Revision History

Date	Revision	Description
October 2020	3.23	Added Shadow Stack support. Preface: Added updates. Chapter 2: Memory Model. Added content. Chapter 3: General-Purpose Programming. Added content.
December 2017	3.22	Clarified Items in Notational Conventions in the Preface. Clarified Memory Fence, Serializing Instructions and Internal Caches in Chapter 3. Added Instruction Cache Coherency in Chapter 3. Removed redundant information Section 3.11. Corrected description of streaming instructions in section 4.12.4.
October 2013	3.21	Integrated the AVX2 instruction subset into Chapter 4, “Streaming SIMD Extensions Media and Scientific Programming,” on page 111.
May 2013	3.20	Clarified Section 3.11. “Cross-Modifying Code” on page 107.
March 2012	3.19	Added description of the MOVBE instruction to discussion of move instructions on page 45.
December 2011	3.18	Added corrections and clarifications to “Legacy Prefixes” on page 76. Corrected some formatting issues on figure titles in Chapter 4.
September 2011	3.17	Completed integration of extended SSE instruction set into application programming discussion.
May 2011	3.16	Updated application programming model to include the YMM Registers. Added descriptions for SSE4.1 and SSE4.2 instructions. Added F16C to Section 4.6.3. Added BMI and TBM instructions to Section 3.3. Added descriptive information for XOP instructions in appropriate section 4.5 locations. Added description of 256-bit data types to Section 4.4.
November 2009	3.15	Modified description of the Auxiliary Carry Flag. Clarified section, “Load Segment Registers.” Added section “Atomicity of accesses.” Revised section, “Cross-Modifying Code.”
September 2007	3.14	Incorporated minor clarifications and formatting changes.

Date	Revision	Description
July 2007	3.13	Revised rFLAGS register table. Added section “Cross-Modifying Code.” Added section “Feature Detection in a Virtualized Environment”. Merged table of MXCSR register reset values into Figure. Added “Misaligned Exception Mask (MM)”. Revised indefinite-value encodings in tables. Revised section “Precision.” Made minor editorial changes for purposes of clarification.
September 2006	3.12	Incorporated minor clarifications and formatting changes.
December 2005	3.11	Updated index entries.
February 2005	3.10	Clarified section “Self-Modifying Code.” Added general descriptions of SSE3 instructions to Chapter 4. Added description of the CMPXCHG16B instruction to Chapter 3. Elaborated explanation of PREFETCH/*evel* instructions.
September 2003	3.09	Corrected several factual errors.
September 2002	3.07	Corrected minor organizational problems in sections dealing with ‘Prefetch’ instructions in Chapters 3, 4, and 5. Clarified the general description of the operation of certain 128-bit media instructions in Chapter 1. Corrected a factual error in the description of the FNINIT/FINIT instructions in Chapter 6. Corrected operand descriptions for the CMOVcc instructions in Chapter 3. Added Revision History. Corrected marketing denotations.

Preface

About This Book

This book is part of a multivolume work entitled the *AMD64 Architecture Programmer's Manual*. This table lists each volume and its order number.

Title	Order No.
Volume 1: Application Programming	24592
Volume 2: System Programming	24593
Volume 3: General-Purpose and System Instructions	24594
Volume 4: 128-Bit and 256-Bit Media Instructions	26568
Volume 5: 64-Bit Media and x87 Floating-Point Instructions	26569

Audience

This volume is intended for programmers writing application programs, compilers, or assemblers. It assumes prior experience in microprocessor programming, although it does not assume prior experience with the legacy x86 or AMD64 microprocessor architecture.

This volume describes the AMD64 architecture's resources and functions that are accessible to application software, including memory, registers, instructions, operands, I/O facilities, and application-software aspects of control transfers (including interrupts and exceptions) and performance optimization.

System-programming topics—including the use of instructions running at a current privilege level (CPL) of 0 (most-privileged)—are described in Volume 2. Details about each instruction are described in Volumes 3, 4, and 5.

Organization

This volume begins with an overview of the architecture and its memory organization and is followed by chapters that describe the four application-programming models available in the AMD64 architecture:

- *General-Purpose Programming*—This model uses the integer general-purpose registers (GPRs). The chapter describing it also describes the basic application environment for exceptions, control transfers, I/O, and memory optimization that applies to all other application-programming models.

- *Streaming SIMD Extensions (SSE) Programming*—This model uses the SSE (YMM/XMM) registers and supports integer and floating-point operations on vector (packed) and scalar data types.
- *Multimedia Extensions (MMX™) Programming*—This model uses the 64-bit MMX registers and supports integer and floating-point operations on vector (packed) and scalar data types.
- *x87 Floating-Point Programming*—This model uses the 80-bit x87 registers and supports floating-point operations on scalar data types.

The index at the end of this volume cross-references topics within the volume. For other topics relating to the AMD64 architecture, see the tables of contents and indexes of the other volumes.

Conventions and Definitions

The following section **Notational Conventions** describes notational conventions used in this volume and in the remaining volumes of this *AMD64 Architecture Programmer's Manual.* This is followed by a **Definitions** section which lists a number of terms used in the manual along with their technical definitions. Some of these definitions assume knowledge of the legacy x86 architecture. See "Related Documents" on page xxx for further information about the legacy x86 architecture. Finally, the **Registers** section lists the registers which are a part of the application programming model.

Notational Conventions

#GP(0)

An instruction exception—in this example, a general-protection exception with error code of 0.

1011b

A binary value—in this example, a 4-bit value.

F0EA_0B02h

A hexadecimal value. Underscore characters may be inserted to improve readability.

128

Numbers without an alpha suffix are decimal unless the context indicates otherwise.

7:4

A bit range, from bit 7 to 4, inclusive. The high-order bit is shown first. Commas may be inserted to indicate gaps.

CR0–CR4

A register range, from register CR0 through CR4, inclusive, with the low-order register first.

CR0[PE], CR0.PE

Notation for referring to a field within a register—in this case, the PE field of the CR0 register.

CR0[PE] = 1, CR0.PE = 1

The PE field of the CR0 register is set (contains the value 1).

EFER[LME] = 0, EFER.LME = 0

The LME field of the EFER register is cleared (contains a value of 0).

DS:SI

A far pointer or logical address. The real address or segment descriptor specified by the segment register (DS in this example) is combined with the offset contained in the second register (SI in this example) to form a real or virtual address.

RFLAGS[13:12]

A field within a register identified by its bit range. In this example, corresponding to the IOPL field.

Definitions

128-bit media instructions

Instructions that operate on the various 128-bit vector data types. Supported within both the *legacy SSE* and *extended SSE* instruction sets.

256-bit media instructions

Instructions that operate on the various 256-bit vector data types. Supported within the *extended SSE* instruction set.

64-bit media instructions

Instructions that operate on the 64-bit vector data types. These are primarily a combination of MMX and 3DNow!™ instruction sets and their extensions, with some additional instructions from the *SSE1* and *SSE2* instruction sets.

16-bit mode

Legacy mode or compatibility mode in which a 16-bit address size is active. See *legacy mode* and *compatibility mode*.

32-bit mode

Legacy mode or compatibility mode in which a 32-bit address size is active. See *legacy mode* and *compatibility mode*.

64-bit mode

A submode of *long mode*. In 64-bit mode, the default address size is 64 bits and new features, such as register extensions, are supported for system and application software.

absolute

Said of a displacement that references the base of a code segment rather than an instruction pointer. Contrast with *relative*.

AES

Advance Encryption Standard (AES) algorithm acceleration instructions; part of *Streaming SIMD Extensions (SSE)*.

ASID

Address space identifier.

AVX

Extension of the SSE instruction set supporting 128- and 256-bit vector (packed) operands. See *Streaming SIMD Extensions*.

AVX2

Extension of the AVX instruction subset that adds more support for 256-bit vector (mostly packed integer) operands and a few new SIMD instructions. See *Streaming SIMD Extensions*.

biased exponent

The sum of a floating-point value's exponent and a constant bias for a particular floating-point data type. The bias makes the range of the biased exponent always positive, which allows reciprocation without overflow.

byte

Eight bits.

clear

To write a bit value of 0. Compare *set*.

compatibility mode

A submode of *long mode*. In compatibility mode, the default address size is 32 bits, and legacy 16-bit and 32-bit applications run without modification.

commit

To irreversibly write, in program order, an instruction's result to software-visible storage, such as a register (including flags), the data cache, an internal write buffer, or memory.

CPL

Current privilege level.

direct

Referencing a memory location whose address is included in the instruction's syntax as an immediate operand. The address may be an absolute or relative address. Compare *indirect*.

dirty data

Data held in the processor's caches or internal buffers that is more recent than the copy held in main memory.

displacement

A signed value that is added to the base of a segment (absolute addressing) or an instruction pointer (relative addressing). Same as *offset*.

doubleword

Two words, or four bytes, or 32 bits.

double quadword

Eight words, or 16 bytes, or 128 bits. Also called *octword*.

effective address size

The address size for the current instruction after accounting for the default address size and any address-size override prefix.

effective operand size

The operand size for the current instruction after accounting for the default operand size and any operand-size override prefix.

element

See *vector*.

exception

An abnormal condition that occurs as the result of executing an instruction. The processor's response to an exception depends on the type of the exception. For all exceptions except SSE floating-point exceptions and x87 floating-point exceptions, control is transferred to the handler (or service routine) for that exception, as defined by the exception's vector. For floating-point exceptions defined by the IEEE 754 standard, there are both masked and unmasked responses. When unmasked, the exception handler is called, and when masked, a default response is provided instead of calling the handler.

extended SSE

Enhanced set of SIMD instructions supporting 256-bit vector data types and allowing the specification of up to four operands. A subset of the *Streaming SIMD Extensions (SSE).* Includes the *AVX*, *AVX2*, *FMA*, *FMA4*, and *XOP* instructions. Compare *legacy SSE*.

flush

An often ambiguous term meaning (1) writeback, if modified, and invalidate, as in "flush the cache line," or (2) invalidate, as in "flush the pipeline," or (3) change a value, as in "flush to zero."

FMA4

Fused Multiply Add, four operand. Part of the *extended SSE* instruction set.

FMA

Fused Multiply Add. Part of the *extended SSE* instruction set.

GDT
: Global descriptor table.

GIF
: Global interrupt flag.

IDT
: Interrupt descriptor table.

IGN
: Ignored. Value written is ignored by hardware. Value returned on a read is indeterminate. See *reserved*.

indirect
: Referencing a memory location whose address is in a register or other memory location. The address may be an absolute or relative address. Compare *direct*.

IRB
: The virtual-8086 mode interrupt-redirection bitmap.

IST
: The long-mode interrupt-stack table.

IVT
: The real-address mode interrupt-vector table.

LDT
: Local descriptor table.

legacy x86
: The legacy x86 architecture. See “Related Documents” on page xxx for descriptions of the legacy x86 architecture.

legacy mode
: An operating mode of the AMD64 architecture in which existing 16-bit and 32-bit applications and operating systems run without modification. A processor implementation of the AMD64 architecture can run in either *long mode* or *legacy mode*. Legacy mode has three submodes, *real mode*, *protected mode*, and *virtual-8086 mode*.

legacy SSE
: A subset of the *Streaming SIMD Extensions (SSE)* composed of the *SSE1*, *SSE2*, *SSE3*, *SSSE3*, *SSE4.1*, *SSE4.2*, and *SSE4A* instruction sets. Compare *extended SSE*.

LIP
: Linear Instruction Pointer. LIP = (CS.base + rIP).

long mode

An operating mode unique to the AMD64 architecture. A processor implementation of the AMD64 architecture can run in either *long mode* or *legacy mode*. Long mode has two submodes, *64-bit mode* and *compatibility mode*.

lsb

Least-significant bit.

LSB

Least-significant byte.

main memory

Physical memory, such as RAM and ROM (but not cache memory) that is installed in a particular computer system.

mask

(1) A control bit that prevents the occurrence of a floating-point exception from invoking an exception-handling routine. (2) A field of bits used for a control purpose.

MBZ

Must be zero. If software attempts to set an MBZ bit to 1, a general-protection exception (#GP) occurs. See *reserved*.

memory

Unless otherwise specified, *main memory*.

msb

Most-significant bit.

MSB

Most-significant byte.

multimedia instructions

Those instructions that operate simultaneously on multiple elements within a vector data type. Comprises the *256-bit media instructions*, *128-bit media instructions,* and *64-bit media instructions*.

octword

Same as *double quadword.*

offset

Same as *displacement*.

overflow

The condition in which a floating-point number is larger in magnitude than the largest, finite, positive or negative number that can be represented in the data-type format being used.

packed
See *vector*.

PAE
Physical-address extensions.

physical memory
Actual memory, consisting of *main memory* and cache.

probe
A check for an address in a processor's caches or internal buffers. *External probes* originate outside the processor, and *internal probes* originate within the processor.

procedure stack
A portion of a stack segment in memory that is used to link procedures. Also known as a *program stack.*

program stack
See *procedure stack.*

protected mode
A submode of *legacy mode*.

quadword
Four words, or eight bytes, or 64 bits.

RAZ
Read as zero. Value returned on a read is always zero (0) regardless of what was previously written. (See *reserved*)

real-address mode
See *real mode*.

real mode
A short name for *real-address mode,* a submode of *legacy mode*.

relative
Referencing with a displacement (also called offset) from an instruction pointer rather than the base of a code segment. Contrast with *absolute*.

reserved
Fields marked as reserved may be used at some future time.

To preserve compatibility with future processors, reserved fields require special handling when read or written by software. Software must not depend on the state of a reserved field (unless qualified as RAZ), nor upon the ability of such fields to return a previously written state.

If a field is marked reserved without qualification, software must not change the state of that field; it must reload that field with the same value returned from a prior read.

Reserved fields may be qualified as IGN, MBZ, RAZ, or SBZ (see definitions).

REX

An instruction encoding prefix that specifies a 64-bit operand size and provides access to additional registers.

RIP-relative addressing

Addressing relative to the 64-bit RIP instruction pointer.

SBZ

Should be zero. An attempt by software to set an SBZ bit to 1 results in undefined behavior. See *reserved*.

scalar

An atomic value existing independently of any specification of location, direction, etc., as opposed to *vectors*.

set

To write a bit value of 1. Compare *clear*.

shadow stack

A shadow stack is a separate, protected stack that is conceptually parallel to the procedure stack and used only by the shadow stack feature.

SIB

A byte following an instruction opcode that specifies address calculation based on scale (S), index (I), and base (B).

SIMD

Single instruction, multiple data. See *vector*.

Streaming SIMD Extensions (SSE)

Instructions that operate on scalar or vector (packed) integer and floating point numbers. The SSE instruction set comprises the *legacy SSE* and *extended SSE* instruction sets.

SSE1

Original SSE instruction set. Includes instructions that operate on vector operands in both the MMX and the XMM registers.

SSE2

Extensions to the SSE instruction set.

SSE3

Further extensions to the SSE instruction set.

SSSE3

Further extensions to the SSE instruction set.

SSE4.1

Further extensions to the SSE instruction set.

SSE4.2

Further extensions to the SSE instruction set.

SSE4A

A minor extension to the SSE instruction set adding the instructions EXTRQ, INSERTQ, MOVNTSS, and MOVNTSD.

sticky bit

A bit that is set or cleared by hardware and that remains in that state until explicitly changed by software.

TOP

The x87 top-of-stack pointer.

TSS

Task-state segment.

underflow

The condition in which a floating-point number is smaller in magnitude than the smallest nonzero, positive or negative number that can be represented in the data-type format being used.

vector

(1) A set of integer or floating-point values, called *elements*, that are packed into a single operand. Most of the media instructions support vectors as operands. Vectors are also called *packed* or *SIMD* (single-instruction multiple-data) operands.

(2) An index into an interrupt descriptor table (IDT), used to access exception handlers. Compare *exception*.

VEX

An instruction encoding escape prefix that opens a new extended instruction encoding space, specifies a 64-bit operand size, and provides access to additional registers. See *XOP prefix*.

virtual-8086 mode

A submode of *legacy mode*.

VMCB

Virtual machine control block.

VMM
: Virtual machine monitor.

word
: Two bytes, or 16 bits.

XOP instructions
: Part of the extended SSE instruction set using the XOP prefix. See *Streaming SIMD Extensions*.

XOP prefix
: Extended instruction identifier prefix, used by XOP instructions allowing the specification of up to four operands and 128 or 256-bit operand widths.

Registers

In the following list of registers, the names are used to refer either to a given register or to the contents of that register:

AH–DH
: The high 8-bit AH, BH, CH, and DH registers. Compare *AL–DL.*

AL–DL
: The low 8-bit AL, BL, CL, and DL registers. Compare *AH–DH.*

AL–r15B
: The low 8-bit AL, BL, CL, DL, SIL, DIL, BPL, SPL, and R8B–R15B registers, available in 64-bit mode.

BP
: Base pointer register.

CR*n*
: Control register number *n*.

CS
: Code segment register.

eAX–eSP
: The 16-bit AX, BX, CX, DX, DI, SI, BP, and SP registers or the 32-bit EAX, EBX, ECX, EDX, EDI, ESI, EBP, and ESP registers. Compare *rAX–rSP.*

EFER
: Extended features enable register.

eFLAGS
: 16-bit or 32-bit flags register. Compare *rFLAGS*.

EFLAGS
: 32-bit (extended) flags register.

eIP
: 16-bit or 32-bit instruction-pointer register. Compare *rIP*.

EIP
: 32-bit (extended) instruction-pointer register.

FLAGS
: 16-bit flags register.

GDTR
: Global descriptor table register.

GPRs
: General-purpose registers. For the 16-bit data size, these are AX, BX, CX, DX, DI, SI, BP, and SP. For the 32-bit data size, these are EAX, EBX, ECX, EDX, EDI, ESI, EBP, and ESP. For the 64-bit data size, these include RAX, RBX, RCX, RDX, RDI, RSI, RBP, RSP, and R8–R15.

IDTR
: Interrupt descriptor table register.

IP
: 16-bit instruction-pointer register.

LDTR
: Local descriptor table register.

MSR
: Model-specific register.

r8–r15
: The 8-bit R8B–R15B registers, or the 16-bit R8W–R15W registers, or the 32-bit R8D–R15D registers, or the 64-bit R8–R15 registers.

rAX–rSP
: The 16-bit AX, BX, CX, DX, DI, SI, BP, and SP registers, or the 32-bit EAX, EBX, ECX, EDX, EDI, ESI, EBP, and ESP registers, or the 64-bit RAX, RBX, RCX, RDX, RDI, RSI, RBP, and RSP registers. Replace the placeholder *r* with nothing for 16-bit size, “E” for 32-bit size, or “R” for 64-bit size.

RAX
: 64-bit version of the EAX register.

RBP
64-bit version of the EBP register.

RBX
64-bit version of the EBX register.

RCX
64-bit version of the ECX register.

RDI
64-bit version of the EDI register.

RDX
64-bit version of the EDX register.

rFLAGS
16-bit, 32-bit, or 64-bit flags register. Compare *RFLAGS*.

RFLAGS
64-bit flags register. Compare *rFLAGS*.

rIP
16-bit, 32-bit, or 64-bit instruction-pointer register. Compare *RIP*.

RIP
64-bit instruction-pointer register.

RSI
64-bit version of the ESI register.

RSP
64-bit version of the ESP register.

SP
Stack pointer register.

SS
Stack segment register.

SSP
Shadow-stack pointer register.

TPR
Task priority register (CR8), a new register introduced in the AMD64 architecture to speed interrupt management.

TR

Task register.

Endian Order

The x86 and AMD64 architectures address memory using little-endian byte-ordering. Multibyte values are stored with their least-significant byte at the lowest byte address, and they are illustrated with their least significant byte at the right side. Strings are illustrated in reverse order, because the addresses of their bytes increase from right to left.

1 Overview of the AMD64 Architecture

1.1 Introduction

The AMD64 architecture is a simple yet powerful 64-bit, backward-compatible extension of the industry-standard (legacy) x86 architecture. It adds 64-bit addressing and expands register resources to support higher performance for recompiled 64-bit programs, while supporting legacy 16-bit and 32-bit applications and operating systems without modification or recompilation. It is the architectural basis on which new processors can provide seamless, high-performance support for both the vast body of existing software and 64-bit software required for higher-performance applications.

The need for a 64-bit x86 architecture is driven by applications that address large amounts of virtual and physical memory, such as high-performance servers, database management systems, and CAD tools. These applications benefit from both 64-bit addresses and an increased number of registers. The small number of registers available in the legacy x86 architecture limits performance in computation-intensive applications. Increasing the number of registers provides a performance boost to many such applications.

1.1.1 AMD64 Features

The AMD64 architecture includes these features:

- Register Extensions (see Figure 1-1 on page 2):
  - 8 additional general-purpose registers (GPRs).
  - All 16 GPRs are 64 bits wide.
  - 8 additional YMM/XMM registers.
  - Uniform byte-register addressing for all GPRs.
  - An instruction prefix (REX) accesses the extended registers.
- Long Mode (see Table 1-1 on page 2):
  - Up to 64 bits of virtual address.
  - 64-bit instruction pointer (RIP).
  - Instruction-pointer-relative data-addressing mode.
  - Flat address space.

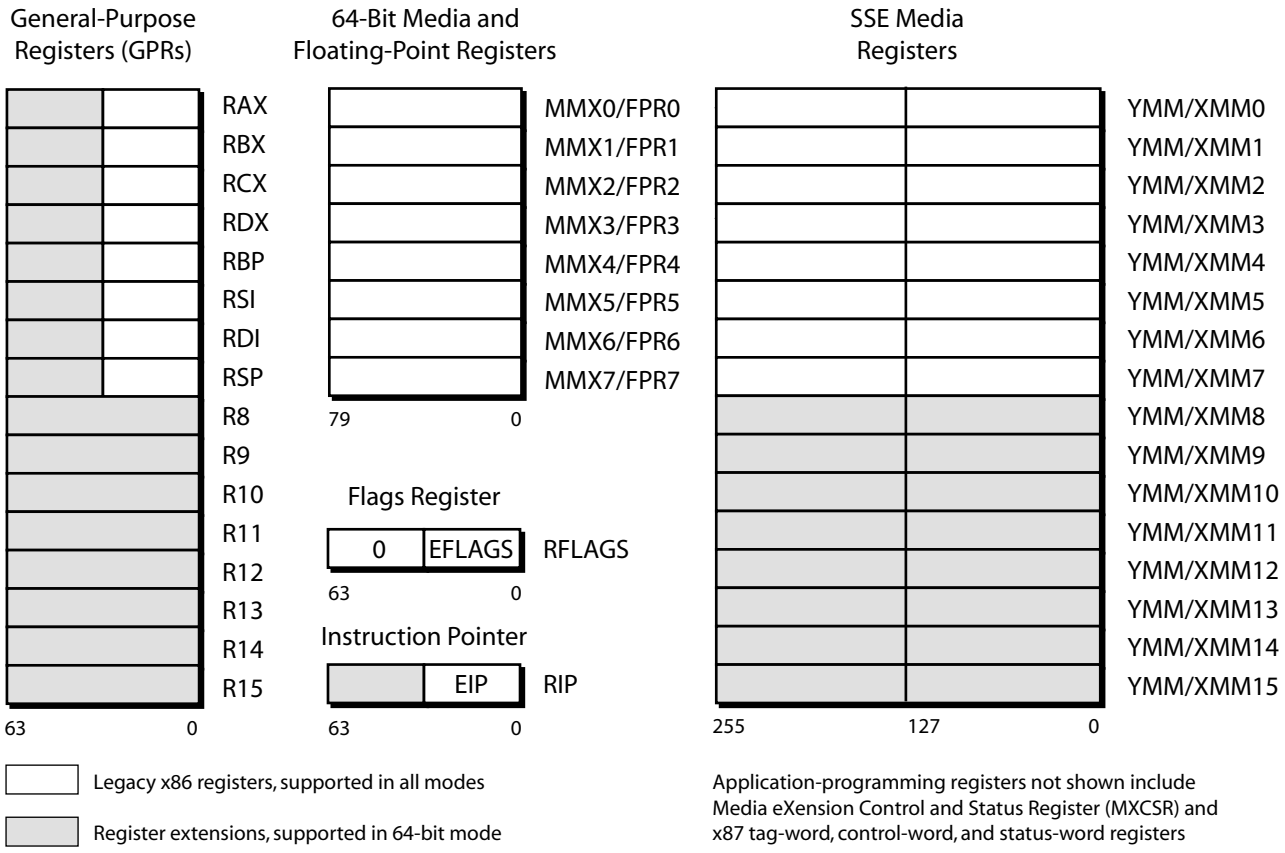

Figure 1-1. Application-Programming Register Set

Table 1-1. Operating Modes

Operating Mode		Operating System Required	Application Recompile Required	Defaults		Register Extensions	Typical
				Address Size (bits)	Operand Size (bits)		GPR Width (bits)
Long Mode	64-Bit Mode	64-bit OS	yes	64	32	yes	64
	Compatibility Mode		no	32		no	32
				16	16		16
Legacy Mode	Protected Mode	Legacy 32-bit OS	no	32	32	no	32
				16	16		
	Virtual-8086 Mode			16	16		16
	Real Mode	Legacy 16-bit OS					

1.1.2 Registers

Table 1-2 compares the register and stack resources available to application software, by operating mode. The left set of columns shows the legacy x86 resources, which are available in the AMD64 architecture's legacy and compatibility modes. The right set of columns shows the comparable resources in 64-bit mode. Gray shading indicates differences between the modes. These register differences (not including stack-width difference) represent the *register extensions* shown in Figure 1-1.

