM register.

PMOVZXWQ VPMOVZXWQ — Packed Move with Zero-Extension Word to Quadword

Zero-extends two or four packed 16-bit unsigned integers to 64 bits and writes the packed quadword positive signed integers to the destination.

If the source operand is a register, the 16-bit signed integers are taken from least-significant words of the register.

There are legacy and extended forms of the instruction:

PMOVZXWQ

The source operand is either an XMM register or a 32-bit memory location. The destination is an XMM register. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VPMOVZXWQ

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

The source operand is either an XMM register or a 32-bit memory location. The destination is an XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding

The source operand is either an XMM register or a 64-bit memory location. The destination is a YMM register.

PMULDQ Packed Multiply
VPMULDQ Signed Doubleword to Quadword

Multiplies two or four pairs of 32-bit signed integers in the first and second source operands and writes two or four packed quadword signed integer products to the destination.

For the 128-bit form of the instruction, the following operations are performed:

dest is the destination register – either an XMM register or the corresponding YMM register.
src1 is the first source operand. src2 is the second source operand.

```
dest[63:0] = (src1[31:0] * src2[31:0])
dest[127:64] = (src1[95:64] * src2[95:64])
```

Additionally, for the 256-bit form of the instruction, the following operations are performed:

```
dest[191:128] = (src1[159:128] * src2[159:128])
dest[255:192] = (src1[223:192] * src2[223:192])
```

There are legacy and extended forms of the instruction:

PMULDQ

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The first source register is also the destination. Bits [255:128] of the YMM register that corresponds to the destination are not affected.

VPMULDQ

The extended form of the instruction has 128-bit and 256-bit encodings.

XMM Encoding

The first source operand is an XMM register. The second source operand is either an XMM register or a 128-bit memory location. The destination is a third XMM register. Bits [255:128] of the YMM register that corresponds to the destination are cleared.

YMM Encoding