Table 1-2. Application Registers and Stack, by Operating Mode

Register or Stack	Legacy and Compatibility Modes			64-Bit Mode[1]		
	Name	Number	Size (bits)	Name	Number	Size (bits)
General-Purpose Registers (GPRs)[2]	EAX, EBX, ECX, EDX, EBP, ESI, EDI, ESP	8	32	RAX, RBX, RCX, RDX, RBP, RSI, RDI, RSP, R8–R15	16	64
256-bit YMM Registers	YMM0–YMM7[3]	8	256	YMM0–YMM15[3]	16	256
128-Bit XMM Registers	XMM0–XMM7[3]	8	128	XMM0–XMM15[3]	16	128
64-Bit MMX Registers	MMX0–MMX7[4]	8	64	MMX0–MMX7[4]	8	64
x87 Registers	FPR0–FPR7[4]	8	80	FPR0–FPR7[4]	8	80
Instruction Pointer[2]	EIP	1	32	RIP	1	64
Flags[2]	EFLAGS	1	32	RFLAGS	1	64
Stack	—		16 or 32	—		64

Note:

1. *Gray-shaded entries indicate differences between the modes. These differences (except stack-width difference) are the AMD64 architecture's register extensions.*
2. *GPRs are listed using their full-width names. In legacy and compatibility modes,16-bit and 8-bit mappings of the registers are also accessible. In 64-bit mode, 32-bit, 16-bit, and 8-bit mappings of the registers are accessible. See Section 3.1. "Registers" on page 23.*
3. *The XMM registers overlay the lower octword of the YMM registers. See Section 4.2. "Registers" on page 113.*
4. *The MMX0–MMX7 registers are mapped onto the FPR0–FPR7 physical registers, as shown in Figure 1-1. The x87 stack registers, ST(0)–ST(7), are the logical mappings of the FPR0–FPR7 physical registers.*

As Table 1-2 shows, the legacy x86 architecture (called *legacy mode* in the AMD64 architecture) supports eight GPRs. In reality, however, the general use of at least four registers (EBP, ESI, EDI, and ESP) is compromised because they serve special purposes when executing many instructions. The AMD64 architecture's addition of eight GPRs—and the increased width of these registers from 32 bits to 64 bits—allows compilers to substantially improve software performance. Compilers have more flexibility in using registers to hold variables. Compilers can also minimize memory traffic—and thus boost performance—by localizing work within the GPRs.

1.1.3 Instruction Set

The AMD64 architecture supports the full legacy x86 instruction set, with additional instructions to support long mode (see Table 1-1 on page 2 for a summary of operating modes). The application-programming instructions are organized into four subsets, as follows:

- *General-Purpose Instructions*—These are the basic x86 integer instructions used in virtually all programs. Most of these instructions load, store, or operate on data located in the general-purpose registers (GPRs) or memory. Some of the instructions alter sequential program flow by branching to other program locations.
- *Streaming SIMD Extensions Instructions (SSE)*—These instructions load, store, or operate on data located primarily in the YMM/XMM registers. 128-bit media instructions operate on the lower half of the YMM registers. SSE instructions perform integer and floating-point operations on vector (packed) and scalar data types. Because the vector instructions can independently and simultaneously perform a single operation on multiple sets of data, they are called *single-instruction, multiple-data* (SIMD) instructions. They are useful for high-performance media and scientific applications that operate on blocks of data.
- *Multimedia Extension Instructions*—These include the MMX™ technology and AMD 3DNow!™ technology instructions. These instructions load, store, or operate on data located primarily in the 64-bit MMX registers which are mapped onto the 80-bit x87 floating-point registers. Like the SSE instructions, they perform integer and floating-point operations on vector (packed) and scalar data types. These instructions are useful in media applications that do not require high precision. Multimedia Extension Instructions use saturating mathematical operations that do not generate operation exceptions. AMD has de-emphasized the use of 3DNow! instructions, which have been superceded by their more efficient SSE counterparts. Relevant recommendations are provided in Chapter 5, “64-Bit Media Programming” on page 239, and in the *AMD64 Programmer’s Manual Volume 4: 64-Bit Media and x87 Floating-Point Instructions*.
- *x87 Floating-Point Instructions*—These are the floating-point instructions used in legacy x87 applications. They load, store, or operate on data located in the 80-bit x87 registers.

Some of these application-programming instructions bridge two or more of the above subsets. For example, there are instructions that move data between the general-purpose registers and the YMM/XMM or MMX registers, and many of the integer vector (packed) instructions can operate on either YMM/XMM or MMX registers, although not simultaneously. If instructions bridge two or more subsets, their descriptions are repeated in all subsets to which they apply.

1.1.4 Media Instructions

Media applications—such as image processing, music synthesis, speech recognition, full-motion video, and 3D graphics rendering—share certain characteristics:

- They process large amounts of data.
- They often perform the same sequence of operations repeatedly across the data.
- The data are often represented as small quantities, such as 8 bits for pixel values, 16 bits for audio samples, and 32 bits for object coordinates in floating-point format.

SSE and MMX instructions are designed to accelerate these applications. The instructions use a form of vector (or packed) parallel processing known as single-instruction, multiple data (SIMD) processing. This vector technology has the following characteristics:

- A single register can hold multiple independent pieces of data. For example, a single YMM register can hold 32 8-bit integer data elements, or eight 32-bit single-precision floating-point data elements.
- The vector instructions can operate on all data elements in a register, independently and simultaneously. For example, a PADDB instruction operating on byte elements of two vector operands in 128-bit XMM registers performs 16 simultaneous additions and returns 16 independent results in a single operation.

SSE and MMX instructions take SIMD vector technology a step further by including special instructions that perform operations commonly found in media applications. For example, a graphics application that adds the brightness values of two pixels must prevent the add operation from wrapping around to a small value if the result overflows the destination register, because an overflow result can produce unexpected effects such as a dark pixel where a bright one is expected. These instructions include saturating-arithmetic instructions to simplify this type of operation. A result that otherwise would wrap around due to overflow or underflow is instead forced to saturate at the largest or smallest value that can be represented in the destination register.

1.1.5 Floating-Point Instructions

The AMD64 architecture provides three floating-point instruction subsets, using three distinct register sets:

- SSE instructions support 32-bit single-precision and 64-bit double-precision floating-point operations, in addition to integer operations. Operations on both vector data and scalar data are supported, with a dedicated floating-point exception-reporting mechanism. These floating-point operations comply with the IEEE-754 standard.
- MMX Instructions support single-precision floating-point operations. Operations on both vector data and scalar data are supported, but these instructions do not support floating-point exception reporting.
- x87 Floating-Point Instructions support single-precision, double-precision, and 80-bit extended-precision floating-point operations. Only scalar data are supported, with a dedicated floating-point exception-reporting mechanism. The x87 floating-point instructions contain special instructions for performing trigonometric and logarithmic transcendental operations. The single-precision and double-precision floating-point operations comply with the IEEE-754 standard.

Maximum floating-point performance can be achieved using the 256-bit media instructions. One of these vector instructions can support up to eight single-precision (or four double-precision) operations in parallel. A total of 16 256-bit YMM registers, available in 64-bit mode, speeds up applications by providing more registers to hold intermediate results, thus reducing the need to store these results in memory. Fewer loads and stores results in better performance.

1.2 Modes of Operation

Table 1-1 on page 2 summarizes the modes of operation supported by the AMD64 architecture. In most cases, the default address and operand sizes can be overridden with instruction prefixes. The register extensions shown in the second-from-right column of Table 1-1 are those illustrated in Figure 1-1 on page 2.

1.2.1 Long Mode

Long mode is an extension of legacy protected mode. Long mode consists of two submodes: *64-bit mode* and *compatibility mode*. 64-bit mode supports all of the features and register extensions of the AMD64 architecture. Compatibility mode supports binary compatibility with existing 16-bit and 32-bit applications. Long mode does not support legacy real mode or legacy virtual-8086 mode, and it does not support hardware task switching.

Throughout this document, references to *long mode* refer to both *64-bit mode* and *compatibility mode*. If a function is specific to either of these submodes, then the name of the specific submode is used instead of the name *long mode*.

1.2.2 64-Bit Mode

64-bit mode—a submode of long mode—supports the full range of 64-bit virtual-addressing and register-extension features. This mode is enabled by the operating system on an individual code-segment basis. Because 64-bit mode supports a 64-bit virtual-address space, it requires a 64-bit operating system and tool chain. Existing application binaries can run without recompilation in compatibility mode, under an operating system that runs in 64-bit mode, or the applications can also be recompiled to run in 64-bit mode.

Addressing features include a 64-bit instruction pointer (RIP) and an RIP-relative data-addressing mode. This mode accommodates modern operating systems by supporting only a flat address space, with single code, data, and stack space.

Register Extensions. 64-bit mode implements register extensions through a group of instruction prefixes, called REX prefixes. These extensions add eight GPRs (R8–R15), widen all GPRs to 64 bits, and add eight YMM/XMM registers (YMM/XMM8–15).

The REX instruction prefixes also provide a byte-register capability that makes the low byte of any of the sixteen GPRs available for byte operations. This results in a uniform set of byte, word, doubleword, and quadword registers that is better suited to compiler register-allocation.

64-Bit Addresses and Operands. In 64-bit mode, the default virtual-address size is 64 bits (implementations can have fewer). The default operand size for most instructions is 32 bits. For most instructions, these defaults can be overridden on an instruction-by-instruction basis using instruction prefixes. REX prefixes specify the 64-bit operand size and register extensions.

RIP-Relative Data Addressing. 64-bit mode supports data addressing relative to the 64-bit instruction pointer (RIP). The legacy x86 architecture supports IP-relative addressing only in control-

transfer instructions. RIP-relative addressing improves the efficiency of position-independent code and code that addresses global data.

Opcodes. A few instruction opcodes and prefix bytes are redefined to allow register extensions and 64-bit addressing. These differences are described in Appendix B “General-Purpose Instructions in 64-Bit Mode” and Appendix C “Differences Between Long Mode and Legacy Mode” in Volume 3.

1.2.3 Compatibility Mode

Compatibility mode—the second submode of long mode—allows 64-bit operating systems to run existing 16-bit and 32-bit x86 applications. These legacy applications run in compatibility mode without recompilation.

Applications running in compatibility mode use 32-bit or 16-bit addressing and can access the first 4GB of virtual-address space. Legacy x86 instruction prefixes toggle between 16-bit and 32-bit address and operand sizes.

As with 64-bit mode, compatibility mode is enabled by the operating system on an individual code-segment basis. Unlike 64-bit mode, however, x86 segmentation functions the same as in the legacy x86 architecture, using 16-bit or 32-bit protected-mode semantics. From the application viewpoint, compatibility mode looks like the legacy x86 protected-mode environment. From the operating-system viewpoint, however, address translation, interrupt and exception handling, and system data structures use the 64-bit long-mode mechanisms.

1.2.4 Legacy Mode

Legacy mode preserves binary compatibility not only with existing 16-bit and 32-bit applications but also with existing 16-bit and 32-bit operating systems. Legacy mode consists of the following three submodes:

- *Protected Mode*—Protected mode supports 16-bit and 32-bit programs with memory segmentation, optional paging, and privilege-checking. Programs running in protected mode can access up to 4GB of memory space.
- *Virtual-8086 Mode*—Virtual-8086 mode supports 16-bit real-mode programs running as tasks under protected mode. It uses a simple form of memory segmentation, optional paging, and limited protection-checking. Programs running in virtual-8086 mode can access up to 1MB of memory space.
- *Real Mode*—Real mode supports 16-bit programs using simple register-based memory segmentation. It does not support paging or protection-checking. Programs running in real mode can access up to 1MB of memory space.

Legacy mode is compatible with existing 32-bit processor implementations of the x86 architecture. Processors that implement the AMD64 architecture boot in legacy real mode, just like processors that implement the legacy x86 architecture.

Throughout this document, references to *legacy mode* refer to all three submodes—*protected mode*, *virtual-8086 mode*, and *real mode*. If a function is specific to either of these submodes, then the name of the specific submode is used instead of the name *legacy mode*.

2 Memory Model

This chapter describes the memory characteristics that apply to application software in the various operating modes of the AMD64 architecture. These characteristics apply to all instructions in the architecture. Several additional system-level details about memory and cache management are described in Volume 2.

2.1 Memory Organization

2.1.1 Virtual Memory

Virtual memory consists of the entire address space available to programs. It is a large linear-address space that is translated by a combination of hardware and operating-system software to a smaller physical-address space, parts of which are located in memory and parts on disk or other external storage media.

Figure 2-1 on page 10 shows how the virtual-memory space is treated in the two submodes of long mode:

- *64-bit mode*—This mode uses a flat segmentation model of virtual memory. The 64-bit virtual-memory space is treated as a single, flat (unsegmented) address space. Program addresses access locations that can be anywhere in the linear 64-bit address space. The operating system can use separate selectors for code, stack, and data segments for memory-protection purposes, but the base address of all these segments is always 0. (For an exception to this general rule, see “FS and GS as Base of Address Calculation” on page 17.)
- *Compatibility mode*—This mode uses a protected, multi-segment model of virtual memory, just as in legacy protected mode. The 32-bit virtual-memory space is treated as a segmented set of address spaces for code, stack, and data segments, each with its own base address and protection parameters. A segmented space is specified by adding a segment selector to an address.

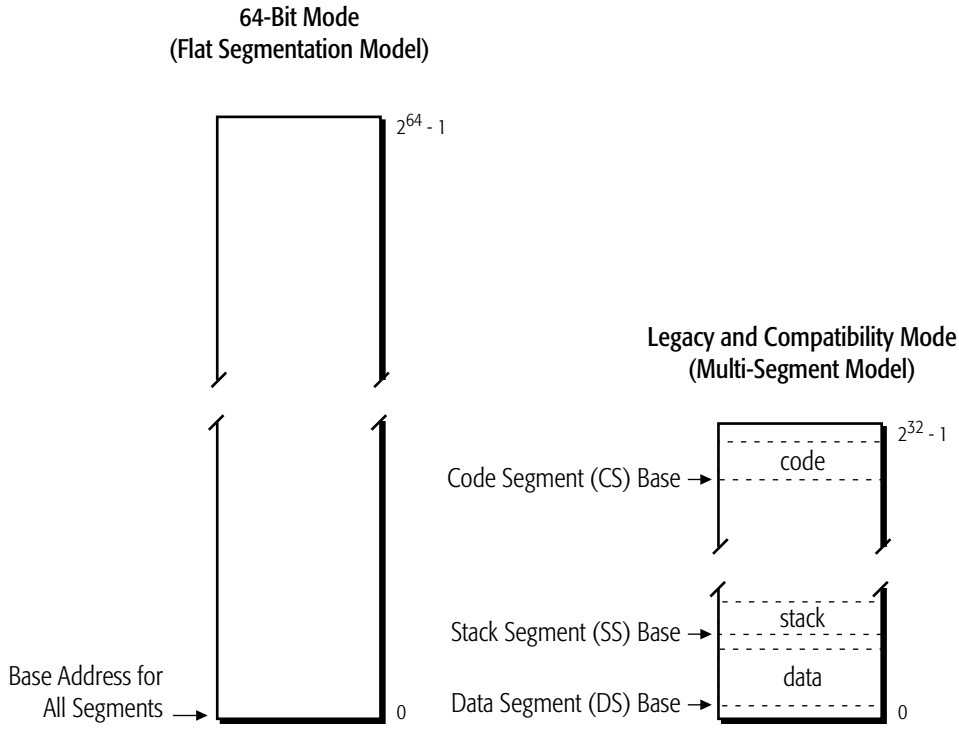

Figure 2-1. Virtual-Memory Segmentation

Operating systems have used segmented memory as a method to isolate programs from the data they used, in an effort to increase the reliability of systems running multiple programs simultaneously. However, most modern operating systems do not use the segmentation features available in the legacy x86 architecture. Instead, these operating systems handle segmentation functions entirely in software. For this reason, the AMD64 architecture dispenses with most of the legacy segmentation functions in 64-bit mode. This allows 64-bit operating systems to be coded more simply, and it supports more efficient management of multi-tasking environments than is possible in the legacy x86 architecture.

2.1.2 Segment Registers

Segment registers hold the selectors used to access memory segments. Figure 2-2 on page 11 shows the application-visible portion of the segment registers. In legacy and compatibility modes, all segment registers are accessible to software. In 64-bit mode, only the CS, FS, and GS segments are recognized by the processor, and software can use the FS and GS segment-base registers as base registers for address calculation, as described in “FS and GS as Base of Address Calculation” on page 17. For references to the DS, ES, or SS segments in 64-bit mode, the processor assumes that the base for each of these segments is zero, neither their segment limit nor attributes are checked, and the processor simply checks that all such addresses are in canonical form, as described in “64-Bit Canonical Addresses” on page 15.

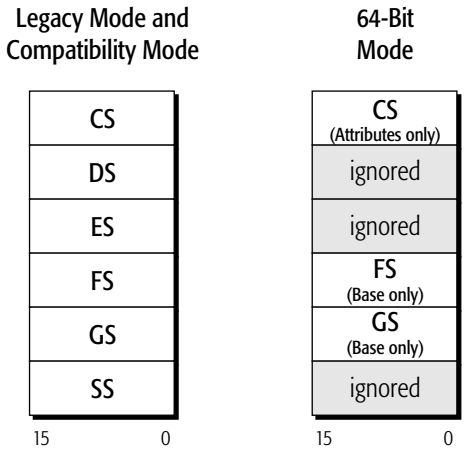

Figure 2-2. Segment Registers

For details on segmentation and the segment registers, see "Segmented Virtual Memory" in Volume 2.

2.1.3 Physical Memory

Physical memory is the installed memory (excluding cache memory) in a particular computer system that can be accessed through the processor's bus interface. The maximum size of the physical memory space is determined by the number of address bits on the bus interface. In a virtual-memory system, the large virtual-address space (also called *linear-address space*) is translated to a smaller physical-address space by a combination of segmentation and paging hardware and software.

Segmentation is illustrated in Figure 2-1 on page 10. Paging is a mechanism for translating linear (virtual) addresses into fixed-size blocks called *pages*, which the operating system can move, as needed, between memory and external storage media (typically disk). The AMD64 architecture supports an expanded version of the legacy x86 paging mechanism, one that is able to translate the full 64-bit virtual-address space into the physical-address space supported by the particular implementation.

2.1.4 Memory Management

Memory management strategies translate addresses generated by programs into addresses in physical memory using segmentation and/or paging. Memory management is not visible to application programs. It is handled by the operating system and processor hardware. The following description gives a very brief overview of these functions. Details are given in "System-Management Instructions" in Volume 2.

2.1.4.1 Long-Mode Memory Management

Figure 2-3 shows the flow, from top to bottom, of memory management functions performed in the two submodes of long mode.

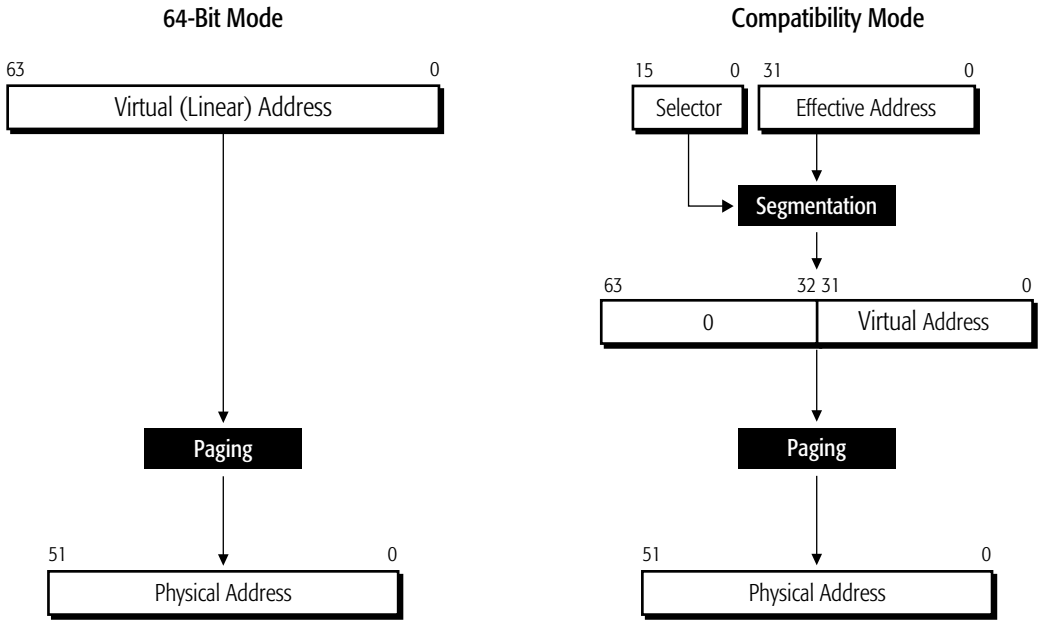

Figure 2-3. Long-Mode Memory Management

In 64-bit mode, programs generate virtual (linear) addresses that can be up to 64 bits in size. The virtual addresses are passed to the long-mode paging function, which generates physical addresses that can be up to 52 bits in size. (Specific implementations of the architecture can support smaller virtual-address and physical-address sizes.)

In compatibility mode, legacy 16-bit and 32-bit applications run using legacy x86 protected-mode segmentation semantics. The 16-bit or 32-bit effective addresses generated by programs are combined with their segments to produce 32-bit virtual (linear) addresses that are zero-extended to a maximum of 64 bits. The paging that follows is the same long-mode paging function used in 64-bit mode. It translates the virtual addresses into physical addresses. The combination of segment selector and effective address is also called a *logical address* or *far pointer*. The *virtual address* is also called the *linear address*.

2.1.4.2 Legacy-Mode Memory Management

Figure 2-4 on page 13 shows the memory-management functions performed in the three submodes of legacy mode.

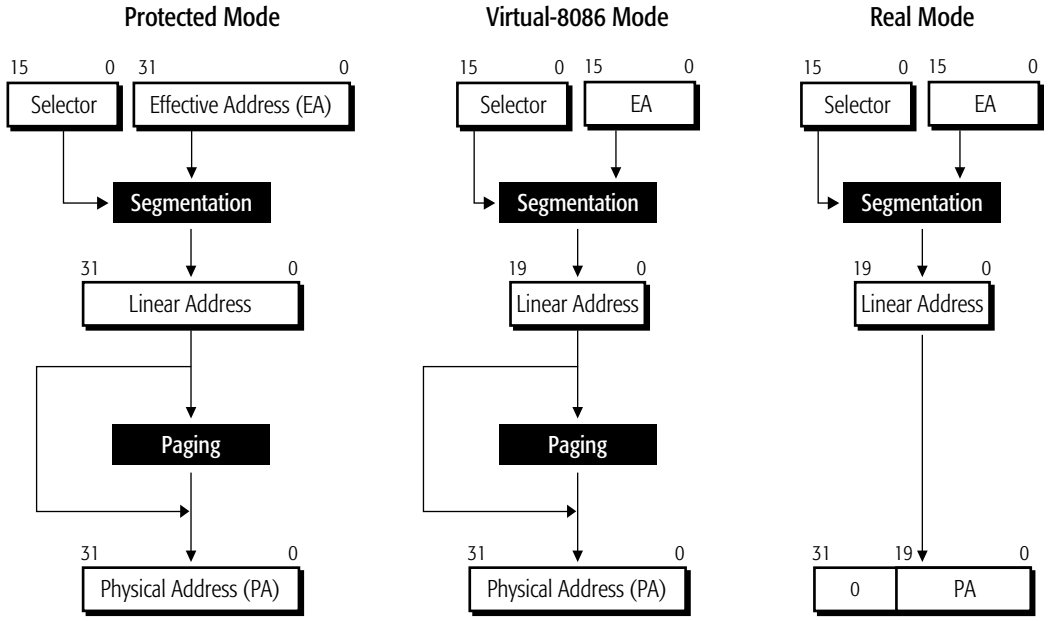

Figure 2-4. Legacy-Mode Memory Management

The memory-management functions differ, depending on the submode, as follows:

- *Protected Mode*—Protected mode supports 16-bit and 32-bit programs with table-based memory segmentation, paging, and privilege-checking. The segmentation function takes 32-bit effective addresses and 16-bit segment selectors and produces 32-bit linear addresses into one of 16K memory segments, each of which can be up to 4GB in size. Paging is optional. The 32-bit physical addresses are either produced by the paging function or the linear addresses are used without modification as physical addresses.
- *Virtual-8086 Mode*—Virtual-8086 mode supports 16-bit programs running as tasks under protected mode. 20-bit linear addresses are formed in the same way as in real mode, but they can optionally be translated through the paging function to form 32-bit physical addresses that access up to 4GB of memory space.
- *Real Mode*—Real mode supports 16-bit programs using register-based shift-and-add segmentation, but it does not support paging. Sixteen-bit effective addresses are zero-extended and added to a 16-bit segment-base address that is left-shifted four bits, producing a 20-bit linear address. The linear address is zero-extended to a 32-bit physical address that can access up to 1MB of memory space.

2.2 Memory Addressing

2.2.1 Byte Ordering

Instructions and data are stored in memory in *little-endian* byte order. Little-endian ordering places the least-significant byte of the instruction or data item at the lowest memory address and the most-significant byte at the highest memory address.

Figure 2-5 shows a generalization of little-endian memory and register images of a quadword data type. The least-significant byte is at the lowest address in memory and at the right-most byte location of the register image.

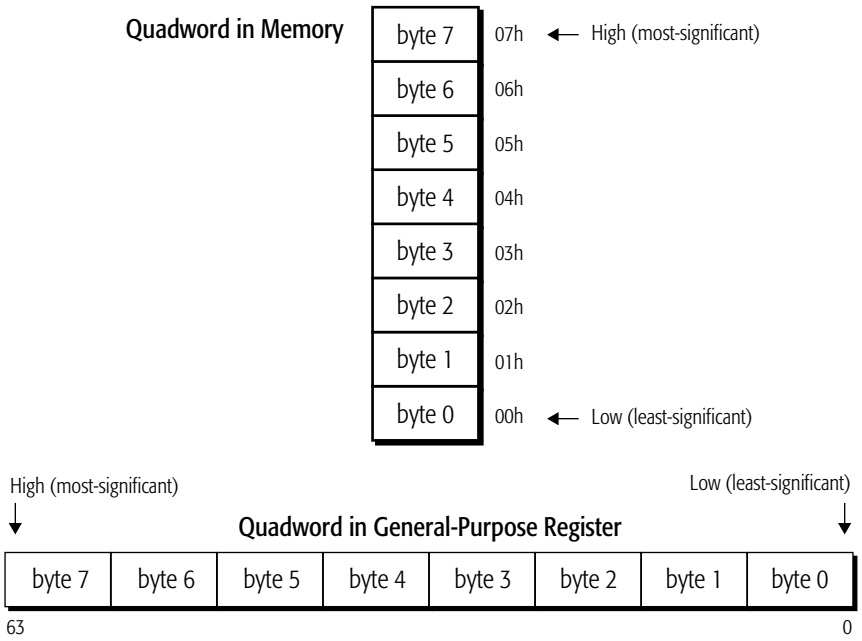

Figure 2-5. Byte Ordering

Figure 2-6 on page 15 shows the memory image of a 10-byte instruction. Instructions are byte data types. They are read from memory one byte at a time, starting with the least-significant byte (lowest address). For example, the following instruction specifies the 64-bit instruction MOV RAX, 1122334455667788 instruction that consists of the following ten bytes:

```
48 B8 8877665544332211
```

48 is a REX instruction prefix that specifies a 64-bit operand size, B8 is the opcode that—together with the REX prefix—specifies the 64-bit RAX destination register, and 8877665544332211 is the 8-byte immediate value to be moved, where 88 represents the eighth (least-significant) byte and 11 represents the first (most-significant) byte. In memory, the REX prefix byte (48) would be stored at the lowest address, and the first immediate byte (11) would be stored at the highest instruction address.

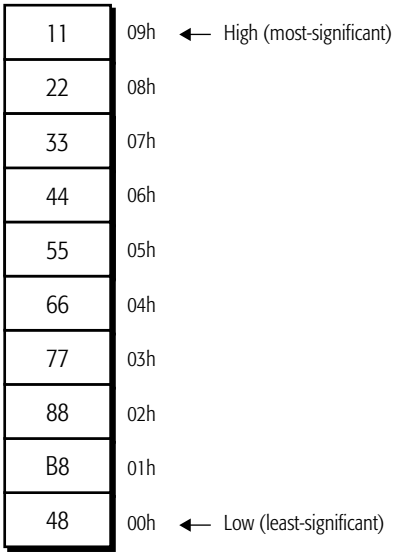

Figure 2-6. Example of 10-Byte Instruction in Memory

2.2.2 64-Bit Canonical Addresses

Long mode defines 64 bits of virtual address, but implementations of the AMD64 architecture may support fewer bits of virtual address. Although implementations might not use all 64 bits of the virtual address, they check bits 63 through the most-significant implemented bit to see if those bits are all zeros or all ones. An address that complies with this property is said to be in *canonical address form*. If a virtual-memory reference is not in canonical form, the implementation causes a general-protection exception or stack fault.

2.2.3 Effective Addresses

Programs provide effective addresses to the hardware prior to segmentation and paging translations. Long-mode effective addresses are a maximum of 64 bits wide, as shown in Figure 2-3 on page 12. Programs running in compatibility mode generate (by default) 32-bit effective addresses, which the hardware zero-extends to 64 bits. Legacy-mode effective addresses, with no address-size override, are 32 or 16 bits wide, as shown in Figure 2-4 on page 13. These sizes can be overridden with an address-size instruction prefix, as described in “Instruction Prefixes” on page 76.

There are five methods for generating effective addresses, depending on the specific instruction encoding:

- *Absolute Addresses*—These addresses are given as displacements (or offsets) from the base address of a data segment. They point directly to a memory location in the data segment.
- *Instruction-Relative Addresses*—These addresses are given as displacements (or offsets) from the current instruction pointer (IP), also called the program counter (PC). They are generated by control-transfer instructions. A displacement in the instruction encoding, or one read from

memory, serves as an offset from the address that follows the transfer. See “RIP-Relative Addressing” on page 18 for details about RIP-relative addressing in 64-bit mode.

- *Indexed Register-Indirect Addresses*—These addresses are calculated off a base address contained in a general-purpose register specified by the instruction (base). Different encodings allow offsets from this base using a signed displacement or using the sum of the displacement and a scaled index value. Instruction encodings may utilize up to ten bytes—the ModRM byte, the optional SIB (scale, index, base) byte and a variable length displacement—to specify the values to be used in the effective address calculation. The base and index values are contained in general-purpose registers specified by the SIB byte. The scale and displacement values are specified directly in the instruction encoding. Figure 2-7 shows the components of the address calculation. The resultant effective address is added to the data-segment base address to form a linear address, as described in “Segmented Virtual Memory” in Volume 2. “Instruction Formats” in Volume 3 gives further details on specifying this form of address.

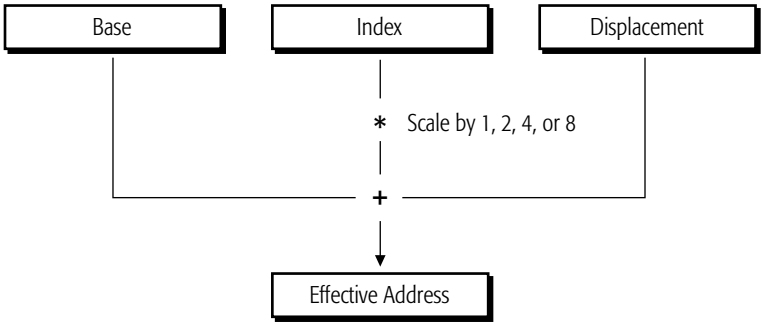

Figure 2-7. Complex Address Calculation (Protected Mode)

- *Stack Addresses*—PUSH, POP, CALL, RET, IRET, and INT instructions implicitly use the stack pointer, which contains the address of the procedure stack. See “Stack Operation” on page 19 for details about the size of the stack pointer.
- *String Addresses*—String instructions generate sequential addresses using the rDI and rSI registers, as described in “Implicit Uses of GPRs” on page 30.

In 64-bit mode, with no address-size override, the size of effective-address calculations is 64 bits. An effective-address calculation uses 64-bit base and index registers and sign-extends displacements to 64 bits. Due to the flat address space in 64-bit mode, virtual addresses are equal to effective addresses. (For an exception to this general rule, see “FS and GS as Base of Address Calculation” on page 17.)

2.2.3.1 Long-Mode Zero-Extension of 16-Bit and 32-Bit Addresses

In long mode, all 16-bit and 32-bit address calculations are zero-extended to form 64-bit addresses. Address calculations are first truncated to the effective-address size of the current mode (64-bit mode or compatibility mode), as overridden by any address-size prefix. The result is then zero-extended to the full 64-bit address width.

Because of this, 16-bit and 32-bit applications running in compatibility mode can access only the low 4GB of the long-mode virtual-address space. Likewise, a 32-bit address generated in 64-bit mode can access only the low 4GB of the long-mode virtual-address space.

2.2.3.2 Displacements and Immediates

In general, the maximum size of address displacements and immediate operands is 32 bits. They can be 8, 16, or 32 bits in size, depending on the instruction or, for displacements, the effective address size. In 64-bit mode, displacements are sign-extended to 64 bits during use, but their actual size (for value representation) remains a maximum of 32 bits. The same is true for immediates in 64-bit mode, when the operand size is 64 bits. However, support is provided in 64-bit mode for some 64-bit displacement and immediate forms of the MOV instruction.

2.2.3.3 FS and GS as Base of Address Calculation

In 64-bit mode, the FS and GS segment-base registers (unlike the DS, ES, and SS segment-base registers) can be used as non-zero data-segment base registers for address calculations, as described in "Segmented Virtual Memory" in Volume 2. 64-bit mode assumes all other data-segment registers (DS, ES, and SS) have a base address of 0.

2.2.4 Address-Size Prefix

The default address size of an instruction is determined by the default-size (D) bit and long-mode (L) bit in the current code-segment descriptor (for details, see "Segmented Virtual Memory" in Volume 2). Application software can override the default address size in any operating mode by using the 67h address-size instruction prefix byte. The address-size prefix allows mixing 32-bit and 64-bit addresses on an instruction-by-instruction basis.

Table 2-1 on page 18 shows the effects of using the address-size prefix in all operating modes. In 64-bit mode, the default address size is 64 bits. The address size can be overridden to 32 bits. 16-bit addresses are not supported in 64-bit mode. In compatibility and legacy modes, the address-size prefix works the same as in the legacy x86 architecture.

Table 2-1. Address-Size Prefixes

Operating Mode		Default Address Size (Bits)	Effective Address Size (Bits)	Address-Size Prefix (67h)[1] Required?
Long Mode	64-Bit Mode	64	64	no
			32	yes
	Compatibility Mode	32	32	no
			16	yes
		16	32	yes
			16	no
Legacy Mode (Protected, Virtual-8086, or Real Mode)		32	32	no
			16	yes
		16	32	yes
			16	no

Note:
1. *"No" indicates that the default address size is used.*

2.2.5 RIP-Relative Addressing

RIP-relative addressing—that is, addressing relative to the 64-bit instruction pointer (also called program counter)—is available in 64-bit mode. The effective address is formed by adding the displacement to the 64-bit RIP of the next instruction.

In the legacy x86 architecture, addressing relative to the instruction pointer (IP or EIP) is available only in control-transfer instructions. In the 64-bit mode, any instruction that uses ModRM addressing (see "ModRM and SIB Bytes" in Volume 3) can use RIP-relative addressing. The feature is particularly useful for addressing data in position-independent code and for code that addresses global data.

Programs usually have many references to data, especially global data, that are not register-based. To load such a program, the loader typically selects a location for the program in memory and then adjusts the program's references to global data based on the load location. RIP-relative addressing of data makes this adjustment unnecessary.

2.2.5.1 Range of RIP-Relative Addressing

Without RIP-relative addressing, instructions encoded with a ModRM byte address memory relative to zero. With RIP-relative addressing, instructions with a ModRM byte can address memory relative to the 64-bit RIP using a signed 32-bit displacement. This provides an offset range of ±2 GBytes from the RIP.

2.2.5.2 Effect of Address-Size Prefix on RIP-Relative Addressing

RIP-relative addressing is enabled by 64-bit mode, not by a 64-bit address-size. Conversely, use of the address-size prefix does not disable RIP-relative addressing. The effect of the address-size prefix is to truncate and zero-extend the computed effective address to 32 bits, like any other addressing mode.

2.2.5.3 Encoding

For details on instruction encoding of RIP-relative addressing, see in "Encoding for RIP-Relative Addressing" in Volume 3.

2.3 Pointers

Pointers are variables that contain addresses rather than data. They are used by instructions to reference memory. Instructions access data using near and far pointers. Stack pointers locate the current stack.

2.3.1 Near and Far Pointers

Near pointers contain only an effective address, which is used as an offset into the current segment. Far pointers contain both an effective address and a segment selector that specifies one of several segments. Figure 2-8 illustrates the two types of pointers.

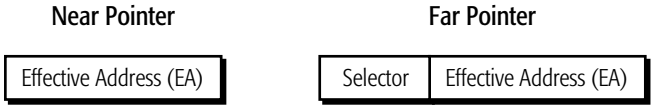

Figure 2-8. Near and Far Pointers

In 64-bit mode, the AMD64 architecture supports only the flat-memory model in which there is only one data segment, so the effective address is used as the virtual (linear) address and far pointers are not needed. In compatibility mode and legacy protected mode, the AMD64 architecture supports multiple memory segments, so effective addresses can be combined with segment selectors to form far pointers, and the terms *logical address* (segment selector and effective address) and *far pointer* are synonyms. Near pointers can also be used in compatibility mode and legacy mode.

2.4 Stack Operation

A procedure stack (also known as a '*program stack*') is a portion of a stack segment in memory that is used to link procedures. Software conventions typically define stacks using a *stack frame*, which consists of two registers—a *stack-frame base pointer* (rBP) and a *stack pointer* (rSP)—as shown in Figure 2-9 on page 20. These stack pointers can be either near pointers or far pointers.

The stack-segment (SS) register, points to the base address of the current stack segment. The stack pointers contain offsets from the base address of the current stack segment. All instructions that address memory using the rBP or rSP registers cause the processor to access the current stack segment.

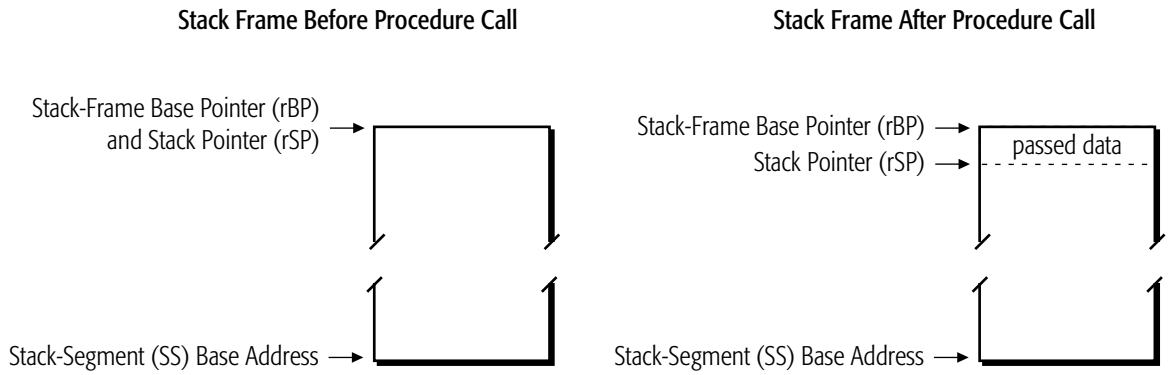

Figure 2-9. Stack Pointer Mechanism

In typical APIs, the stack-frame base pointer and the stack pointer point to the same location before a procedure call (the top-of-stack of the prior stack frame). After data is pushed onto the procedure stack, the stack-frame base pointer remains where it was and the stack pointer advances downward to the address below the pushed data, where it becomes the new top-of-stack.

In legacy and compatibility modes, the default stack pointer size is 16 bits (SP) or 32 bits (ESP), depending on the default-size (B) bit in the stack-segment descriptor, and multiple stacks can be maintained in separate stack segments. In 64-bit mode, stack pointers are always 64 bits wide (RSP).

Further application-programming details on the procedure stack mechanism are described in “Control Transfers” on page 80. System-programming details on the stack segments are described in “Segmented Virtual Memory” in Volume 2.

A shadow stack is a separate, protected stack that is conceptually parallel to the procedure stack and used only by the shadow stack feature. When enabled by system software, the shadow stack feature provides, in a manner that is transparent to application software, protection against a class of computer exploit known as 'return oriented programming'. System-programming details on the shadow stack feature are described in “Shadow Stacks” in Volume 2.

2.5 Instruction Pointer

The instruction pointer is used in conjunction with the code-segment (CS) register to locate the next instruction in memory. The instruction-pointer register contains the displacement (offset)—from the base address of the current CS segment, or from address 0 in 64-bit mode—to the next instruction to be executed. The pointer is incremented sequentially, except for branch instructions, as described in “Control Transfers” on page 80.

In legacy and compatibility modes, the instruction pointer is a 16-bit (IP) or 32-bit (EIP) register. In 64-bit mode, the instruction pointer is extended to a 64-bit (RIP) register to support 64-bit offsets. The case-sensitive acronym, *rIP,* is used to refer to any of these three instruction-pointer sizes, depending on the software context.

Figure 2-10 on page 21 shows the relationship between RIP, EIP, and IP. The 64-bit RIP can be used for RIP-relative addressing, as described in "RIP-Relative Addressing" on page 18.

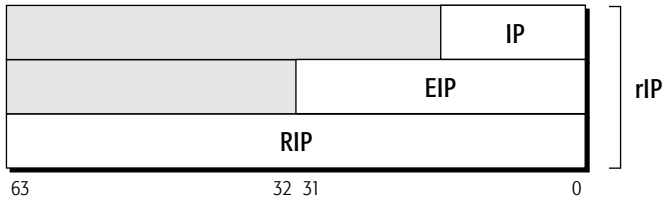

Figure 2-10. Instruction Pointer (rIP) Register

The contents of the rIP are not directly readable by software. However, the rIP is pushed onto the stack by a call instruction.

The memory model described in this chapter is used by all of the programming environments that make up the AMD64 architecture. The next four chapters of this volume describe the application programming environments, which include:

- General-purpose programming (Chapter 3 on page 23).
- Streaming SIMD extensions used in media and scientific programming (Chapter 4 on page 111).
- 64-bit media programming (Chapter 5 on page 239).
- x87 floating-point programming (Chapter 6 on page 285).

3 General-Purpose Programming

The general-purpose programming model includes the general-purpose registers (GPRs), integer instructions and operands that use the GPRs, program-flow control methods, memory optimization methods, and I/O. This programming model includes the original x86 integer-programming architecture, plus 64-bit extensions and a few additional instructions. Only the application-programming instructions and resources are described in this chapter. Integer instructions typically used in system programming, including all of the privileged instructions, are described in Volume 2, along with other system-programming topics.

The general-purpose programming model is used to some extent by almost all programs, including programs consisting primarily of 256-bit or 128-bit media instructions, 64-bit media instructions, x87 floating-point instructions, or system instructions. For this reason, an understanding of the general-purpose programming model is essential for any programming work using the AMD64 instruction set architecture.

3.1 Registers

Figure 3-1 on page 24 shows an overview of the registers used in general-purpose application programming. They include the general-purpose registers (GPRs), segment registers, flags register, and instruction-pointer register. The number and width of available registers depends on the operating mode.

The registers and register ranges shaded *light gray* in Figure 3-1 on page 24 are available only in 64-bit mode. Those shaded *dark gray* are available only in legacy mode and compatibility mode. Thus, in 64-bit mode, the 32-bit general-purpose, flags, and instruction-pointer registers available in legacy mode and compatibility mode are extended to 64-bit widths, eight new GPRs are available, and the DS, ES, and SS segment registers are ignored.

When naming registers, if reference is made to multiple register widths, a lower-case *r* notation is used. For example, the notation *rAX* refers to the 16-bit AX, 32-bit EAX, or 64-bit RAX register, depending on an instruction's effective operand size.

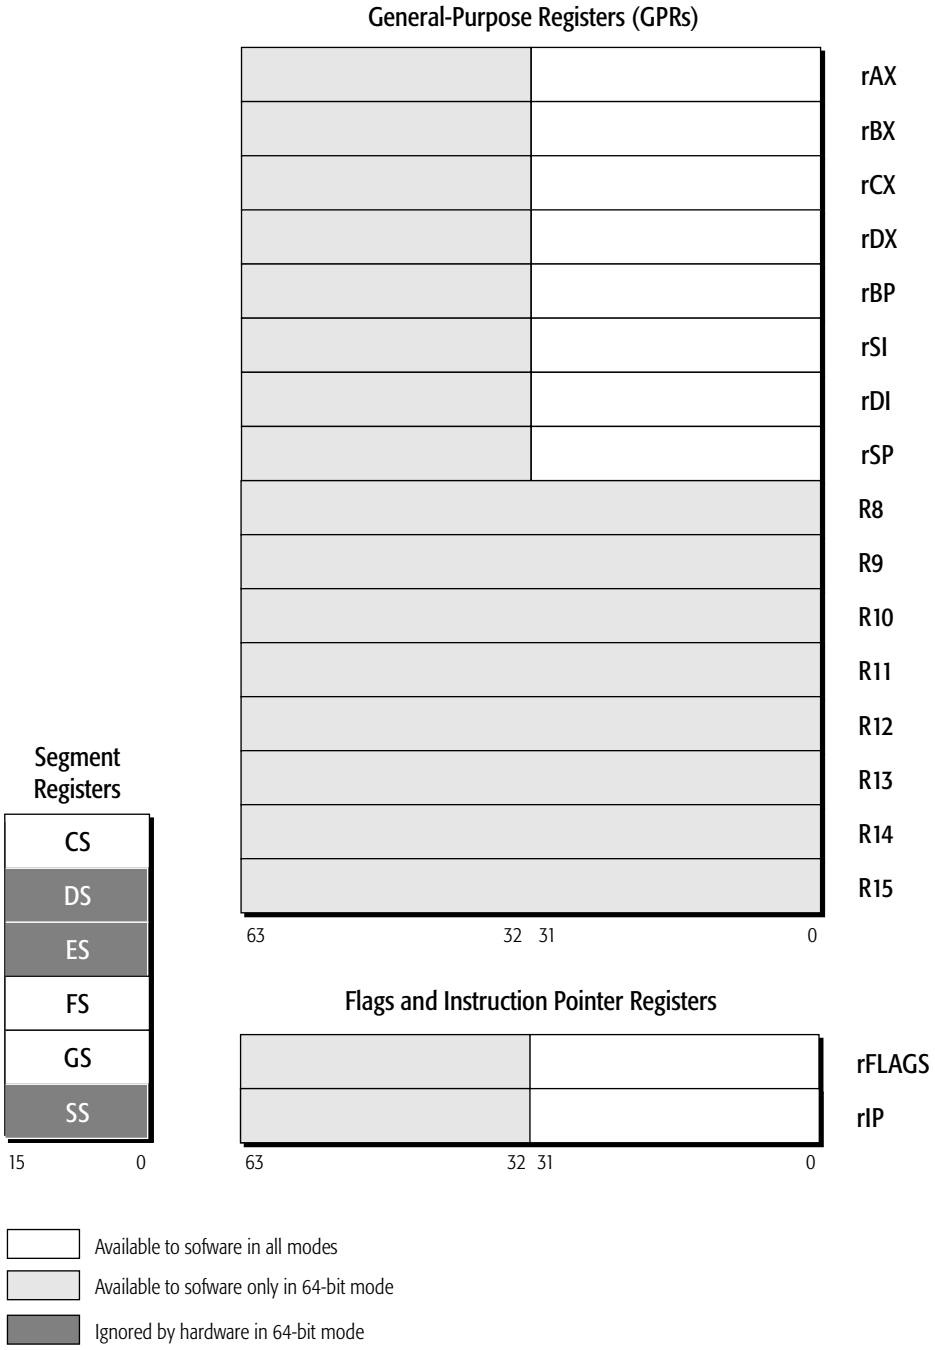

Figure 3-1. General-Purpose Programming Registers

3.1.1 Legacy Registers

In legacy and compatibility modes, all of the legacy x86 registers are available. Figure 3-2 on page 25 shows a detailed view of the GPR, flag, and instruction-pointer registers.

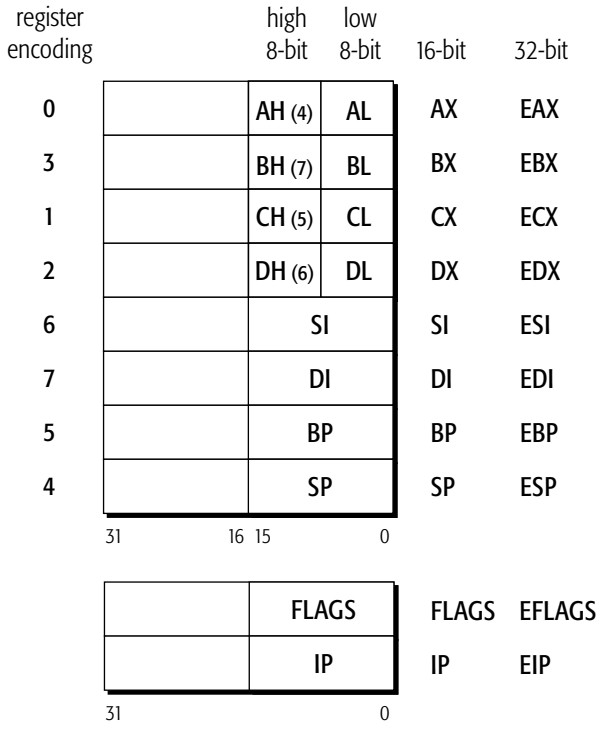

Figure 3-2. General Registers in Legacy and Compatibility Modes

The legacy GPRs include:

- Eight 8-bit registers (AH, AL, BH, BL, CH, CL, DH, DL).
- Eight 16-bit registers (AX, BX, CX, DX, DI, SI, BP, SP).
- Eight 32-bit registers (EAX, EBX, ECX, EDX, EDI, ESI, EBP, ESP).

The size of register used by an instruction depends on the effective operand size or, for certain instructions, the opcode, address size, or stack size. The 16-bit and 32-bit registers are encoded as 0 through 7 in Figure 3-2. For opcodes that specify a byte operand, registers encoded as 0 through 3 refer to the low-byte registers (AL, BL, CL, DL) and registers encoded as 4 through 7 refer to the high-byte registers (AH, BH, CH, DH).

The 16-bit FLAGS register, which is also the low 16 bits of the 32-bit EFLAGS register, shown in Figure 3-2, contains control and status bits accessible to application software, as described in Section 3.1.4, “Flags Register,” on page 34. The 16-bit IP or 32-bit EIP instruction-pointer register contains the address of the next instruction to be executed, as described in Section 2.5, “Instruction Pointer,” on page 20.

3.1.2 64-Bit-Mode Registers

In 64-bit mode, eight new GPRs are added to the eight legacy GPRs, all 16 GPRs are 64 bits wide, and the low bytes of all registers are accessible. Figure 3-3 on page 27 shows the GPRs, flags register, and instruction-pointer register available in 64-bit mode. The GPRs include:

- Sixteen 8-bit low-byte registers (AL, BL, CL, DL, SIL, DIL, BPL, SPL, R8B, R9B, R10B, R11B, R12B, R13B, R14B, R15B).
- Four 8-bit high-byte registers (AH, BH, CH, DH), addressable only when no REX prefix is used.
- Sixteen 16-bit registers (AX, BX, CX, DX, DI, SI, BP, SP, R8W, R9W, R10W, R11W, R12W, R13W, R14W, R15W).
- Sixteen 32-bit registers (EAX, EBX, ECX, EDX, EDI, ESI, EBP, ESP, R8D, R9D, R10D, R11D, R12D, R13D, R14D, R15D).
- Sixteen 64-bit registers (RAX, RBX, RCX, RDX, RDI, RSI, RBP, RSP, R8, R9, R10, R11, R12, R13, R14, R15).

The size of register used by an instruction depends on the effective operand size or, for certain instructions, the opcode, address size, or stack size. For most instructions, access to the extended GPRs requires a REX prefix (Section 3.5.2, “REX Prefixes,” on page 79). The four high-byte registers (AH, BH, CH, DH) available in legacy mode are not addressable when a REX prefix is used.

In general, byte and word operands are stored in the low 8 or 16 bits of GPRs without modifying their high 56 or 48 bits, respectively. Doubleword operands, however, are normally stored in the low 32 bits of GPRs and zero-extended to 64 bits.

The 64-bit RFLAGS register, shown in Figure 3-3 on page 27, contains the legacy EFLAGS in its low 32-bit range. The high 32 bits are reserved. They can be written with anything but they always read as zero (RAZ). The 64-bit RIP instruction-pointer register contains the address of the next instruction to be executed, as described in Section 3.1.5, “Instruction Pointer Register,” on page 36.

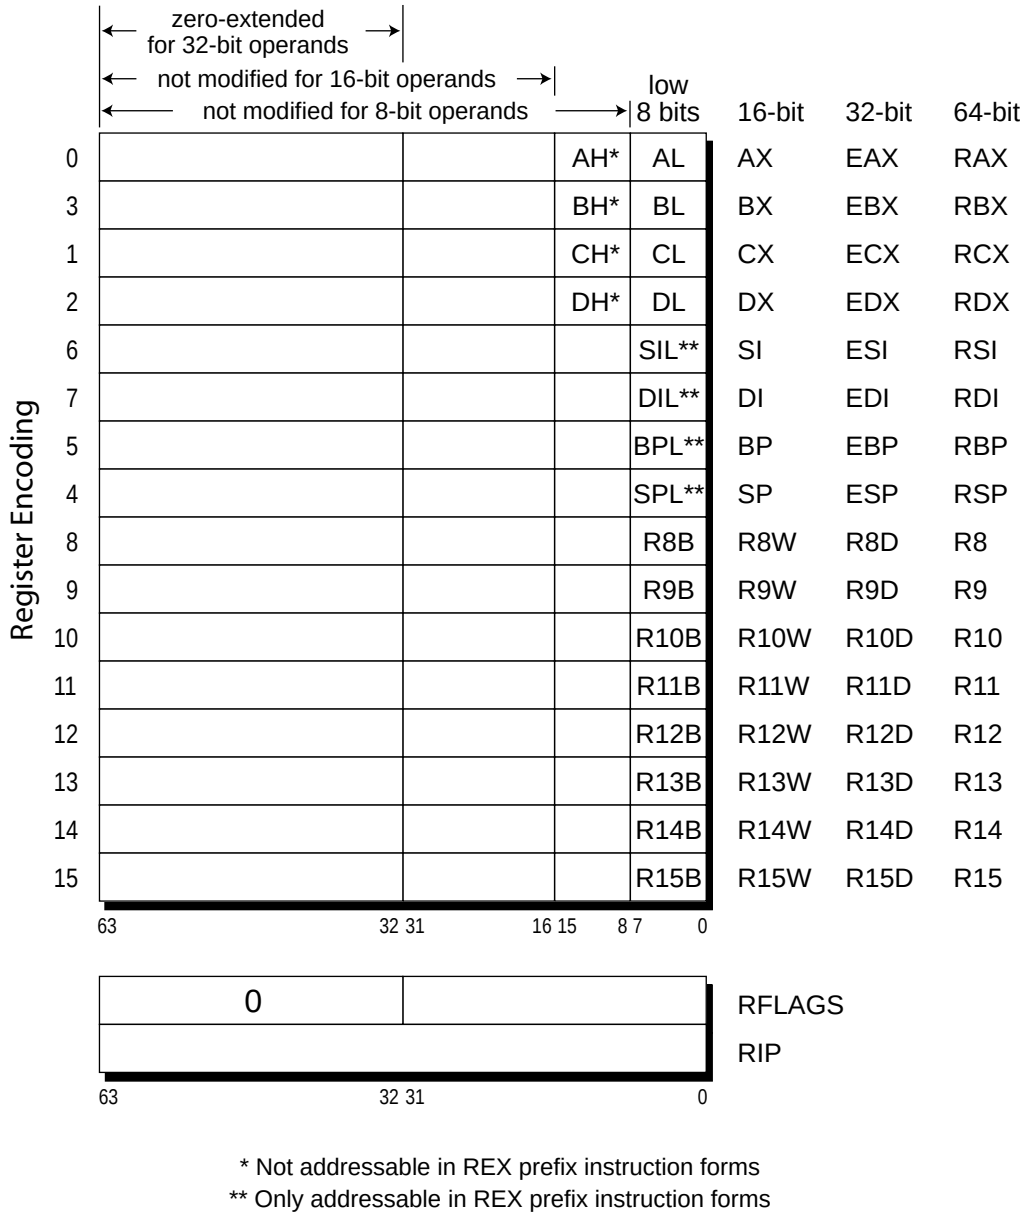

Figure 3-3. General Purpose Registers in 64-Bit Mode

Figure 3-4 on page 28 illustrates another way of viewing the 64-bit-mode GPRs, showing how the legacy GPRs overlay the extended GPRs. Gray-shaded bits are not modified in 64-bit mode.

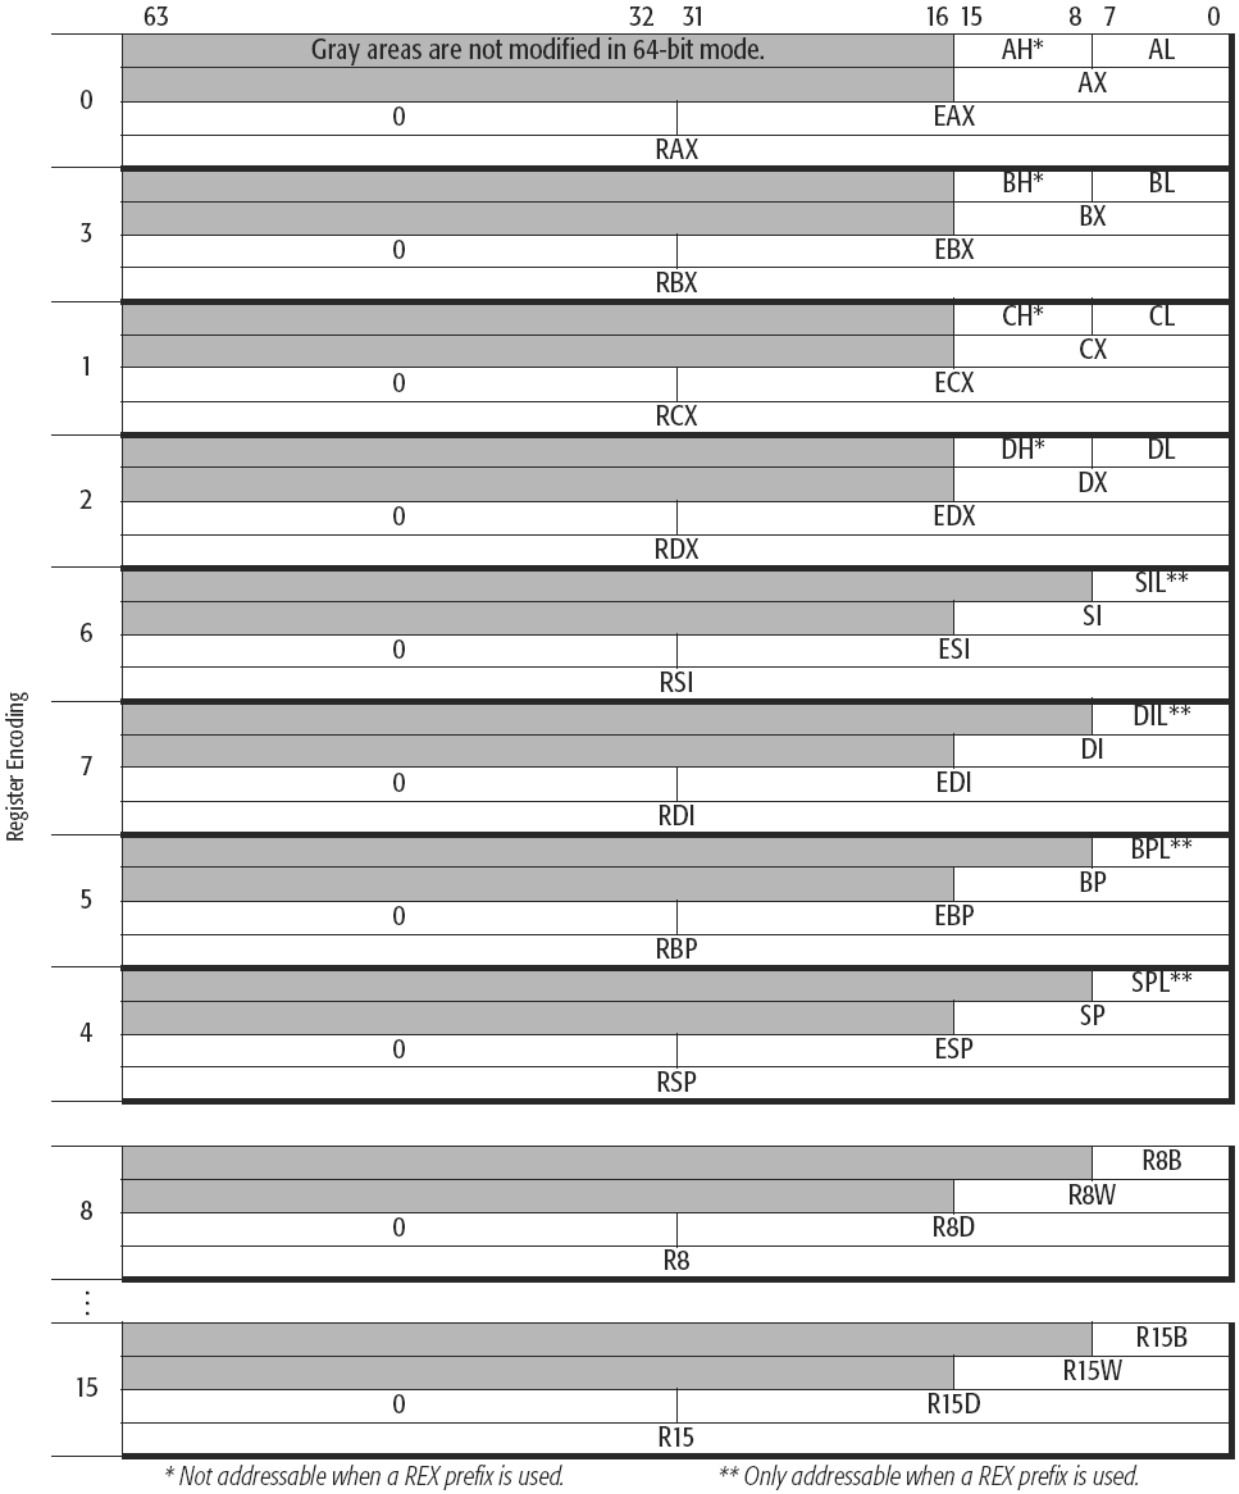

Figure 3-4. GPRs in 64-Bit Mode

3.1.2.1 Default Operand Size

For most instructions, the default operand size in 64-bit mode is 32 bits. To access 16-bit operand sizes, an instruction must contain an operand-size prefix (66h), as described in Section 3.2.3, "Operand Sizes and Overrides," on page 41. To access the full 64-bit operand size, most instructions must contain a REX prefix.

For details on operand size, see Section 3.2.3, "Operand Sizes and Overrides," on page 41.

3.1.2.2 Byte Registers

64-bit mode provides a uniform set of low-byte, low-word, low-doubleword, and quadword registers that is well-suited for register allocation by compilers. Access to the four new low-byte registers in the legacy-GPR range (SIL, DIL, BPL, SPL), or any of the low-byte registers in the extended registers (R8B–R15B), requires a REX instruction prefix. However, the legacy high-byte registers (AH, BH, CH, DH) are not accessible when a REX prefix is used.

3.1.2.3 Zero-Extension of 32-Bit Results

As Figure 3-3 on page 27 and Figure 3-4 on page 28 show, when performing 32-bit operations with a GPR destination in 64-bit mode, the processor zero-extends the 32-bit result into the full 64-bit destination. 8-bit and 16-bit operations on GPRs preserve all unwritten upper bits of the destination GPR. This is consistent with legacy 16-bit and 32-bit semantics for partial-width results.

Software should explicitly sign-extend the results of 8-bit, 16-bit, and 32-bit operations to the full 64-bit width before using the results in 64-bit address calculations.

The following four code examples show how 64-bit, 32-bit, 16-bit, and 8-bit ADDs work. In these examples, "48" is a REX prefix specifying 64-bit operand size, and "01C3" and "00C3" are the opcode and ModRM bytes of each instruction (see "Opcode Syntax" in Volume 3 for details on the opcode and ModRM encoding).

Example 1: 64-bit Add:

```
Before:RAX =0002_0001_8000_2201
       RBX =0002_0002_0123_3301

       48 01C3 ADD RBX,RAX ;48 is a REX prefix for size.

Result:RBX = 0004_0003_8123_5502
```

Example 2: 32-bit Add:

```
Before:RAX = 0002_0001_8000_2201
       RBX = 0002_0002_0123_3301

       01C3 ADD EBX,EAX ;32-bit add

 Result:RBX = 0000_0000_8123_5502
       (32-bit result is zero extended)
```

Example 3: 16-bit Add:

```
Before:RAX = 0002_0001_8000_2201
       RBX = 0002_0002_0123_3301

       66 01C3 ADD BX,AX ;66 is 16-bit size override

Result:RBX = 0002_0002_0123_5502
       (bits 63:16 are preserved)
```

Example 4: 8-bit Add:

```
Before:RAX = 0002_0001_8000_2201
       RBX = 0002_0002_0123_3301

       00C3 ADD BL,AL ;8-bit add

 Result:RBX = 0002_0002_0123_3302
       (bits 63:08 are preserved)
```

3.1.2.4 GPR High 32 Bits Across Mode Switches

The processor does not preserve the upper 32 bits of the 64-bit GPRs across switches from 64-bit mode to compatibility or legacy modes. When using 32-bit operands in compatibility or legacy mode, the high 32 bits of GPRs are undefined. Software must not rely on these undefined bits, because they can change from one implementation to the next or even on a cycle-to-cycle basis within a given implementation. The undefined bits are not a function of the data left by any previously running process.

3.1.3 Implicit Uses of GPRs

Most instructions can use any of the GPRs for operands. However, as Figure 3-1 on page 31 shows, some instructions use some GPRs implicitly. Details about implicit use of GPRs are described in "General-Purpose Instructions in 64-Bit Mode" in Volume 3.

Table 3-1 on page 31 shows implicit register uses only for application instructions. Certain system instructions also make implicit use of registers. These system instructions are described in "System Instruction Reference" in Volume 3.

Table 3-1. Implicit Uses of GPRs

Registers[1]				Name	Implicit Uses
Low 8-Bit	16-Bit	32-Bit	64-Bit		
AL	AX	EAX	RAX[2]	Accumulator	• Operand for decimal arithmetic, multiply, divide, string, compare-and-exchange, table-translation, and I/O instructions. • Special accumulator encoding for ADD, XOR, and MOV instructions. • Used with EDX to hold double-precision operands. • CPUID processor-feature information.
BL	BX	EBX	RBX[2]	Base	• Address generation in 16-bit code. • Memory address for XLAT instruction. • CPUID processor-feature information.
CL	CX	ECX	RCX[2]	Count	• Bit index for shift and rotate instructions. • Iteration count for loop and repeated string instructions. • Jump conditional if zero. • CPUID processor-feature information.
DL	DX	EDX	RDX[2]	I/O Address	• Operand for multiply and divide instructions. • Port number for I/O instructions. • Used with EAX to hold double-precision operands. • CPUID processor-feature information.
SIL[2]	SI	ESI	RSI[2]	Source Index	• Memory address of source operand for string instructions. • Memory index for 16-bit addresses.

Note:
1. *Gray-shaded registers have no implicit uses.*
2. *Accessible only in 64-bit mode.*

Table 3-1. Implicit Uses of GPRs (continued)

Registers[1]				Name	Implicit Uses
Low 8-Bit	16-Bit	32-Bit	64-Bit		
DIL[2]	DI	EDI	RDI[2]	Destination Index	• Memory address of destination operand for string instructions. • Memory index for 16-bit addresses.
BPL[2]	BP	EBP	RBP[2]	Base Pointer	• Memory address of stack-frame base pointer.
SPL[2]	SP	ESP	RSP[2]	Stack Pointer	• Memory address of last stack entry (top of stack).
R8B–R10B[2]	R8W–R10W[2]	R8D–R10D[2]	R8–R10[2]	None	No implicit uses
R11B[2]	R11W[2]	R11D[2]	R11[2]	None	• Holds the value of RFLAGS on SYSCALL/SYSRET.
R12B–R15B[2]	R12W–R15W[2]	R12D–R15D[2]	R12–R15[2]	None	No implicit uses

Note:
1. *Gray-shaded registers have no implicit uses.*
2. *Accessible only in 64-bit mode.*

3.1.3.1 Arithmetic Operations

Several forms of the add, subtract, multiply, and divide instructions use AL or rAX implicitly. The multiply and divide instructions also use the concatenation of rDX:rAX for double-sized results (multiplies) or quotient and remainder (divides).

3.1.3.2 Sign-Extensions

The instructions that double the size of operands by sign extension (for example, CBW, CWDE, CDQE, CWD, CDQ, CQO) use rAX register implicitly for the operand. The CWD, CDQ, and CQO instructions also uses the rDX register.

3.1.3.3 Special MOVs

The MOV instruction has several opcodes that implicitly use the AL or rAX register for one operand.

3.1.3.4 String Operations

Many types of string instructions use the accumulators implicitly. Load string, store string, and scan string instructions use AL or rAX for data and rDI or rSI for the offset of a memory address.

3.1.3.5 I/O-Address-Space Operations.

The I/O and string I/O instructions use rAX to hold data that is received from or sent to a device located in the I/O-address space. DX holds the device I/O-address (the port number).

3.1.3.6 Table Translations

The table translate instruction (XLATB) uses AL for an memory index and rBX for memory base address.

3.1.3.7 Compares and Exchanges

Compare and exchange instructions (CMPXCHG) use the AL or rAX register for one operand.

3.1.3.8 Decimal Arithmetic

The decimal arithmetic instructions (AAA, AAD, AAM, AAS, DAA, DAS) that adjust binary-coded decimal (BCD) operands implicitly use the AL and AH register for their operations.

3.1.3.9 Shifts and Rotates

Shift and rotate instructions can use the CL register to specify the number of bits an operand is to be shifted or rotated.

3.1.3.10 Conditional Jumps

Special conditional-jump instructions use the rCX register instead of flags. The JCXZ and JrCXZ instructions check the value of the rCX register and pass control to the target instruction when the value of rCX register reaches 0.

3.1.3.11 Repeated String Operations

With the exception of I/O string instructions, all string operations use rSI as the source-operand pointer and rDI as the destination-operand pointer. I/O string instructions use rDX to specify the input-port or output-port number. For repeated string operations (those preceded with a repeat-instruction prefix), the rSI and rDI registers are incremented or decremented as the string elements are moved from the source location to the destination. Repeat-string operations also use rCX to hold the string length, and decrement it as data is moved from one location to the other.

3.1.3.12 Stack Operations

Stack operations make implicit use of the rSP register, and in some cases, the rBP register. The rSP register is used to hold the top-of-stack pointer (or simply, stack pointer). rSP is decremented when items are pushed onto the stack, and incremented when they are popped off the stack. The ENTER and LEAVE instructions use rBP as a stack-frame base pointer. Here, rBP points to the last entry in a data structure that is passed from one block-structured procedure to another.

The use of rSP or rBP as a base register in an address calculation implies the use of SS (stack segment) as the default segment. Using any other GPR as a base register without a segment-override prefix implies the use of the DS data segment as the default segment.

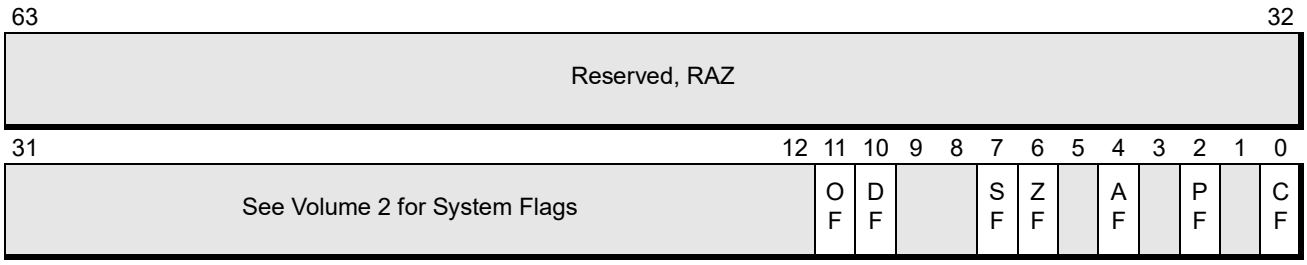
The push all and pop all instructions (PUSHA, PUSHAD, POPA, POPAD) implicitly use all of the GPRs.

3.1.3.13 CPUID Information

The CPUID instruction makes implicit use of the EAX, EBX, ECX, and EDX registers. Software loads a function code into EAX and, for some function codes, a sub-function code in ECX, executes the CPUID instruction, and then reads the associated processor-feature information in EAX, EBX, ECX, and EDX.

3.1.4 Flags Register

Figure 3-5 on page 34 shows the 64-bit RFLAGS register and the flag bits visible to application software. Bits 15:0 are the FLAGS register (accessed in legacy real and virtual-8086 modes), bits 31:0 are the EFLAGS register (accessed in legacy protected mode and compatibility mode), and bits 63:0 are the RFLAGS register (accessed in 64-bit mode). The name *rFLAGS* refers to any of the three register widths, depending on the current software context.



Bits	Mnemonic	Description	R/W
11	OF	Overflow Flag	R/W
10	DF	Direction Flag	R/W
7	SF	Sign Flag	R/W
6	ZF	Zero Flag	R/W
4	AF	Auxiliary Carry Flag	R/W
2	PF	Parity Flag	R/W
0	CF	Carry Flag	R/W

Figure 3-5. rFLAGS Register—Flags Visible to Application Software

The low 16 bits (FLAGS portion) of rFLAGS are accessible by application software and hold the following flags:

- One control flag (the direction flag DF).
- Six status flags (carry flag CF, parity flag PF, auxiliary carry flag AF, zero flag ZF, sign flag SF, and overflow flag OF).

The direction flag (DF) controls the direction of string operations. The status flags provide result information from logical and arithmetic operations and control information for conditional move and jump instructions.

Bits 31:16 of the rFLAGS register contain flags that are accessible only to system software. These flags are described in "System Registers" in Volume 2. The highest 32 bits of RFLAGS are reserved. In 64-bit mode, writes to these bits are ignored. They are read as zeros (RAZ). The rFLAGS register is initialized to 02h on reset, so that all of the programmable bits are cleared to zero.

The effects that rFLAGS bit-values have on instructions are summarized in the following places:

- Conditional Moves (CMOV*cc*)—Table 3-4 on page 46.
- Conditional Jumps (J*cc*)—Table 3-5 on page 60.
- Conditional Sets (SET*cc*)—Table 3-6 on page 64.

The effects that instructions have on rFLAGS bit-values are summarized in "Instruction Effects on RFLAGS" in Volume 3.

The sections below describe each application-visible flag. All of these flags are readable and writable. For example, the POPF, POPFD, POPFQ, IRET, IRETD, and IRETQ instructions write all flags. The carry and direction flags are writable by dedicated application instructions. Other application-visible flags are written indirectly by specific instructions. Reserved bits and bits whose writability is prevented by the current values of system flags, current privilege level (CPL), or the current operating mode, are unaffected by the POPF*x* instructions.

Carry Flag (CF). Bit 0. Hardware sets the carry flag to 1 if the last integer addition or subtraction operation resulted in a carry (for addition) or a borrow (for subtraction) out of the most-significant bit position of the result. Otherwise, hardware clears the flag to 0.

The increment and decrement instructions—unlike the addition and subtraction instructions—do not affect the carry flag. The bit shift and bit rotate instructions shift bits of operands into the carry flag. Logical instructions like AND, OR, XOR clear the carry flag. Bit-test instructions (BTx) set the value of the carry flag depending on the value of the tested bit of the operand.

Software can set or clear the carry flag with the STC and CLC instructions, respectively. Software can complement the flag with the CMC instruction.

Parity Flag (PF). Bit 2. Hardware sets the parity flag to 1 if there is an even number of 1 bits in the least-significant byte of the last result of certain operations. Otherwise (i.e., for an odd number of 1 bits), hardware clears the flag to 0. Software can read the flag to implement parity checking.

Auxiliary Carry Flag (AF). Bit 4. Hardware sets the auxiliary carry flag if an arithmetic operation or a binary-coded decimal (BCD) operation generates a carry (in the case of an addition) or a borrow (in the case of a subtraction) out of bit 3 of the result. Otherwise, AF is cleared to zero.

The main application of this flag is to support decimal arithmetic operations. Most commonly, this flag is used internally by correction commands for decimal addition (AAA) and subtraction (AAS).

Zero Flag (ZF). Bit 6. Hardware sets the zero flag to 1 if the last arithmetic operation resulted in a value of zero. Otherwise (for a non-zero result), hardware clears the flag to 0. The compare and test instructions also affect the zero flag.

The zero flag is typically used to test whether the result of an arithmetic or logical operation is zero, or to test whether two operands are equal.

Sign Flag (SF). Bit 7. Hardware sets the sign flag to 1 if the last arithmetic operation resulted in a negative value. Otherwise (for a positive-valued result), hardware clears the flag to 0. Thus, in such operations, the value of the sign flag is set equal to the value of the most-significant bit of the result. Depending on the size of operands, the most-significant bit is bit 7 (for bytes), bit 15 (for words), bit 31 (for doublewords), or bit 63 (for quadwords).

Direction Flag (DF). Bit 10. The direction flag determines the order in which strings are processed. Software can set the direction flag to 1 to specify decrementing the data pointer for the next string instruction (LODSx, STOSx, MOVSx, SCASx, CMPSx, OUTSx, or INSx). Clearing the direction flag to 0 specifies incrementing the data pointer. The pointers are stored in the rSI or rDI register. Software can set or clear the flag with the STD and CLD instructions, respectively.

Overflow Flag (OF). Bit 11. Hardware sets the overflow flag to 1 to indicate that the most-significant (sign) bit of the result of the last signed integer operation differed from the signs of both source operands. Otherwise, hardware clears the flag to 0. A set overflow flag means that the magnitude of the positive or negative result is too big (overflow) or too small (underflow) to fit its defined data type.

The OF flag is undefined after the DIV instruction and after a shift of more than one bit. Logical instructions clear the overflow flag.

3.1.5 Instruction Pointer Register

The instruction pointer register—IP, EIP, or RIP, or simply rIP for any of the three depending on the context—is used in conjunction with the code-segment (CS) register to locate the next instruction in memory. See Section 2.5, “Instruction Pointer,” on page 20 for details.

3.2 Operands

Operands are either referenced by an instruction's encoding or included as an immediate value in the instruction encoding. Depending on the instruction, referenced operands can be located in registers, memory locations, or I/O ports.

3.2.1 Fundamental Data Types

At the most fundamental level, a datum is an ordered string of a specific length composed of binary digits (bits). Bits are indexed from *0* to *length-1*. While technically the size of a datum is not restricted, for convenience in storing and manipulating data the Architecture defines a finite number of data objects of specific size and names them.

A datum of length 1 is simply a *bit*. A datum of length 4 is a *nibble*, a datum of length 8 is a *byte*, a datum of length 16 is a *word*, a datum of length 32 is a *doubleword*, a datum of length 64 is a *quadword*, a datum of length 128 is a *double quadword* (also called an *octword*), a datum of length 256 is a *double octword*.

For instructions that move or reorder data, the significance of each bit within the datum is immaterial. An instruction of this type may operate on bits, bytes, words, doublewords, and so on. The majority of instructions, however, expect operand data to be of a specific format. The format assigns a particular significance to each bit based on its position within the datum. This assignment of significance or meaning to each bit is called data typing.

The Architecture defines the following fundamental data types:

- Untyped data objects
  - bit
  - nibble (4 bits)
  - byte (8 bits)
  - word (16 bits)
  - doubleword (32 bits)
  - quadword (64 bits)
  - double quadword (octword) (128 bits)
  - double octword (256 bits)
- Unsigned integers
  - 8-bit (byte) unsigned integer
  - 16-bit (word) unsigned integer
  - 32-bit (doubleword) unsigned integer
  - 64-bit (quadword) unsigned integer
  - 128-bit (octword) unsigned integer
- Signed (two's-complement) integers
  - 8-bit (byte) signed integer
  - 16-bit (word) signed integer
  - 32-bit (doubleword) signed integer
  - 64-bit (quadword) signed integer
  - 128-bit (octword) signed integer
- Binary coded decimal (BCD) digits
- Floating-point data types
  - half-precision floating point (16 bits)
  - single-precision floating point (32 bits)
  - double-precision floating point (64 bits)

These fundamental data types may be aggregated into composite data types. The defined composite data types are:

- strings

  - character strings (composed of bytes or words)
  - doubleword and quadword
- packed BCD
- packed signed and unsigned integers (also called integer vectors)
- packed single- or double-precision floating point (also called floating-point vectors)

Integer, BCD, and string data types are described in the following section. The floating-point and vector data types are discussed in Section 4.3.3, “SSE Instruction Data Types,” on page 121.

3.2.2 General-Purpose Instruction Data types

The following data types are supported in the general-purpose programming environment:

- Signed (two's-complement) integers.
- Unsigned integers.
- BCD digits.
- Packed BCD digits.
- Strings, including bit strings.
- Untyped data objects.

Figure 3-6 on page 39 illustrates the data types used by most general-purpose instructions. Software can define data types in ways other than those shown, but the AMD64 architecture does not directly support such interpretations and software must handle them entirely on its own. Note that the bit positions are numbered from right to left starting with *0* and ending with *length-1*. The untyped data objects bit, nibble, byte, word, doubleword, quadword, and octword are not shown.

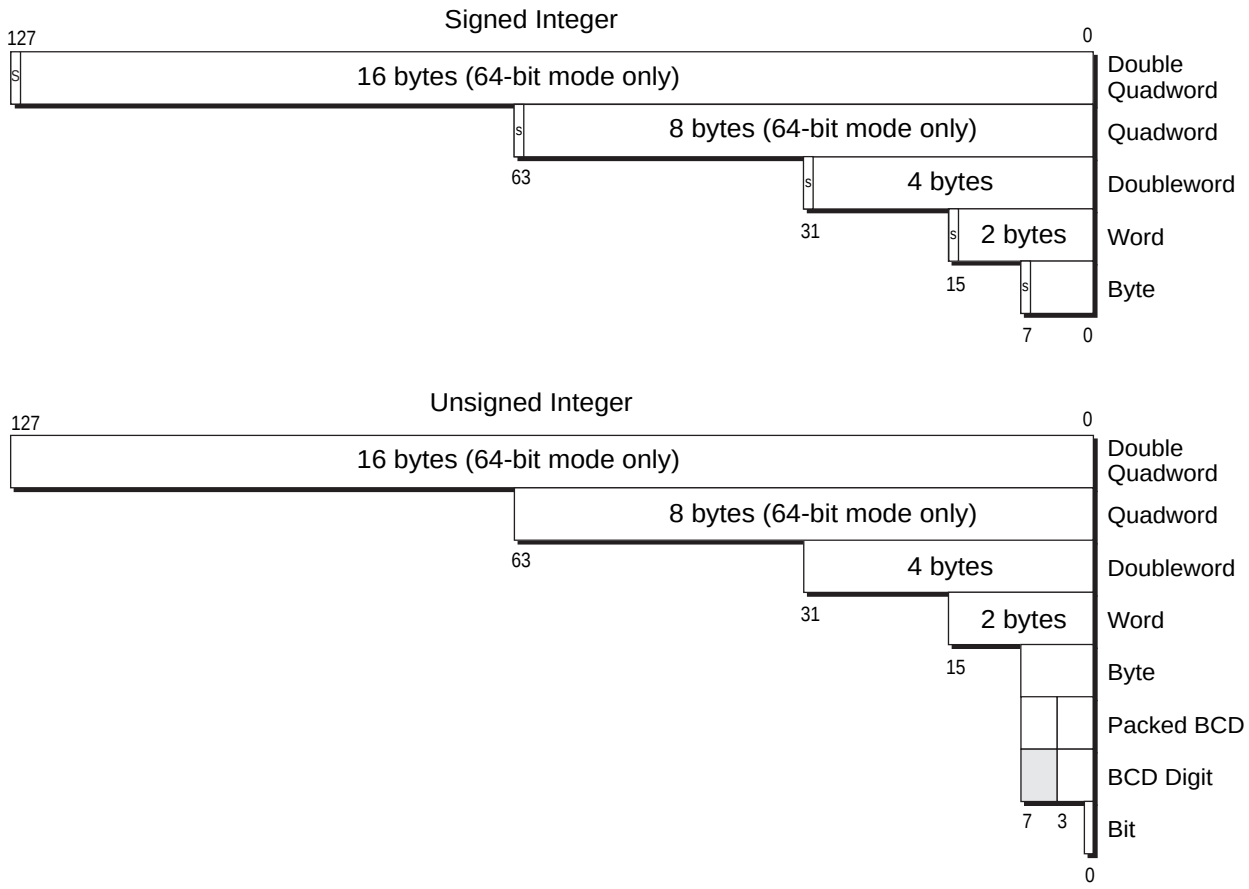


Figure 3-6. General-Purpose Data Types

3.2.2.1 Signed and Unsigned Integers

The architecture supports signed and unsigned 1-byte, 2-byte, 4- byte, 8-byte, and 16-byte integers. The sign bit (S) occupies the most significant bit (datum bit position *length-1*). Signed integers are represented in two's complement format. S = 0 represents positive numbers and S = 1 negative numbers.

The table below presents the representable range of values for each integer data type and the BCD data types discussed in the following section:

Table 3-2. Representable Values of General-Purpose Data Types

Data Type	Byte	Word	Doubleword	Quadword	Double Quadword[2]
Signed Integers[1]	-2^7 to $+(2^7-1)$	-2^{15} to $+(2^{15}-1)$	-2^{31} to $+(2^{31}-1)$	-2^{63} to $+(2^{63}-1)$	-2^{127} to $+(2^{127}-1)$
Unsigned Integers	0 to $+2^8-1$ (0 to 255)	0 to $+2^{16}-1$ (0 to 65,535)	0 to $+2^{32}-1$ (0 to 4.29×10^9)	0 to $+2^{64}-1$ (0 to 1.84×10^{19})	0 to $+2^{128}-1$ (0 to 3.40×10^{38})
Packed BCD Digits	00 to 99	multiple packed BCD-digit bytes			
BCD Digit	0 to 9	multiple BCD-digit bytes			

Note:
1. *The sign bit is the most-significant bit (e.g., bit 7 for a byte, bit 15 for a word, etc.).*
2. *The double quadword data type is supported in the RDX:RAX registers by the MUL, IMUL, DIV, IDIV, and CQO instructions.*

In 64-bit mode, the double quadword (octword) integer data type is supported in the RDX:RAX registers by the MUL, IMUL, DIV, IDIV, and CQO instructions.

3.2.2.2 Binary-Coded-Decimal (BCD) Digits

BCD digits have values ranging from 0 to 9. These values can be represented in binary encoding with four bits. For example, 0000b represents the decimal number 0 and 1001b represents the decimal number 9. Values ranging from 1010b to 1111b are invalid for this data type. Because a byte contains eight bits, two BCD digits can be stored in a single byte. This is referred to as *packed-BCD*. If a single BCD digit is stored per byte, it is referred to as *unpacked-BCD*. In the x87 floating-point programming environment (described in Section 6, "x87 Floating-Point Programming," on page 285) an 80-bit packed BCD data type is also supported, along with conversions between floating-point and BCD data types, so that data expressed in the BCD format can be operated on as floating-point values.

Integer add, subtract, multiply, and divide instructions can be used to operate on single (unpacked) BCD digits. The result must be adjusted to produce a correct BCD representation. For unpacked BCD numbers, the ASCII-adjust instructions are provided to simplify that correction. In the case of division, the adjustment must be made prior to executing the integer-divide instruction.

Similarly, integer add and subtract instructions can be used to operate on packed-BCD digits. The result must be adjusted to produce a correct packed-BCD representation. Decimal-adjust instructions are provided to simplify packed-BCD result corrections.

3.2.2.3 Strings

Strings are a continuous sequence of a single data type. The string instructions can be used to operate on byte, word, doubleword, or quadword data types. The maximum length of a string of any data type is $2^{32}-1$ bytes, in legacy or compatibility modes, or $2^{64}-1$ bytes in 64-bit mode. One of the more common types of strings used by applications are byte data-type strings known as ASCII strings, which can be used to represent character data.

Bit strings are also supported by instructions that operate specifically on bit strings. In general, bit strings can start and end at any bit location within any byte, although the BT*x* bit-string instructions assume that strings start on a byte boundary. The length of a bit string can range in size from a single bit up to 2^{32}–1 bits, in legacy or compatibility modes, or 2^{64}–1 bits in 64-bit mode.

3.2.2.4 Untyped Data Objects

Move instructions: register to register, memory to register (load) or register to memory (store); pack, unpack, swap, permutate, and merge instructions operate on data without regard to data type.

SIMD instructions operate on vector data types based on the fundamental data types described above. See Section 4.3. “Operands” on page 118 for a discussion of vector data types

3.2.3 Operand Sizes and Overrides

3.2.3.1 Default Operand Size

In legacy and compatibility modes, the default operand size is either 16 bits or 32 bits, as determined by the default-size (D) bit in the current code-segment descriptor (for details, see “Segmented Virtual Memory” in Volume 2). In 64-bit mode, the default operand size for most instructions is 32 bits.

Application software can override the default operand size by using an operand-size instruction prefix. Table 3-3 shows the instruction prefixes for operand-size overrides in all operating modes. In 64-bit mode, the default operand size for most instructions is 32 bits. A REX prefix (see Section 3.5.2, “REX Prefixes,” on page 79) specifies a 64-bit operand size, and a 66h prefix specifies a 16-bit operand size. The REX prefix takes precedence over the 66h prefix.

Table 3-3. Operand-Size Overrides

Operating Mode		Default Operand Size (Bits)	Effective Operand Size (Bits)	Instruction Prefix	
				66h[1]	REX
Long Mode	64-Bit Mode	32[2]	64	x	yes
			32	no	no
			16	yes	no
	Compatibility Mode	32	32	no	Not Applicable
			16	yes	
		16	32	yes	
			16	no	
Legacy Mode (Protected, Virtual-8086, or Real Mode)		32	32	no	
			16	yes	
		16	32	yes	
			16	no	

Note:
1. *A "no" indicates that the default operand size is used. An "x" means "don't care."*
2. *Near branches, instructions that implicitly reference the stack pointer, and certain other instructions default to 64-bit operand size. See "General-Purpose Instructions in 64-Bit Mode" in Volume 3*

There are several exceptions to the 32-bit operand-size default in 64-bit mode, including near branches and instructions that implicitly reference the RSP stack pointer. For example, the near CALL, near JMP, J*cc*, LOOP*cc*, POP, and PUSH instructions all default to a 64-bit operand size in 64-bit mode. Such instructions do not need a REX prefix for the 64-bit operand size. For details, see "General-Purpose Instructions in 64-Bit Mode" in Volume 3.

3.2.3.2 Effective Operand Size

The term *effective operand size* describes the operand size for the current instruction, after accounting for the instruction's default operand size and any operand-size override or REX prefix that is used with the instruction.

3.2.3.3 Immediate Operand Size

In legacy mode and compatibility modes, the size of immediate operands can be 8, 16, or 32 bits, depending on the instruction. In 64-bit mode, the maximum size of an immediate operand is also 32 bits, except that 64-bit immediates can be copied into a 64-bit GPR using the MOV instruction.

When the operand size of a MOV instruction is 64 bits, the processor sign-extends immediates to 64 bits before using them. Support for true 64-bit immediates is accomplished by expanding the semantics of the `MOV reg, imm16/32` instructions. In legacy and compatibility modes, these instructions—opcodes B8h through BFh—copy a 16-bit or 32-bit immediate (depending on the

effective operand size) into a GPR. In 64-bit mode, if the operand size is 64 bits (requires a REX prefix), these instructions can be used to copy a true 64-bit immediate into a GPR.

3.2.4 Operand Addressing

Operands for general-purpose instructions are referenced by the instruction's syntax or they are incorporated in the instruction as an immediate value. Referenced operands can be in registers, memory, or I/O ports.

3.2.4.1 Register Operands

Most general-purpose instructions that take register operands reference the general-purpose registers (GPRs). A few general-purpose instructions reference operands in the RFLAGS register, XMM registers, or MMX™ registers.

The type of register addressed is specified in the instruction syntax. When addressing GPRs or XMM registers, the REX instruction prefix can be used to access the extended GPRs or XMM registers, as described in Section 3.5, “Instruction Prefixes,” on page 76.

3.2.4.2 Memory Operands

Many general-purpose instructions can access operands in memory. Section 2.2, “Memory Addressing,” on page 14 describes the general methods and conditions for addressing memory operands.

3.2.4.3 I/O Ports

Operands in I/O ports are referenced according to the conventions described in Section 3.8, “Input/Output,” on page 95.

3.2.4.4 Immediate Operands

In certain instructions, a source operand—called an *immediate operand*, or simply *immediate*—is included as part of the instruction rather than being accessed from a register or memory location. For details on the size of immediate operands, see “Immediate Operand Size” on page 42.

3.2.5 Data Alignment

A data access is *aligned* if its address is a multiple of its operand size, in bytes. The following examples illustrate this definition:

- *Byte* accesses are always aligned. Bytes are the smallest addressable parts of memory.
- *Word* (two-byte) accesses are aligned if their address is a multiple of 2.
- *Doubleword* (four-byte) accesses are aligned if their address is a multiple of 4.
- *Quadword* (eight-byte) accesses are aligned if their address is a multiple of 8.

The AMD64 architecture does not impose data-alignment requirements for accessing data in memory. However, depending on the location of the misaligned operand with respect to the width of the data

bus and other aspects of the hardware implementation (such as store-to-load forwarding mechanisms), a misaligned memory access can require more bus cycles than an aligned access. For maximum performance, avoid misaligned memory accesses.

Performance on many hardware implementations will benefit from observing the following operand-alignment and operand-size conventions:

- Avoid misaligned data accesses.
- Maintain consistent use of operand size across all loads and stores. Larger operand sizes (doubleword and quadword) tend to make more efficient use of the data bus and any data-forwarding features that are implemented by the hardware.
- When using word or byte stores, avoid loading data from the same doubleword of memory, other than the identical start addresses of the stores.

3.3 Instruction Summary

This section summarizes the functions of the general-purpose instructions. The instructions are organized by functional group—such as, data-transfer instructions, arithmetic instructions, and so on. Details on individual instructions are given in the alphabetically organized "General-Purpose Instructions in 64-Bit Mode" in Volume 3.

3.3.1 Syntax

Each instruction has a *mnemonic syntax* used by assemblers to specify the operation and the operands to be used for source and destination (result) data. Figure 3-7 shows an example of the mnemonic syntax for a compare (CMP) instruction. In this example, the CMP mnemonic is followed by two operands, a 32-bit register or memory operand and an 8-bit immediate operand.

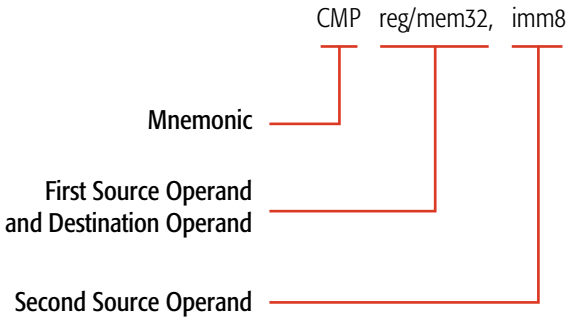

Figure 3-7. Mnemonic Syntax Example

In most instructions that take two operands, the first (left-most) operand is both a source operand and the destination operand. The second (right-most) operand serves only as a source. Instructions can have one or more prefixes that modify default instruction functions or operand properties. These

prefixes are summarized in Section 3.5, “Instruction Prefixes,” on page 76. Instructions that access 64-bit operands in a general-purpose register (GPR) or any of the extended GPR or XMM registers require a REX instruction prefix.

Unless otherwise stated in this section, the word *register* means a general-purpose register (GPR). Several instructions affect the flag bits in the RFLAGS register. “Instruction Effects on RFLAGS” in Volume 3 summarizes the effects that instructions have on rFLAGS bits.

3.3.2 Data Transfer

The data-transfer instructions copy data between registers and memory.

Move

- MOV—Move
- MOVBE—Move Big-Endian
- MOVSX—Move with Sign-Extend
- MOVZX—Move with Zero-Extend
- MOVD—Move Doubleword or Quadword
- MOVNTI—Move Non-temporal Doubleword or Quadword

The move instructions copy a byte, word, doubleword, or quadword from a register or memory location to a register or memory location. The source and destination cannot both be memory locations. For MOVBE, both operands cannot be registers and the operand size must be greater than one byte. MOVBE performs a reordering of the bytes within the source operand as it is copied.

An immediate constant can be used as a source operand with the MOV instruction. For most move instructions, the destination must be of the same size as the source, but the MOVSX and MOVZX instructions copy values of smaller size to a larger size by using sign-extension or zero-extension respectively. The MOVD instruction copies a doubleword or quadword between a general-purpose register or memory and an XMM or MMX register.

The MOV instruction is in many aspects similar to the assignment operator in high-level languages. The simplest example of their use is to initialize variables. To initialize a register to 0, rather than using a MOV instruction it may be more efficient to use the XOR instruction with identical destination and source operands.

The MOVNTI instruction stores a doubleword or quadword from a register into memory as “non-temporal” data, which assumes a single access (as opposed to frequent subsequent accesses of “temporal data”). The operation therefore minimizes cache pollution. The exact method by which cache pollution is minimized depends on the hardware implementation of the instruction. For further information, see Section 3.9, “Memory Optimization,” on page 98.

Conditional Move

- CMOV*cc*—Conditional Move If *condition*

The CMOV*cc* instructions conditionally copy a word, doubleword, or quadword from a register or memory location to a register location. The source and destination must be of the same size.

The CMOV*cc* instructions perform the same task as MOV but work conditionally, depending on the state of status flags in the RFLAGS register. If the condition is not satisfied, the instruction has no effect and control is passed to the next instruction. The mnemonics of CMOV*cc* instructions indicate the condition that must be satisfied. Several mnemonics are often used for one opcode to make the mnemonics easier to remember. For example, CMOVE (conditional move if equal) and CMOVZ (conditional move if zero) are aliases and compile to the same opcode. Table 3-4 shows the RFLAGS values required for each CMOV*cc* instruction.

In assembly languages, the conditional move instructions correspond to small conditional statements like:

```
IF a = b THEN x = y
```

CMOV*cc* instructions can replace two instructions—a conditional jump and a move. For example, to perform a high-level statement like:

```
IF ECX = 5 THEN EAX = EBX
```

without a CMOV*cc* instruction, the code would look like:

```
cmp ecx, 5          ; test if ecx equals 5
jnz Continue        ; test condition and skip if not met
mov eax, ebx        ; move
Continue:           ; continuation
```

but with a CMOV*cc* instruction, the code would look like:

```
cmp ecx, 5          ; test if ecx equals to 5
cmovz eax, ebx      ; test condition and move
```

Replacing conditional jumps with conditional moves also has the advantage that it can avoid branch-prediction penalties that may be caused by conditional jumps.

Support for CMOV*cc* instructions depends on the processor implementation. To find out if a processor is able to perform CMOV*cc* instructions, use the CPUID instruction. For more information on using the CPUID instruction, see Section 3.6, “Feature Detection,” on page 79.

Table 3-4. rFLAGS for CMOV*cc* Instructions

Mnemonic	Required Flag State	Description
CMOVO	OF = 1	Conditional move if overflow
CMOVNO	OF = 0	Conditional move if not overflow
CMOVB CMOVC CMOVNAE	CF = 1	Conditional move if below Conditional move if carry Conditional move if not above or equal

Table 3-4. rFLAGS for CMOV*cc* Instructions (continued)

Mnemonic	Required Flag State	Description
CMOVAE CMOVNB CMOVNC	CF = 0	Conditional move if above or equal Conditional move if not below Conditional move if not carry
CMOVE CMOVZ	ZF = 1	Conditional move if equal Conditional move if zero
CMOVNE CMOVNZ	ZF = 0	Conditional move if not equal Conditional move if not zero
CMOVBE CMOVNA	CF = 1 or ZF = 1	Conditional move if below or equal Conditional move if not above
CMOVA CMOVNBE	CF = 0 and ZF = 0	Conditional move if not below or equal Conditional move if not below or equal
CMOVS	SF = 1	Conditional move if sign
CMOVNS	SF = 0	Conditional move if not sign
CMOVP CMOVPE	PF = 1	Conditional move if parity Conditional move if parity even
CMOVNP CMOVPO	PF = 0	Conditional move if not parity Conditional move if parity odd
CMOVL CMOVNGE	SF <> OF	Conditional move if less Conditional move if not greater or equal
CMOVGE CMOVNL	SF = OF	Conditional move if greater or equal Conditional move if not less
CMOVLE CMOVNG	ZF = 1 or SF <> OF	Conditional move if less or equal Conditional move if not greater
CMOVG CMOVNLE	ZF = 0 and SF = OF	Conditional move if greater Conditional move if not less or equal

Stack Operations

- POP—Pop Stack
- POPA—Pop All to GPR Words
- POPAD—Pop All to GPR Doublewords
- PUSH—Push onto Stack
- PUSHA—Push All GPR Words onto Stack
- PUSHAD—Push All GPR Doublewords onto Stack
- ENTER—Create Procedure Stack Frame
- LEAVE—Delete Procedure Stack Frame

PUSH copies the specified register, memory location, or immediate value to the top of stack. This instruction decrements the stack pointer by 2, 4, or 8, depending on the operand size, and then copies the operand into the memory location pointed to by SS:rSP.

POP copies a word, doubleword, or quadword from the memory location pointed to by the SS:rSP registers (the top of stack) to a specified register or memory location. Then, the rSP register is incremented by 2, 4, or 8. After the POP operation, rSP points to the new top of stack.

PUSHA or PUSHAD stores eight word-sized or doubleword-sized registers onto the stack: eAX, eCX, eDX, eBX, eSP, eBP, eSI and eDI, in that order. The stored value of eSP is sampled at the moment when the PUSHA instruction started. The resulting stack-pointer value is decremented by 16 or 32.

POPA or POPAD extracts eight word-sized or doubleword-sized registers from the stack: eDI, eSI, eBP, eSP, eBX, eDX, eCX and eAX, in that order (which is the reverse of the order used in the PUSHA instruction). The stored eSP value is ignored by the POPA instruction. The resulting stack pointer value is incremented by 16 or 32.

It is a common practice to use PUSH instructions to pass parameters (via the stack) to functions and subroutines. The typical instruction sequence used at the beginning of a subroutine looks like:

```
push  ebp          ; save current EBP
mov   ebp, esp     ; set stack frame pointer value
sub   esp, N       ; allocate space for local variables
```

The rBP register is used as a *stack frame pointer*—a base address of the stack area used for parameters passed to subroutines and local variables. Positive offsets of the stack frame pointed to by rBP provide access to parameters passed while negative offsets give access to local variables. This technique allows creating re-entrant subroutines.

The ENTER and LEAVE instructions provide support for procedure calls, and are mainly used in high-level languages. The ENTER instruction is typically the first instruction of the procedure, and the LEAVE instruction is the last before the RET instruction.

The ENTER instruction creates a stack frame for a procedure. The first operand, *size*, specifies the number of bytes allocated in the stack. The second operand, *depth*, specifies the number of stack-frame pointers copied from the calling procedure's stack (i.e., the nesting level). The depth should be an integer in the range 0–31.

Typically, when a procedure is called, the stack contains the following four components:

- Parameters passed to the called procedure (created by the calling procedure).
- Return address (created by the CALL instruction).
- Array of stack-frame pointers (pointers to stack frames of procedures with smaller nesting-level depth) which are used to access the local variables of such procedures.
- Local variables used by the called procedure.

All these data are called the *stack frame*. The ENTER instruction simplifies management of the last two components of a stack frame. First, the current value of the rBP register is pushed onto the stack. The value of the rSP register at that moment is a *frame pointer* for the current procedure: positive offsets from this pointer give access to the parameters passed to the procedure, and negative offsets give access to the local variables which will be allocated later. During procedure execution, the value of the frame pointer is stored in the rBP register, which at that moment contains a frame pointer of the

calling procedure. This frame pointer is saved in a temporary register. If the depth operand is greater than one, the array of *depth-1* frame pointers of procedures with smaller nesting level is pushed onto the stack. This array is copied from the stack frame of the calling procedure, and it is addressed by the rBP register from the calling procedure. If the depth operand is greater than zero, the saved frame pointer of the current procedure is pushed onto the stack (forming an array of *depth* frame pointers). Finally, the saved value of the frame pointer is copied to the rBP register, and the rSP register is decremented by the value of the first operand, allocating space for local variables used in the procedure. See “Stack Operations” on page 47 for a parameter-passing instruction sequence using PUSH that is equivalent to ENTER.

The LEAVE instruction removes local variables and the array of frame pointers, allocated by the previous ENTER instruction, from the stack frame. This is accomplished by the following two steps: first, the value of the frame pointer is copied from the rBP register to the rSP register. This releases the space allocated by local variables and an array of frame pointers of procedures with smaller nesting levels. Second, the rBP register is popped from the stack, restoring the previous value of the frame pointer (or simply the value of the rBP register, if the depth operand is zero). Thus, the LEAVE instruction is equivalent to the following code:

```
mov rSP, rBP
pop rBP
```

3.3.3 Data Conversion

The data-conversion instructions perform various transformations of data, such as operand-size doubling by sign extension, conversion of little-endian to big-endian format, extraction of sign masks, searching a table, and support for operations with decimal numbers.

Sign Extension

- CBW—Convert Byte to Word
- CWDE—Convert Word to Doubleword
- CDQE—Convert Doubleword to Quadword
- CWD—Convert Word to Doubleword
- CDQ—Convert Doubleword to Quadword
- CQO—Convert Quadword to Octword

The CBW, CWDE, and CDQE instructions sign-extend the AL, AX, or EAX register to the upper half of the AX, EAX, or RAX register, respectively. By doing so, these instructions create a double-sized destination operand in rAX that has the same numerical value as the source operand. The CBW, CWDE, and CDQE instructions have the same opcode, and the action taken depends on the effective operand size.

The CWD, CDQ and CQO instructions sign-extend the AX, EAX, or RAX register to all bit positions of the DX, EDX, or RDX register, respectively. By doing so, these instructions create a double-sized destination operand in rDX:rAX that has the same numerical value as the source operand. The CWD,

CDQ, and CQO instructions have the same opcode, and the action taken depends on the effective operand size.

Flags are not affected by these instructions. The instructions can be used to prepare an operand for signed division (performed by the IDIV instruction) by doubling its storage size.

Extract Sign Mask

- (V)MOVMSKPS—Extract Packed Single-Precision Floating-Point Sign Mask
- (V)MOVMSKPD—Extract Packed Double-Precision Floating-Point Sign Mask

The MOVMSKPS instruction moves the sign bits of four packed single-precision floating-point values in an XMM register to the four low-order bits of a general-purpose register, with zero-extension. MOVMSKPD does a similar operation for two packed double-precision floating-point values: it moves the two sign bits to the two low-order bits of a general-purpose register, with zero-extension. The result of either instruction is a sign-bit mask.

Translate

- XLAT—Translate Table Index

The XLAT instruction replaces the value stored in the AL register with a table element. The initial value in AL serves as an unsigned index into the table, and the start (base) of table is specified by the DS:rBX registers (depending on the effective address size).

This instruction is not recommended. The following instruction serves to replace it:

```
MOV AL,[rBX + AL]
```

ASCII Adjust

- AAA—ASCII Adjust After Addition
- AAD—ASCII Adjust Before Division
- AAM—ASCII Adjust After Multiply
- AAS—ASCII Adjust After Subtraction

The AAA, AAD, AAM, and AAS instructions perform corrections of arithmetic operations with non-packed BCD values (i.e., when the decimal digit is stored in a byte register). There are no instructions which directly operate on decimal numbers (either packed or non-packed BCD). However, the ASCII-adjust instructions correct decimal-arithmetic results. These instructions assume that an arithmetic instruction, such as ADD, was performed on two BCD operands, and that the result was stored in the AL or AX register. This result can be incorrect or it can be a non-BCD value (for example, when a decimal carry occurs). After executing the proper ASCII-adjust instruction, the AX register contains a correct BCD representation of the result. (The AAD instruction is an exception to this, because it should be applied *before* a DIV instruction, as explained below). All of the ASCII-adjust instructions are able to operate with multiple-precision decimal values.

AAA should be applied after addition of two non-packed decimal digits. AAS should be applied after subtraction of two non-packed decimal digits. AAM should be applied after multiplication of two non-

packed decimal digits. AAD should be applied *before* the division of two non-packed decimal numbers.

Although the base of the numeration for ASCII-adjust instructions is assumed to be 10, the AAM and AAD instructions can be used to correct multiplication and division with other bases.

BCD Adjust

- DAA—Decimal Adjust after Addition
- DAS—Decimal Adjust after Subtraction

The DAA and DAS instructions perform corrections of addition and subtraction operations on packed BCD values. (Packed BCD values have two decimal digits stored in a byte register, with the higher digit in the higher four bits, and the lower one in the lower four bits.) There are no instructions for correction of multiplication and division with packed BCD values.

DAA should be applied after addition of two packed-BCD numbers. DAS should be applied after subtraction of two packed-BCD numbers.

DAA and DAS can be used in a loop to perform addition or subtraction of two multiple-precision decimal numbers stored in packed-BCD format. Each loop cycle would operate on corresponding bytes (containing two decimal digits) of operands.

Endian Conversion

- BSWAP—Byte Swap

The BSWAP instruction changes the byte order of a doubleword or quadword operand in a register, as shown in Figure 3-8. In a doubleword, bits 7:0 are exchanged with bits 31:24, and bits 15:8 are exchanged with bits 23:16. In a quadword, bits 7:0 are exchanged with bits 63:56, bits 15:8 with bits 55:48, bits 23:16 with bits 47:40, and bits 31:24 with bits 39:32. See the following illustration.

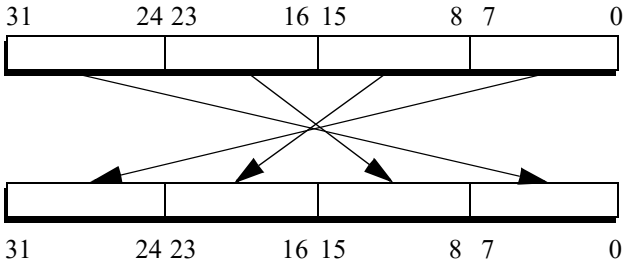

Figure 3-8. BSWAP Doubleword Exchange

A second application of the BSWAP instruction to the same operand restores its original value. The result of applying the BSWAP instruction to a 16-bit register is undefined. To swap bytes of a 16-bit register, use the XCHG instruction.

The BSWAP instruction is used to convert data between little-endian and big-endian byte order.

3.3.4 Load Segment Registers

These instructions load segment registers.

- LDS, LES, LFS, LGS, LSS—Load Far Pointer
- MOV segReg—Move Segment Register
- POP segReg—Pop Stack Into Segment Register

The LDS, LES, LFD, LGS, and LSS instructions atomically (with respect to interrupts only, not contending memory accesses) load the two parts of a far pointer into a segment register and a general-purpose register. A far pointer is a 16-bit segment selector and a 16-bit or 32-bit offset. The load copies the segment-selector portion of the pointer from memory into the segment register and the offset portion of the pointer from memory into a general-purpose register.

The effective operand size determines the size of the offset loaded by the LDS, LES, LFD, LGS, and LSS instructions. The instructions load not only the software-visible segment selector into the segment register, but they also cause the hardware to load the associated segment-descriptor information into the software-invisible (hidden) portion of that segment register.

The MOV segReg and POP segReg instructions load a segment selector from a general-purpose register or memory (for MOV segReg) or from the top of the stack (for POP segReg) to a segment register. These instructions not only load the software-visible segment selector into the segment register but also cause the hardware to load the associated segment-descriptor information into the software-invisible (hidden) portion of that segment register.

In 64-bit mode, the POP DS, POP ES, and POP SS instructions are invalid.

3.3.5 Load Effective Address

- LEA—Load Effective Address

The LEA instruction calculates and loads the effective address (offset within a given segment) of a source operand and places it in a general-purpose register.

LEA is related to MOV, which copies data from a memory location to a register, but LEA takes the address of the source operand, whereas MOV takes the contents of the memory location specified by the source operand. In the simplest cases, LEA can be replaced with MOV. For example:

```
lea eax, [ebx]
```

has the same effect as:

```
mov eax, ebx
```

However, LEA allows software to use any valid addressing mode for the source operand. For example:

```
lea eax, [ebx+edi]
```

loads the sum of EBX and EDI registers into the EAX register. This could not be accomplished by a single MOV instruction.

LEA has a limited capability to perform multiplication of operands in general-purpose registers using scaled-index addressing. For example:

```
lea eax, [ebx+ebx*8]
```

loads the value of the EBX register, multiplied by 9, into the EAX register.

3.3.6 Arithmetic

The arithmetic instructions perform basic arithmetic operations, such as addition, subtraction, multiplication, and division on integer operands.

Add and Subtract

- ADC—Add with Carry
- ADD—Signed or Unsigned Add
- SBB—Subtract with Borrow
- SUB—Subtract
- NEG—Two's Complement Negation

The ADD instruction performs addition of two integer operands. There are opcodes that add an immediate value to a byte, word, doubleword, or quadword register or a memory location. In these opcodes, if the size of the immediate is smaller than that of the destination, the immediate is first sign-extended to the size of the destination operand. The arithmetic flags (OF, SF, ZF, AF, CF, PF) are set according to the resulting value of the destination operand.

The ADC instruction performs addition of two integer operands, plus 1 if the carry flag (CF) is set.

The SUB instruction performs subtraction of two integer operands.

The SBB instruction performs subtraction of two integer operands, and it also subtracts an additional 1 if the carry flag is set.

The ADC and SBB instructions simplify addition and subtraction of multiple-precision integer operands, because they correctly handle carries (and borrows) between parts of a multiple-precision operand.

The NEG instruction performs negation of an integer operand. The value of the operand is replaced with the result of subtracting the operand from zero.

Multiply and Divide

- MUL—Multiply Unsigned
- IMUL—Signed Multiply
- DIV—Unsigned Divide
- IDIV—Signed Divide

The MUL instruction performs multiplication of unsigned integer operands. The size of operands can be byte, word, doubleword, or quadword. The product is stored in a destination which is double the size of the source operands (multiplicand and factor).

The MUL instruction's mnemonic has only one operand, which is a factor. The multiplicand operand is always assumed to be an accumulator register. For byte-sized multiplies, AL contains the multiplicand, and the result is stored in AX. For word-sized, doubleword-sized, and quadword-sized multiplies, rAX contains the multiplicand, and the result is stored in rDX and rAX. In 64-bit mode

The IMUL instruction performs multiplication of signed integer operands. There are forms of the IMUL instruction with one, two, and three operands, and it is thus more powerful than the MUL instruction. The one-operand form of the IMUL instruction behaves similarly to the MUL instruction, except that the operands and product are signed integer values. In the two-operand form of IMUL, the multiplicand and product use the same register (the first operand), and the factor is specified in the second operand. In the three-operand form of IMUL, the product is stored in the first operand, the multiplicand is specified in the second operand, and the factor is specified in the third operand.

The DIV instruction performs division of unsigned integers. The instruction divides a double-sized dividend in AH:AL or rDX:rAX by the divisor specified in the operand of the instruction. It stores the quotient in AL or rAX and the remainder in AH or rDX.

The IDIV instruction performs division of signed integers. It behaves similarly to DIV, with the exception that the operands are treated as signed integer values.

Division is the slowest of all integer arithmetic operations and should be avoided wherever possible. One possibility for improving performance is to replace division with multiplication, such as by replacing *i/j/k* with *i/(j*k)*. This replacement is possible if no overflow occurs during the computation of the product. This can be determined by considering the possible ranges of the divisors.

Increment and Decrement

- DEC—Decrement by 1
- INC—Increment by 1

The INC and DEC instructions are used to increment and decrement, respectively, an integer operand by one. For both instructions, an operand can be a byte, word, doubleword, or quadword register or memory location.

These instructions behave in all respects like the corresponding ADD and SUB instructions, with the second operand as an immediate value equal to 1. The only exception is that the carry flag (CF) is not affected by the INC and DEC instructions.

Apart from their obvious arithmetic uses, the INC and DEC instructions are often used to modify addresses of operands. In this case it can be desirable to preserve the value of the carry flag (to use it later), so these instructions do not modify the carry flag.

3.3.7 Rotate and Shift

The rotate and shift instructions perform cyclic rotation or non-cyclic shift, by a given number of bits (called the *count*), in a given byte-sized, word-sized, doubleword-sized or quadword-sized operand.

When the count is greater than 1, the result of the rotate and shift instructions can be considered as an iteration of the same 1-bit operation by *count* number of times. Because of this, the descriptions below describe the result of 1-bit operations.

The count can be 1, the value of the CL register, or an immediate 8-bit value. To avoid redundancy and make rotation and shifting quicker, the count is masked to the 5 or 6 least-significant bits, depending on the effective operand size, so that its value does not exceed 31 or 63 before the rotation or shift takes place.

Rotate

- RCL—Rotate Through Carry Left
- RCR—Rotate Through Carry Right
- ROL—Rotate Left
- ROR—Rotate Right

The RC*x* instructions rotate the bits of the first operand to the left or right by the number of bits specified by the source (count) operand. The bits rotated out of the destination operand are rotated into the carry flag (CF) and the carry flag is rotated into the opposite end of the first operand.

The RO*x* instructions rotate the bits of the first operand to the left or right by the number of bits specified by the source operand. Bits rotated out are rotated back in at the opposite end. The value of the CF flag is determined by the value of the last bit rotated out. In single-bit left-rotates, the overflow flag (OF) is set to the XOR of the CF flag after rotation and the most-significant bit of the result. In single-bit right-rotates, the OF flag is set to the XOR of the two most-significant bits. Thus, in both cases, the OF flag is set to 1 if the single-bit rotation changed the value of the most-significant bit (sign bit) of the operand. The value of the OF flag is undefined for multi-bit rotates.

Bit-rotation instructions provide many ways to reorder bits in an operand. This can be useful, for example, in character conversion, including cryptography techniques.

Shift

- SAL—Shift Arithmetic Left
- SAR—Shift Arithmetic Right
- SHL—Shift Left
- SHR—Shift Right
- SHLD—Shift Left Double
- SHRD—Shift Right Double

The SH*x* instructions (including SHxD) perform shift operations on unsigned operands. The SA*x* instructions operate with signed operands.

SHL and SAL instructions effectively perform multiplication of an operand by a power of 2, in which case they work as more-efficient alternatives to the MUL instruction. Similarly, SHR and SAR instructions can be used to divide an operand (signed or unsigned, depending on the instruction used) by a power of 2.

Although the SAR instruction divides the operand by a power of 2, the behavior is different from the IDIV instruction. For example, shifting –11 (FFFFFFF5h) by two bits to the right (i.e. divide –11 by 4), gives a result of FFFFFFFDh, or –3, whereas the IDIV instruction for dividing –11 by 4 gives a result of –2. This is because the IDIV instruction rounds off the quotient to zero, whereas the SAR instruction rounds off the remainder to zero for positive dividends, and to negative infinity for negative dividends. This means that, for positive operands, SAR behaves like the corresponding IDIV instruction, and for negative operands, it gives the same result if and only if all the shifted-out bits are zeroes, and otherwise the result is smaller by 1.

The SAR instruction treats the most-significant bit (msb) of an operand in a special way: the msb (the sign bit) is not changed, but is copied to the next bit, preserving the sign of the result. The least-significant bit (lsb) is shifted out to the CF flag. In the SAL instruction, the msb is shifted out to CF flag, and the lsb is cleared to 0.

The SH*x* instructions perform *logical shift*, i.e. without special treatment of the sign bit. SHL is the same as SAL (in fact, their opcodes are the same). SHR copies 0 into the most-significant bit, and shifts the least-significant bit to the CF flag.

The SHxD instructions perform a double shift. These instructions perform left and right shift of the destination operand, taking the bits to copy into the most-significant bit (for the SHRD instruction) or into the least-significant bit (for the SHLD instruction) from the source operand. These instructions behave like SHx, but use bits from the source operand instead of zero bits to shift into the destination operand. The source operand is not changed.

3.3.8 Bit Manipulation

The bit manipulation instructions manipulate individual bits in a register for purposes such as controlling low-level devices, correcting algorithms, and detecting errors. Following are descriptions of supported bit manipulation instructions.

Extract Bit Field

- BEXTR—Bit Field Extract (register form is a BMI instruction)
- BEXTR—Bit Field Extract (immediate version is a TBM instruction)

The BEXTR instruction (register form and immediate version) extracts a contiguous field of bits from the first source operand, as specified by the control field setting in the second source operand and puts the extracted field into the least significant bit positions of the destination. The remaining bits in the destination register are cleared to 0.

Fill Bit

- BLCFILL—Fill From Lowest Clear Bit
- BLSFILL—Fill From Lowest Set Bit

The BLCFILL instruction finds the least significant zero bit in the source operand, clears all bits below that bit to 0 and writes the result to the destination. If there is no zero bit in the source operand, the destination is written with all zeros.

The BLSFILL instruction finds the least significant one bit in the source operand, sets all bits below that bit to 1 and writes the result to the destination. If there is no one bit in the source operand, the destination is written with all ones.

Isolate Bit

- BLSI— Isolate Lowest Set Bit
- BLCI—Isolate Lowest Clear Bit
- BLCIC—Bit Lowest Clear Isolate Complemented
- BLCS—Set Lowest Clear Bit
- BLSIC— Isolate Lowest Set Bit and Complement

The BLSI instruction clears all bits in the source operand except for the least significant bit that is set to 1 and writes the result to the destination.

The BLCI instruction finds the least significant zero bit in the source operand, sets all other bits to 1 and writes the result to the destination. If there is no zero bit in the source operand, the destination is written with all ones.

The BLCIC instruction finds the least significant zero bit in the source operand, sets that bit to 1, clears all other bits to 0 and writes the result to the destination. If there is no zero bit in the source operand, the destination is written with all zeros.

The BLCS instruction finds the least significant zero bit in the source operand, sets that bit to 1 and writes the result to the destination. If there is no zero bit in the source operand, the source is copied to the destination (and CF in rFLAGS is set to 1).

The BLSIC instruction finds the least significant bit that is set to 1 in the source operand, clears that bit to 0, sets all other bits to 1 and writes the result to the destination. If there is no one bit in the source operand, the destination is written with all ones.

Mask Bit

- BLSMSK—Mask from Lowest Set Bit
- BLCMSK—Mask From Lowest Clear Bit
- T1MSKC — Inverse Mask From Trailing Ones
- TZMSK—Mask From Trailing Zeros

The BLSMSK instruction forms a mask with bits set to 1 from bit 0 up to and including the least significant bit position that is set to 1 in the source operand and writes the mask to the destination.

The BLCMSK instruction finds the least significant zero bit in the source operand, sets that bit to 1, clears all bits above that bit to 0 and writes the result to the destination. If there is no zero bit in the source operand, the destination is written with all ones.

The T1MSKC instruction finds the least significant zero bit in the source operand, clears all bits below that bit to 0, sets all other bits to 1 (including the found bit) and writes the result to the destination. If the least significant bit of the source operand is 0, the destination is written with all ones.

The TZMSK instruction finds the least significant one bit in the source operand, sets all bits below that bit to 1, clears all other bits to 0 (including the found bit) and writes the result to the destination. If the least significant bit of the source operand is 1, the destination is written with all zeros.

Population and Zero Counts

- POPCNT—Bit Population Count
- LZCNT—Count Leading Zeros
- TZCNT—Trailing Zero Count

The POPCNT instruction counts the number of bits having a value of 1 in the source operand and places the total in the destination register.

The LZCNT instruction counts the number of leading zero bits in the 16-, 32-, or 64-bit general purpose register or memory source operand. Counting starts downward from the most significant bit and stops when the highest bit having a value of 1 is encountered or when the least significant bit is encountered. The count is written to the destination register.

The TZCNT instruction counts the number of trailing zero bits in the 16-, 32-, or 64-bit general purpose register or memory source operand. Counting starts upward from the least significant bit and stops when the lowest bit having a value of 1 is encountered or when the most significant bit is encountered. The count is written to the destination register.

Reset Bit

- BLSR—Reset Lowest Set Bit

The BLSR instruction clears the least-significant bit that is set to 1 in the input operand and writes the modified operand to the destination.

Scan Bit

- BSF—Bit Scan Forward
- BSR—Bit Scan Reverse

The BSF and BSR instructions search a source operand for the least-significant (BSF) or most-significant (BSR) bit that is set to 1. If a set bit is found, its bit index is loaded into the destination

operand, and the zero flag (ZF) is set. If no set bit is found, the zero flag is cleared and the contents of the destination are undefined.

3.3.9 Compare and Test

The compare and test instructions perform arithmetic and logical comparison of operands and set corresponding flags, depending on the result of comparison. These instruction are used in conjunction with conditional instructions such as J*cc* or SET*cc* to organize branching and conditionally executing blocks in programs. Assembler equivalents of conditional operators in high-level languages (do…while, if…then…else, and similar) also include compare and test instructions.

Compare

- CMP—Compare

The CMP instruction performs subtraction of the second operand (source) from the first operand (destination), like the SUB instruction, but it does not store the resulting value in the destination operand. It leaves both operands intact. The only effect of the CMP instruction is to set or clear the arithmetic flags (OF, SF, ZF, AF, CF, PF) according to the result of subtraction.

The CMP instruction is often used together with the conditional jump instructions (J*cc*), conditional SET instructions (SET*cc*) and other instructions such as conditional loops (LOOP*cc*) whose behavior depends on flag state.

Test

- TEST—Test Bits

The TEST instruction is in many ways similar to the AND instruction: it performs logical conjunction of the corresponding bits of both operands, but unlike the AND instruction it leaves the operands unchanged. The purpose of this instruction is to update flags for further testing.

The TEST instruction is often used to test whether one or more bits in an operand are zero. In this case, one of the instruction operands would contain a mask in which all bits are cleared to zero except the bits being tested. For more advanced bit testing and bit modification, use the BT*x* instructions.

Bit Test

- BT—Bit Test
- BTC—Bit Test and Complement
- BTR—Bit Test and Reset
- BTS—Bit Test and Set

The BT*x* instructions copy a specified bit in the first operand to the carry flag (CF) and leave the source bit unchanged (BT), or complement the source bit (BTC), or clear the source bit to 0 (BTR), or set the source bit to 1 (BTS).

These instructions are useful for implementing semaphore arrays. Unlike the XCHG instruction, the BT*x* instructions set the carry flag, so no additional test or compare instruction is needed. Also,

because these instructions operate directly on bits rather than larger data types, the semaphore arrays can be smaller than is possible when using XCHG. In such semaphore applications, bit-test instructions should be preceded by the LOCK prefix.

Set Byte on Condition

- SET*cc*—Set Byte if *condition*

The SET*cc* instructions store a 1 or 0 value to their byte operand depending on whether their condition (represented by certain rFLAGS bits) is true or false, respectively. Table 3-5 shows the rFLAGS values required for each SET*cc* instruction.

Table 3-5. rFLAGS for SET*cc* Instructions

Mnemonic	Required Flag State	Description
SETO	OF = 1	Set byte if overflow
SETNO	OF = 0	Set byte if not overflow
SETB SETC SETNAE	CF = 1	Set byte if below Set byte if carry Set byte if not above or equal (unsigned operands)
SETAE SETNB SETNC	CF = 0	Set byte if above or equal Set byte if not below Set byte if not carry (unsigned operands)
SETE SETZ	ZF = 1	Set byte if equal Set byte if zero
SETNE SETNZ	ZF = 0	Set byte if not equal Set byte if not zero
SETBE SETNA	CF = 1 or ZF = 1	Set byte if below or equal Set byte if not above (unsigned operands)
SETA SETNBE	CF = 0 and ZF = 0	Set byte if not below or equal Set byte if not below or equal (unsigned operands)
SETS	SF = 1	Set byte if sign
SETNS	SF = 0	Set byte if not sign
SETP SETPE	PF = 1	Set byte if parity Set byte if parity even
SETNP SETPO	PF = 0	Set byte if not parity Set byte if parity odd
SETL SETNGE	SF <> OF	Set byte if less Set byte if not greater or equal (signed operands)
SETGE SETNL	SF = OF	Set byte if greater or equal Set byte if not less (signed operands)
SETLE SETNG	ZF = 1 or SF <> OF	Set byte if less or equal Set byte if not greater (signed operands)
SETG SETNLE	ZF = 0 and SF = OF	Set byte if greater Set byte if not less or equal (signed operands)

SET*cc* instructions are often used to set logical indicators. Like CMOV*cc* instructions (page 45), SET*cc* instructions can replace two instructions—a conditional jump and a move. Replacing conditional jumps with conditional sets can help avoid branch-prediction penalties that may be caused by conditional jumps.

If the logical value True (logical 1) is represented in a high-level language as an integer with all bits set to 1, software can accomplish such representation by first executing the opposite SET*cc* instruction—for example, the opposite of SETZ is SETNZ—and then decrementing the result.

Bounds

- BOUND—Check Array Bounds

The BOUND instruction checks whether the value of the first operand, a signed integer index into an array, is within the minimal and maximal bound values pointed to by the second operand. The values of array bounds are often stored at the beginning of the array. If the bounds of the range are exceeded, the processor generates a bound-range exception.

The primary disadvantage of using the BOUND instruction is its use of the time-consuming exception mechanism to signal a failure of the bounds test.

3.3.10 Logical

The logical instructions perform bitwise operations.

- AND—Logical AND
- OR—Logical OR
- XOR—Exclusive OR
- NOT—One’s Complement Negation
- ANDN—And Not

The AND, OR, and XOR instructions perform their respective logical operations on the corresponding bits of both operands and store the result in the first operand. The CF flag and OF flag are cleared to 0, and the ZF flag, SF flag, and PF flag are set according to the resulting value of the first operand.

The NOT instruction performs logical inversion of all bits of its operand. Each zero bit becomes one and vice versa. All flags remain unchanged.

The ANDN instruction performs a bitwise AND of the second source operand and the one's complement of the first source operand and stores the result into the destination operand.

Apart from performing logical operations, AND and OR can test a register for a zero or non-zero value, sign (negative or positive), and parity status of its lowest byte. To do this, both operands must be the same register. The XOR instruction with two identical operands is an efficient way of loading the value 0 into a register.

3.3.11 String

The string instructions perform common string operations such as copying, moving, comparing, or searching strings. These instructions are widely used for processing text.

Compare Strings

- CMPS—Compare Strings
- CMPSB—Compare Strings by Byte
- CMPSW—Compare Strings by Word
- CMPSD—Compare Strings by Doubleword
- CMPSQ—Compare Strings by Quadword

The CMPS*x* instructions compare the values of two implicit operands of the same size located at *seg*:[rSI] and ES:[rDI]. After the copy, both the rSI and rDI registers are auto-incremented (if the DF flag is 0) or auto-decremented (if the DF flag is 1).

Scan String

- SCAS—Scan String
- SCASB—Scan String as Bytes
- SCASW—Scan String as Words
- SCASD—Scan String as Doubleword
- SCASQ—Scan String as Quadword

The SCAS*x* instructions compare the values of a memory operands in ES:rDI to a value of the same size in the AL/rAX register. Bits in rFLAGS are set to indicate the outcome of the comparison. After the comparison, the rDI register is auto-incremented (if the DF flag is 0) or auto-decremented (if the DF flag is 1).

Move String

- MOVS—Move String
- MOVSB—Move String Byte
- MOVSW—Move String Word
- MOVSD—Move String Doubleword
- MOVSQ—Move String Quadword

The MOVS*x* instructions copy an operand from the memory location *seg*:[rSI] to the memory location ES:[rDI]. After the copy, both the rSI and rDI registers are auto-incremented (if the DF flag is 0) or auto-decremented (if the DF flag is 1).

Load String

- LODS—Load String

- LODSB—Load String Byte
- LODSW—Load String Word
- LODSD—Load String Doubleword
- LODSQ—Load String Quadword

The LODS*x* instructions load a value from the memory location *seg*:[rSI] to the accumulator register (AL or rAX). After the load, the rSI register is auto-incremented (if the DF flag is 0) or auto-decremented (if the DF flag is 1).

Store String

- STOS—Store String
- STOSB—Store String Bytes
- STOSW—Store String Words
- STOSD—Store String Doublewords
- STOSQ—Store String Quadword

The STOS*x* instructions copy the accumulator register (AL or rAX) to a memory location ES:[rDI]. After the copy, the rDI register is auto-incremented (if the DF flag is 0) or auto-decremented (if the DF flag is 1).

3.3.12 Control Transfer

Control-transfer instructions, or branches, are used to iterate through loops and move through conditional program logic.

Jump

- JMP—Jump

JMP performs an unconditional jump to the specified address. There are several ways to specify the target address.

- *Relative Short Jump* and *Relative Near Jump*—The target address is determined by adding an 8-bit (short jump) or 16-bit or 32-bit (near jump) signed displacement to the rIP of the instruction following the JMP. The jump is performed within the current code segment (CS).
- *Register-Indirect* and *Memory-Indirect Near Jump*—The target rIP value is contained in a register or in a memory location. The jump is performed within the current CS.
- *Direct Far Jump*—For all far jumps, the target address is outside the current code segment. Here, the instruction specifies the 16-bit target-address code segment and the 16-bit or 32-bit offset as an immediate value. The direct far jump form is invalid in 64-bit mode.
- *Memory-Indirect Far Jump*—For this form, the target address (CS:rIP) is in a address outside the current code segment. A 32-bit or 48-bit far pointer in a specified memory location points to the target address.

The size of the target rIP is determined by the effective operand size for the JMP instruction.

For far jumps, the target selector can specify a code-segment selector, in which case it is loaded into CS, and a 16-bit or 32-bit target offset is loaded into rIP. The target selector can also be a call-gate selector or a task-state-segment (TSS) selector, used for performing task switches. In these cases, the target offset of the JMP instruction is ignored, and the new values loaded into CS and rIP are taken from the call gate or from the TSS.

Conditional Jump

- J*cc*—Jump if *condition*

Conditional jump instructions jump to an instruction specified by the operand, depending on the state of flags in the rFLAGS register. The operands specifies a signed relative offset from the current contents of the rIP. If the state of the corresponding flags meets the condition, a conditional jump instruction passes control to the target instruction, otherwise control is passed to the instruction following the conditional jump instruction. The flags tested by a specific J*cc* instruction depend on the opcode. In several cases, multiple mnemonics correspond to one opcode.

Table 3-6 shows the rFLAGS values required for each J*cc* instruction.

Table 3-6. rFLAGS for J*cc* Instructions

Mnemonic	Required Flag State	Description
JO	OF = 1	Jump near if overflow
JNO	OF = 0	Jump near if not overflow
JB JC JNAE	CF = 1	Jump near if below Jump near if carry Jump near if not above or equal
JNB JNC JAE	CF = 0	Jump near if not below Jump near if not carry Jump near if above or equal
JZ JE	ZF = 1	Jump near if 0 Jump near if equal
JNZ JNE	ZF = 0	Jump near if not zero Jump near if not equal
JNA JBE	CF = 1 or ZF = 1	Jump near if not above Jump near if below or equal
JNBE JA	CF = 0 and ZF = 0	Jump near if not below or equal Jump near if above
JS	SF = 1	Jump near if sign
JNS	SF = 0	Jump near if not sign
JP JPE	PF = 1	Jump near if parity Jump near if parity even
JNP JPO	PF = 0	Jump near if not parity Jump near if parity odd
JL JNGE	SF <> OF	Jump near if less Jump near if not greater or equal

Table 3-6. rFLAGS for J*cc* Instructions (continued)

Mnemonic	Required Flag State	Description
JGE JNL	SF = OF	Jump near if greater or equal Jump near if not less
JNG JLE	ZF = 1 or SF <> OF	Jump near if not greater Jump near if less or equal
JNLE JG	ZF = 0 and SF = OF	Jump near if not less or equal Jump near if greater

Unlike the unconditional jump (JMP), conditional jump instructions have only two forms—*near conditional jumps* and *short conditional jumps*. To create a far-conditional-jump code sequence corresponding to a high-level language statement like:

```
IF A = B THEN GOTO FarLabel
```

where FarLabel is located in another code segment, use the opposite condition in a conditional short jump before the unconditional far jump. For example:

```
      cmp   A,B               ; compare operands
      jne   NextInstr         ; continue program if not equal
      jmp   far ptr WhenNE    ; far jump if operands are equal
NextInstr:                    ; continue program
```

Three special conditional jump instructions use the rCX register instead of flags. The JCXZ, JECXZ, and JRCXZ instructions check the value of the CX, ECX, and RCX registers, respectively, and pass control to the target instruction when the value of rCX register reaches 0. These instructions are often used to control safe cycles, preventing execution when the value in rCX reaches 0.

Loop

- LOOP*cc*—Loop if *condition*

The LOOP*cc* instructions include LOOPE, LOOPNE, LOOPNZ, and LOOPZ. These instructions decrement the rCX register by 1 without changing any flags, and then check to see if the loop condition is met. If the condition is met, the program jumps to the specified target code.

LOOPE and LOOPZ are synonyms. Their loop condition is met if the value of the rCX register is non-zero and the zero flag (ZF) is set to 1 when the instruction starts. LOOPNE and LOOPNZ are also synonyms. Their loop condition is met if the value of the rCX register is non-zero and the ZF flag is cleared to 0 when the instruction starts. LOOP, unlike the other mnemonics, does not check the ZF flag. Its loop condition is met if the value of the rCX register is non-zero.

Call

- CALL—Procedure Call

The CALL instruction performs a call to a procedure whose address is specified in the operand. The return address is placed on the stack by the CALL, and points to the instruction immediately following

the CALL. When the called procedure finishes execution and is exited using a return instruction, control is transferred to the return address saved on the stack.

The CALL instruction has the same forms as the JMP instruction, except that CALL lacks the short-relative (1-byte offset) form.

- *Relative Near Call*—These specify an offset relative to the instruction following the CALL instruction. The operand is an immediate 16-bit or 32-bit offset from the called procedure, within the same code segment.
- *Register-Indirect* and *Memory-Indirect Near Call*—These specify a target address contained in a register or memory location.
- *Direct Far Call*—These specify a target address outside the current code segment. The address is pointed to by a 32-bit or 48-bit far-pointer specified by the instruction, which consists of a 16-bit code selector and a 16-bit or 32-bit offset. The direct far call form is invalid in 64-bit mode.
- *Memory-Indirect Far Call*—These specify a target address outside the current code segment. The address is pointed to by a 32-bit or 48-bit far pointer in a specified memory location.

The size of the rIP is in all cases determined by the operand-size attribute of the CALL instruction. CALLs push the return address to the stack. The data pushed on the stack depends on whether a near or far call is performed, and whether a privilege change occurs. See Section 3.7.5, “Procedure Calls,” on page 83 for further information.

For far CALLs, the selector portion of the target address can specify a code-segment selector (in which case the selector is loaded into the CS register), or a call-gate selector, (used for calls that change privilege level), or a task-state-segment (TSS) selector (used for task switches). In the latter two cases, the offset portion of the CALL instruction’s target address is ignored, and the new values loaded into CS and rIP are taken from the call gate or TSS.

Return

- RET—Return from Call

The RET instruction returns from a procedure originally called using the CALL instruction. CALL places a return address (which points to the instruction following the CALL) on the stack. RET takes the return address from the stack and transfers control to the instruction located at that address.

Like CALL instructions, RET instructions have both a near and far form. An optional immediate operand for the RET specifies the number of bytes to be popped from the procedure stack for parameters placed on the stack. See Section 3.7.6, “Returning from Procedures,” on page 86 for additional information.

Interrupts and Exceptions

- INT—Interrupt to Vector Number
- INTO—Interrupt to Overflow Vector
- IRET—Interrupt Return Word
- IRETD—Interrupt Return Doubleword

- IRETQ—Interrupt Return Quadword

The INT instruction implements a *software interrupt* by calling an interrupt handler. The operand of the INT instruction is an immediate byte value specifying an index in the interrupt descriptor table (IDT), which contains addresses of interrupt handlers (see Section 3.7.10, “Interrupts and Exceptions,” on page 91 for further information on the IDT).

The 1-byte INTO instruction calls interrupt 4 (the overflow exception, #OF), if the overflow flag in RFLAGS is set to 1, otherwise it does nothing. Signed arithmetic instructions can be followed by the INTO instruction if the result of the arithmetic operation can potentially overflow. (The 1-byte INT 3 instruction is considered a system instruction and is therefore not described in this volume).

IRET, IRETD, and IRETQ perform a return from an interrupt handler. The mnemonic specifies the operand size, which determines the format of the return addresses popped from the stack (IRET for 16-bit operand size, IRETD for 32-bit operand size, and IRETQ for 64-bit operand size). However, some assemblers can use the IRET mnemonic for all operand sizes. Actions performed by IRET are opposite to actions performed by an interrupt or exception. In real and protected mode, IRET pops the rIP, CS, and RFLAGS contents from the stack, and it pops SS:rSP if a privilege-level change occurs or if it executes from 64-bit mode. In protected mode, the IRET instruction can also cause a task switch if the nested task (NT) bit in the RFLAGS register is set. For details on using IRET to switch tasks, see “Task Management” in Volume 2.

3.3.13 Flags

The flags instructions read and write bits of the RFLAGS register that are visible to application software. “Flags Register” on page 34 illustrates the RFLAGS register.

Push and Pop Flags

- POPF—Pop to FLAGS Word
- POPFD—Pop to EFLAGS Doubleword
- POPFQ—Pop to RFLAGS Quadword
- PUSHF—Push FLAGS Word onto Stack
- PUSHFD—Push EFLAGS Doubleword onto Stack
- PUSHFQ—Push RFLAGS Quadword onto Stack

The push and pop flags instructions copy data between the rFLAGS register and the stack. POPF and PUSHF copy 16 bits of data between the stack and the FLAGS register (the low 16 bits of EFLAGS), leaving the high 48 bits of RFLAGS unchanged. POPFD and PUSHFD copy 32 bits between the stack and the RFLAGS register. POPFQ and PUSHFQ copy 64 bits between the stack and the RFLAGS register. Only the bits illustrated in Figure 3-5 on page 34 are affected. Reserved bits and bits that are write protected by the current values of system flags, current privilege level (CPL), or current operating mode are unaffected by the POPF, POPFQ, and POPFD instructions.

For details on stack operations, see “Control Transfers” on page 80.

Set and Clear Flags

- CLC—Clear Carry Flag
- CMC—Complement Carry Flag
- STC—Set Carry Flag
- CLD—Clear Direction Flag
- STD—Set Direction Flag
- CLI—Clear Interrupt Flag
- STI—Set Interrupt Flag

These instructions change the value of a flag in the rFLAGS register that is visible to application software. Each instruction affects only one specific flag.

The CLC, CMC, and STC instructions change the carry flag (CF). CLC clears the flag to 0, STC sets the flag to 1, and CMC inverts the flag. These instructions are useful prior to executing instructions whose behavior depends on the CF flag—for example, shift and rotate instructions.

The CLD and STD instructions change the direction flag (DF) and influence the function of string instructions (CMPSx, SCASx, MOVSx, LODSx, STOSx, INSx, OUTSx). CLD clears the flag to 0, and STD sets the flag to 1. A cleared DF flag indicates the *forward* direction in string sequences, and a set DF flag indicates the *backward* direction. Thus, in string instructions, the rSI and/or rDI register values are auto-incremented when DF = 0 and auto-decremented when DF = 1.

Two other instructions, CLI and STI, clear and set the interrupt flag (IF). CLI clears the flag, causing the processor to ignore external maskable interrupts. STI sets the flag, allowing the processor to recognize maskable external interrupts. These instructions are used primarily by system software—especially, interrupt handlers—and are described in “Exceptions and Interrupts” in Volume 2.

Load and Store Flags

- LAHF—Load Status Flags into AH Register
- SAHF—Store AH into Flags

LAHF loads the lowest byte of the RFLAGS register into the AH register. This byte contains the carry flag (CF), parity flag (PF), auxiliary flag (AF), zero flag (ZF), and sign flag (SF). SAHF stores the AH register into the lowest byte of the RFLAGS register.

3.3.14 Input/Output

The I/O instructions perform reads and writes of bytes, words, and doublewords from and to the *I/O address space*. This address space can be used to access and manage external devices, and is independent of the main-memory address space. By contrast, *memory-mapped I/O* uses the main-memory address space and is accessed using the MOV instructions rather than the I/O instructions.

When operating in legacy protected mode or in long mode, the RFLAGS register's I/O privilege level (IOPL) field and the I/O-permission bitmap in the current task-state segment (TSS) are used to control access to the I/O addresses (called *I/O ports*). See "Input/Output" on page 95 for further information.

General I/O

- IN—Input from Port
- OUT—Output to Port

The IN instruction reads a byte, word, or doubleword from the I/O port address specified by the source operand, and loads it into the accumulator register (AL or eAX). The source operand can be an immediate byte or the DX register.

The OUT instruction writes a byte, word, or doubleword from the accumulator register (AL or eAX) to the I/O port address specified by the destination operand, which can be either an immediate byte or the DX register.

If the I/O port address is specified with an immediate operand, the range of port addresses accessible by the IN and OUT instructions is limited to ports 0 through 255. If the I/O port address is specified by a value in the DX register, all 65,536 ports are accessible.

String I/O

- INS—Input String
- INSB—Input String Byte
- INSW—Input String Word
- INSD—Input String Doubleword
- OUTS—Output String
- OUTSB—Output String Byte
- OUTSW—Output String Word
- OUTSD—Output String Doubleword

The INS*x* instructions (INSB, INSW, INSD) read a byte, word, or doubleword from the I/O port specified by the DX register, and load it into the memory location specified by ES:[rDI].

The OUTS*x* instructions (OUTSB, OUTSW, OUTSD) write a byte, word, or doubleword from an implicit memory location specified by *seg*:[rSI], to the I/O port address stored in the DX register.

The INS*x* and OUTS*x* instructions are commonly used with a repeat prefix to transfer blocks of data. The memory pointer address is not incremented or decremented. This usage is intended for peripheral I/O devices that are expecting a stream of data.

3.3.15 Semaphores

The semaphore instructions support the implementation of reliable signaling between processors in a multi-processing environment, usually for the purpose of sharing resources.

- CMPXCHG—Compare and Exchange
- CMPXCHG8B—Compare and Exchange Eight Bytes
- CMPXCHG16B—Compare and Exchange Sixteen Bytes
- XADD—Exchange and Add
- XCHG—Exchange

The CMPXCHG instruction compares a value in the AL or rAX register with the first (destination) operand, and sets the arithmetic flags (ZF, OF, SF, AF, CF, PF) according to the result. If the compared values are equal, the source operand is loaded into the destination operand. If they are not equal, the first operand is loaded into the accumulator. CMPXCHG can be used to try to intercept a semaphore, i.e. test if its state is *free*, and if so, load a new value into the semaphore, making its state *busy*. The test and load are performed atomically, so that concurrent processes or threads which use the semaphore to access a shared object will not conflict.

The CMPXCHG8B instruction compares the 64-bit values in the EDX:EAX registers with a 64-bit memory location. If the values are equal, the zero flag (ZF) is set, and the ECX:EBX value is copied to the memory location. Otherwise, the ZF flag is cleared, and the memory value is copied to EDX:EAX.

The CMPXCHG16B instruction compares the 128-bit value in the RDX:RAX and RCX:RBX registers with a 128-bit memory location. If the values are equal, the zero flag (ZF) is set, and the RCX:RBX value is copied to the memory location. Otherwise, the ZF flag is cleared, and the memory value is copied to rDX:rAX.

The XADD instruction exchanges the values of its two operands, then it stores their sum in the first (destination) operand.

A LOCK prefix can be used to make the CMPXCHG, CMPXCHG8B and XADD instructions atomic if one of the operands is a memory location.

The XCHG instruction exchanges the values of its two operands. If one of the operands is in memory, the processor's bus-locking mechanism is engaged automatically during the exchange, whether or not the LOCK prefix is used.

3.3.16 Processor Information

- CPUID—Processor Identification

The CPUID instruction returns information about the processor implementation and its support for instruction subsets and architectural features. Software operating at any privilege level can execute the CPUID instruction to read this information. After the information is read, software can select procedures that optimize performance for a particular hardware implementation.

Some processor implementations may not support the CPUID instruction. Support for the CPUID instruction is determined by testing the RFLAGS.ID bit. If software can write this bit, then the CPUID instruction is supported by the processor implementation. Otherwise, execution of CPUID results in an invalid-opcode exception.

See Section 3.6, “Feature Detection,” on page 79 for details about using the CPUID instruction.

3.3.17 Cache and Memory Management

Applications can use the cache and memory-management instructions to control memory reads and writes to influence the caching of read/write data. “Memory Optimization” on page 98 describes how these instructions interact with the memory subsystem.

- LFENCE—Load Fence
- SFENCE—Store Fence
- MFENCE—Memory Fence
- PREFETCH*level*—Prefetch Data to Cache Level *level*
- PREFETCH—Prefetch L1 Data-Cache Line
- PREFETCHW—Prefetch L1 Data-Cache Line for Write
- CLFLUSH—Cache Line Invalidate
- CLWB—Cache Line Writeback

The LFENCE, SFENCE, and MFENCE instructions can be used to force ordering on memory accesses. The order of memory accesses can be important when the reads and writes are to a memory-mapped I/O device, and in multiprocessor environments where memory synchronization is required. LFENCE affects ordering on memory reads, but not writes. SFENCE affects ordering on memory writes, but not reads. MFENCE orders both memory reads and writes. These instructions do not take operands. They are simply inserted between the memory references that are to be ordered. For details about the fence instructions, see “Forcing Memory Order” on page 100.

The PREFETCH*level*, PREFETCH, and PREFETCHW instructions load data from memory into one or more cache levels. PREFETCH*level* loads a memory block into a specified level in the data-cache hierarchy (including a non-temporal caching level). The size of the memory block is implementation dependent. PREFETCH loads a cache line into the L1 data cache. PREFETCHW loads a cache line into the L1 data cache and sets the cache line’s memory-coherency state to *modified*, in anticipation of subsequent data writes to that line. (Both PREFETCH and PREFETCHW are 3DNow!™ instructions.) For details about the prefetch instructions, see “Cache-Control Instructions” on page 105. For a description of MOESI memory-coherency states, see “Memory System” in Volume 2.

The CLFLUSH instruction writes unsaved data back to memory for the specified cache line from all processor caches, invalidates the specified cache, and causes the processor to send a bus cycle which signals external caching devices to write back and invalidate their copies of the cache line. CLFLUSH provides a finer-grained mechanism than the WBINVD instruction, which writes back and invalidates all cache lines. Moreover, CLFLUSH can be used at all privilege levels, unlike WBINVD which can be used only by system software running at privilege level 0.

Similarly, the unprivileged CLWB instruction can be used to force individual modified cache lines to be written to memory without invalidating them in the cache (leaving them in non-modified state), whereas the privileged WBNOINVD instruction operates on entire caches.

3.3.18 No Operation

- NOP—No Operation

The NOP instructions performs no operation (except incrementing the instruction pointer rIP by one). It is an alternative mnemonic for the XCHG rAX, rAX instruction. Depending on the hardware implementation, the NOP instruction may use one or more cycles of processor time.

3.3.19 System Calls

System Call and Return

- SYSENTER—System Call
- SYSEXIT—System Return
- SYSCALL—Fast System Call
- SYSRET—Fast System Return

The SYSENTER and SYSCALL instructions perform a call to a routine running at current privilege level (CPL) 0—for example, a kernel procedure—from a user level program (CPL 3). The addresses of the target procedure and (for SYSENTER) the target stack are specified implicitly through the model-specific registers (MSRs). Control returns from the operating system to the caller when the operating system executes a SYSEXIT or SYSRET instruction. SYSEXIT are SYSRET are privileged instructions and thus can be issued only by a privilege-level-0 procedure.

The SYSENTER and SYSEXIT instructions form a complementary pair, as do SYSCALL and SYSRET. SYSENTER and SYSEXIT are invalid in 64-bit mode. In this case, use the faster SYSCALL and SYSRET instructions.

For details on these on other system-related instructions, see “System-Management Instructions” in Volume 2 and “System Instruction Reference” in Volume 3.

3.3.20 Application-Targeted Accelerator Instructions

- CRC32—Provides hardware acceleration to calculate cyclic redundancy checks for fast and efficient implementation of data integrity protocols.
- POPCNT—Accelerates software performance in the searching of bit patterns. This instruction calculates the number of bits set to 1 in the second operand (source) and returns the count in the first operand (destination register).

3.4 General Rules for Instructions in 64-Bit Mode

This section provides details of the general-purpose instructions in 64-bit mode, and how they differ from the same instructions in legacy and compatibility modes. The differences apply only to general-purpose instructions. Most of them do not apply to SIMD or x87 floating-point instructions.

3.4.1 Address Size

In 64-bit mode, the following rules apply to address size:

- Defaults to 64 bits.
- Can be overridden to 32 bits (by means of opcode prefix 67h).
- Can't be overridden to 16 bits.

3.4.2 Canonical Address Format

Bits 63 through the most-significant implemented virtual-address bit must be all zeros or all ones in any memory reference. See "64-Bit Canonical Addresses" on page 15 for details. (This rule applies to long mode, which includes both 64-bit mode and compatibility mode.)

3.4.3 Branch-Displacement Size

Branch-address displacements are 8 bits or 32 bits, as in legacy mode, but are sign-extended to 64 bits prior to using them for address computations. See "Displacements and Immediates" on page 17 for details.

3.4.4 Operand Size

In 64-bit mode, the following rules apply to operand size:

- **64-Bit Operand Size Option**: If an instruction's operand size (16-bit or 32-bit) in legacy mode depends on the default-size (D) bit in the current code-segment descriptor and the operand-size prefix, then the operand-size choices in 64-bit mode are extended from 16-bit and 32-bit to include 64 bits (with a REX prefix), or the operand size is fixed at 64 bits. See "General-Purpose Instructions in 64-Bit Mode" in Volume 3 for details.
- **Default Operand Size**: The default operand size for most instructions is 32 bits, and a REX prefix must be used to change the operand size to 64 bits. However, two groups of instructions default to 64-bit operand size and do not need a REX prefix: (1) near branches and (2) all instructions, except far branches, that implicitly reference the RSP. See "General-Purpose Instructions in 64-Bit Mode" in Volume 3 for details.
- **Fixed Operand Size**: If an instruction's operand size is fixed in legacy mode, that operand size is usually fixed at the same size in 64-bit mode. (There are some exceptions.) For example, the CPUID instruction always operates on 32-bit operands, irrespective of attempts to override the operand size. See "General-Purpose Instructions in 64-Bit Mode" in Volume 3 for details.
- **Immediate Operand Size**: The maximum size of immediate operands is 32 bits, as in legacy mode, except that 64-bit immediates can be MOVed into 64-bit GPRs. When the operand size is 64 bits, immediates are sign-extended to 64 bits prior to using them. See "Immediate Operand Size" on page 42 for details.
- **Shift-Count and Rotate-Count Operand Size**: When the operand size is 64 bits, shifts and rotates use one additional bit (6 bits total) to specify shift-count or rotate-count, allowing 64-bit shifts and rotates.

3.4.5 High 32 Bits

In 64-bit mode, the following rules apply to extension of results into the high 32 bits when results smaller than 64 bits are written:

- **Zero-Extension of 32-Bit Results**: 32-bit results are zero-extended into the high 32 bits of 64-bit GPR destination registers.
- **No Extension of 8-Bit and 16-Bit Results**: 8-bit and 16-bit results leave the high 56 or 48 bits, respectively, of 64-bit GPR destination registers unchanged.
- **Undefined High 32 Bits After Mode Change**: The processor does not preserve the upper 32 bits of the 64-bit GPRs across changes from 64-bit mode to compatibility or legacy modes. In compatibility and legacy mode, the upper 32 bits of the GPRs are undefined and not accessible to software.

3.4.6 Invalid and Reassigned Instructions

The following general-purpose instructions are invalid in 64-bit mode:

- AAA—ASCII Adjust After Addition
- AAD—ASCII Adjust Before Division
- AAM—ASCII Adjust After Multiply
- AAS—ASCII Adjust After Subtraction
- BOUND—Check Array Bounds
- CALL (far absolute)—Procedure Call Far
- DAA—Decimal Adjust after Addition
- DAS—Decimal Adjust after Subtraction
- INTO—Interrupt to Overflow Vector
- JMP (far absolute)—Jump Far
- POP DS—Pop Stack into DS Segment
- POP ES—Pop Stack into ES Segment
- POP SS—Pop Stack into SS Segment
- POPA, POPAD—Pop All to GPR Words or Doublewords
- PUSH CS—Push CS Segment Selector onto Stack
- PUSH DS—Push DS Segment Selector onto Stack
- PUSH ES—Push ES Segment Selector onto Stack
- PUSH SS—Push SS Segment Selector onto Stack
- PUSHA, PUSHAD—Push All to GPR Words or Doublewords

The following general-purpose instructions are invalid in long mode (64-bit mode and compatibility mode):

- SYSENTER—System Call (use SYSCALL instead)
- SYSEXIT—System Exit (use SYSRET instead)

The opcodes for the following general-purpose instructions are reassigned in 64-bit mode:

- ARPL—Adjust Requestor Privilege Level. Opcode becomes the MOVSXD instruction.
- DEC (one-byte opcode only)—Decrement by 1. Opcode becomes a REX prefix. Use the two-byte DEC opcode instead.
- INC (one-byte opcode only)—Increment by 1. Opcode becomes a REX prefix. Use the two-byte INC opcode instead.
- LDS—Load DS Segment Register
- LES—Load ES Segment Register

3.4.7 Instructions with 64-Bit Default Operand Size

Most instructions default to 32-bit operand size in 64-bit mode. However, the following near branches instructions and instructions that implicitly reference the stack pointer (RSP) default to 64-bit operand size in 64-bit mode:

- *Near Branches:*
  - J*cc*—Jump Conditional Near
  - JMP—Jump Near
  - LOOP—Loop
  - LOOP*cc*—Loop Conditional
- *Instructions That Implicitly Reference RSP:*
  - ENTER—Create Procedure Stack Frame
  - LEAVE—Delete Procedure Stack Frame
  - POP *reg/mem*—Pop Stack (register or memory)
  - POP *reg*—Pop Stack (register)
  - POP FS—Pop Stack into FS Segment Register
  - POP GS—Pop Stack into GS Segment Register
  - POPF, POPFD, POPFQ—Pop to rFLAGS Word, Doubleword, or Quadword
  - PUSH *imm32*—Push onto Stack (sign-extended doubleword)
  - PUSH *imm8*—Push onto Stack (sign-extended byte)
  - PUSH *reg/mem*—Push onto Stack (register or memory)
  - PUSH *reg*—Push onto Stack (register)
  - PUSH FS—Push FS Segment Register onto Stack
  - PUSH GS—Push GS Segment Register onto Stack
  - PUSHF, PUSHFD, PUSHFQ—Push rFLAGS Word, Doubleword, or Quadword onto Stack

The default 64-bit operand size eliminates the need for a REX prefix with these instructions when registers RAX–RSP (the first set of eight GPRs) are used as operands. A REX prefix is still required if R8–R15 (the extended set of eight GPRs) are used as operands, because the prefix is required to address the extended registers.

The 64-bit default operand size can be overridden to 16 bits using the 66h operand-size override. However, it is not possible to override the operand size to 32 bits, because there is no 32-bit operand-size override prefix for 64-bit mode. For details on the operand-size prefix, see "Legacy Instruction Prefixes" in Volume 3.

For details on near branches, see "Near Branches in 64-Bit Mode" on page 90. For details on instructions that implicitly reference RSP, see "Stack Operand-Size in 64-Bit Mode" on page 82.

For details on opcodes and operand-size overrides, see "General-Purpose Instructions in 64-Bit Mode" in Volume 3.

3.5 Instruction Prefixes

An instruction prefix is a byte that precedes an instruction's opcode and modifies the instruction's operation or operands. Instruction prefixes are of three types:

- Legacy Prefixes
- REX Prefixes
- Extended Prefixes

Legacy prefixes are organized into five groups, in which each prefix has a unique value. REX prefixes, which enable use of the AMD64 register extensions in 64-bit mode, are organized as a single group in which the value of the prefix indicates the combination of register-extension features to be enabled. The extended prefixes provide an escape mechanism that opens entirely new instruction encoding spaces for instructions with new capabilities. Currently there are two sets of extended prefixes—VEX and XOP. VEX is used to encode the AVX instructions and XOP is used to encode the XOP instructions.

3.5.1 Legacy Prefixes

Table 3-7 on page 77 shows the legacy prefixes. These are organized into five groups, as shown in the left-most column of the table. Each prefix has a unique hexadecimal value. The legacy prefixes can appear in any order in the instruction, but only one prefix from each of the five groups can be used in a single instruction. The result of using multiple prefixes from a single group is undefined.

There are several restrictions on the use of prefixes. For example, the address-size override prefix (67h) changes the address size used in the read or write access of a single memory operand and applies only to the instruction immediately following the prefix. In general, the operand-size prefix cannot be used with x87 floating-point instructions. When used in the encoding of SSE or 64-bit media instructions, the 66h prefix is repurposed to modify the opcode. The repeat prefixes cause repetition only with certain string instructions. When used in the encoding of SSE or 64-bit media instructions,

the prefixes are repurposed to modify the opcode. The lock prefix can be used with only a small number of general-purpose instructions.

Table 3-7 on page 77 summarizes the functionality of instruction prefixes. Details about the prefixes and their restrictions are given in “Legacy Instruction Prefixes” in Volume 3.

Table 3-7. Legacy Instruction Prefixes

Prefix Group	Mnemonic	Prefix Code (Hex)	Description
Operand-Size Override	none	66[1]	Changes the default operand size of a memory or register operand, as shown in Table 3-3 on page 42.
Address-Size Override	none	67	Changes the default address size of a memory operand, as shown in Table 2-1 on page 18.
Segment Override	CS	2E	Forces use of the CS segment for memory operands.
	DS	3E	Forces use of the DS segment for memory operands.
	ES	26	Forces use of the ES segment for memory operands.
	FS	64	Forces use of the FS segment for memory operands.
	GS	65	Forces use of the GS segment for memory operands.
	SS	36	Forces use of the SS segment for memory operands.
Lock	LOCK	F0	Causes certain read-modify-write instructions on memory to occur atomically.
Repeat	REP	F3[1]	Repeats a string operation (INS, MOVS, OUTS, LODS, and STOS) until the rCX register equals 0.
	REPE or REPZ		Repeats a compare-string or scan-string operation (CMPS*x* and SCAS*x*) until the rCX register equals 0 or the zero flag (ZF) is cleared to 0.
	REPNE or REPNZ	F2[1]	Repeats a compare-string or scan-string operation (CMPS*x* and SCAS*x*) until the rCX register equals 0 or the zero flag (ZF) is set to 1.

Note:
1. *When used with SSE or 64-bit media instructions, this prefix is repurposed to modify the opcode.*

3.5.1.1 Operand-Size and Address-Size Prefixes

The operand-size and address-size prefixes allow mixing of data and address sizes on an instruction-by-instruction basis. An instruction’s default address size can be overridden in any operating mode by using the 67h address-size prefix.

Table 3-3 on page 42 shows the operand-size overrides for all operating modes. In 64-bit mode, the default operand size for most general-purpose instructions is 32 bits. A REX prefix (described in “REX Prefixes” on page 79) specifies a 64-bit operand size, and a 66h prefix specifies a 16-bit operand size. The REX prefix takes precedence over the 66h prefix.

Table 2-1 on page 18 shows the address-size overrides for all operating modes. In 64-bit mode, the default address size is 64 bits. The address size can be overridden to 32 bits. 16-bit addresses are not

supported in 64-bit mode. In compatibility mode, the address-size prefix works the same as in the legacy x86 architecture.

For further details on these prefixes, see “Operand-Size Override Prefix” and “Address-Size Override Prefix” in Volume 3.

3.5.1.2 Segment Override Prefix

The DS segment is the default segment for most memory operands. Many instructions allow this default data segment to be overridden using one of the six segment-override prefixes shown in Table 3-7 on page 77. Data-segment overrides will be ignored when accessing data in the following cases:

- When a stack reference is made that pushes data onto or pops data off of the stack. In those cases, the SS segment is always used.
- When the destination of a string is memory it is always referenced using the ES segment.

Instruction fetches from the CS segment cannot be overridden. However, the CS segment-override prefix can be used to access instructions as data objects and to access data stored in the code segment.

For further details on these prefixes, see “Segment-Override Prefixes” in Volume 3.

3.5.1.3 Lock Prefix

The LOCK prefix causes certain read-modify-write instructions that access memory to occur atomically. The mechanism for doing so is implementation-dependent (for example, the mechanism may involve locking of data-cache lines that contain copies of the referenced memory operands, and/or bus signaling or packet-messaging on the bus). The prefix is intended to give the processor exclusive use of shared memory operands in a multiprocessor system.

The prefix can only be used with forms of the following instructions that write a memory operand: ADC, ADD, AND, BTC, BTR, BTS, CMPXCHG, CMPXCHG8B, DEC, INC, NEG, NOT, OR, SBB, SUB, XADD, XCHG, and XOR. An invalid-opcode exception occurs if LOCK is used with any other instruction.

For further details on these prefixes, see “Lock Prefix” in Volume 3.

3.5.1.4 Repeat Prefixes

There are two repeat prefixes byte codes, F3h and F2h. Byte code F3h is the more general and is usually treated as two distinct instructions by assemblers. Byte code F2h is only used with CMPS*x* and SCAS*x* instructions:

- REP (F3h)—This more generalized repeat prefix repeats its associated string instruction the number of times specified in the counter register (rCX). Repetition stops when the value in rCX reaches 0. This prefix is used with the INS, LODS, MOVS, OUTS, and STOS instructions.
- REPE or REPZ (F3h)—This version of REP prefix repeats its associated string instruction the number of times specified in the counter register (rCX). Repetition stops when the value in rCX

reaches 0 or when the zero flag (ZF) is cleared to 0. The prefix can only be used with the CMPS*x* and SCAS*x* instructions.

- REPNE or REPNZ (F2h)—The REPNE or REPNZ prefix repeats its associated string instruction the number of times specified in the counter register (rCX). Repetition stops when the value in rCX reaches 0 or when the zero flag (ZF) is set to 1. The prefix can only be used with the CMPS*x* and SCAS*x* instructions.

The size of the rCX counter is determined by the effective *address size*. For further details about these prefixes, including optimization of their use, see "Repeat Prefixes" in Volume 3.

3.5.2 REX Prefixes

REX prefixes can be used only in 64-bit mode. They enable the 64-bit register extensions. REX prefixes specify the following features:

- Use of an extended GPR register, shown in Figure 3-3 on page 27.
- Use of an extended YMM/XMM register, shown in Figure 4-1 on page 114.
- Use of a 64-bit (quadword) operand size, as described in "Operands" on page 36.
- Use of extended control and debug registers, as described in Volume 2.

REX prefix bytes have a value in the range 40h to 4Fh, depending on the particular combination of register extensions desired. With few exceptions, a REX prefix is required in order to access a 64-bit GPR or one of the extended GPR or XMM registers. A few instructions (described in "General-Purpose Instructions in 64-Bit Mode" in Volume 3) default to 64-bit operand size and do not need the REX prefix to access an extended 64-bit GPR.

Only one REX prefix is needed to express the full selection of 64-bit-mode register extension features. When used, the REX prefix must immediately precede the opcode byte of an instruction, or opcode map escape prefix if present. Any other placement of a REX prefix is ignored.

For further details on the REX prefixes, see "REX Prefixes" in Volume 3.

3.5.3 VEX and XOP Prefixes

The VEX and XOP prefixes extend instruction encoding and operand specification capabilities beyond those of the REX prefixes. They allow the encoding of new instructions and the specification of three, four, or five operands. The VEX prefixes are C4h and C5h and the XOP prefix is 8Eh.

For further details on the VEX and XOP prefixes, see "Encoding Using the VEX and XOP Prefixes" in Volume 3.

3.6 Feature Detection

The CPUID instruction provides information about the processor implementation and its capabilities. Software operating at any privilege level can execute the CPUID instruction to collect this

information. After the information is collected, software can select procedures that optimize performance for a particular hardware implementation.

Support for the CPUID instruction is implementation-dependent, as determined by software's ability to write the RFLAGS.ID bit. After software has determined that the processor implementation supports the CPUID instruction, software can test for support for a specific feature by loading the appropriate function number into the EAX register and executing the CPUID instruction. Processor feature information is returned in the EAX, EBX, ECX, and EDX registers.

See "CPUID" in the *AMD64 Architecture Programmer's Manual Volume 3: General Purpose and System Instructions*, order# 24594, for a full description of the CPUID instruction. See Appendix D of Volume 3 for a description of processor feature flags associated with instruction support and Appendix E for an exhaustive list of all processor information accessible via the CPUID instruction.

3.6.1 Feature Detection in a Virtualized Environment

Software writers must assume that their software may be executed as a guest in a virtualized environment. A virtualized guest may be migrated between processors of differing capabilities, so the CPUID indication of a feature's presence must be respected. Operating systems, user programs and libraries must all ensure that the CPUID instruction indicates a feature is present before using that feature. The hypervisor is responsible for ensuring consistent CPUID values across the system.

For example, an OS, program, or library typically detects a feature during initialization and then configures code paths or internal copies of feature indications based on the detection of that feature, with the feature detection occurring once per initialization. In this case, the feature must be detected by use of the CPUID instruction rather than by ignoring CPUID and testing for the presence of that feature.

To ensure guest migration between processors across multiple generations of processors, while allowing for features to be deprecated in future generations of processors, it is imperative that software check the CPUID bit once per program or library initialization before using instructions that are indicated by a CPUID bit; otherwise inconsistent behavior may result.

3.7 Control Transfers

3.7.1 Overview

From the application-program's viewpoint, program-control flow is sequential—that is, instructions are addressed and executed sequentially—except when a branch instruction (a call, return, jump, interrupt, or return from interrupt) is encountered, in which case program flow changes to the branch instruction's target address. Branches are used to iterate through loops and move through conditional program logic. Branches cause a new instruction pointer to be loaded into the rIP register, and sometimes cause the CS register to point to a different code segment. The CS:rIP values can be specified as part of a branch instruction, or they can be read from a register or memory.

Branches can also be used to transfer control to another program or procedure running at a different privilege level. In such cases, the processor automatically checks the source program and target program privileges to ensure that the transfer is allowed before loading CS:rIP with the new values.

3.7.2 Privilege Levels

The processor's *protected* modes include legacy protected mode and long mode (both compatibility mode and 64-bit mode). In all protected modes and virtual x86 mode, privilege levels are used to isolate and protect programs and data from each other. The privilege levels are designated with a numerical value from 0 to 3, with 0 being the most privileged and 3 being the least privileged. Privilege 0 is normally reserved for critical system-software components that require direct access to, and control over, all processor and system resources. Privilege 3 is used by application software. The intermediate privilege levels (1 and 2) are used, for example, by device drivers and library routines that access and control a limited set of processor and system resources.

Figure 3-9 shows the relationship of the four privilege-levels to each other. The protection scheme is implemented using the segmented memory-management mechanism described in "Segmented Virtual Memory" in Volume 2.

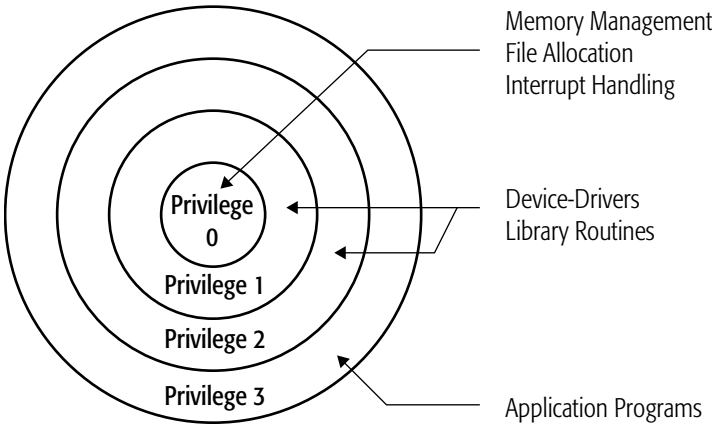

Figure 3-9. Privilege-Level Relationships

3.7.3 Procedure Stack

A procedure stack (also known as 'program stack') is often used by control transfer operations, particularly those that change privilege levels. Information from the calling program is passed to the target program on the procedure stack. CALL instructions, interrupts, and exceptions all push information onto the procedure stack. The pushed information includes a return pointer to the calling program and, for call instructions, optionally includes parameters. When a privilege-level change occurs, the calling program's stack pointer (the pointer to the top of the stack) is pushed onto the stack. Interrupts and exceptions also push a copy of the calling program's rFLAGs register and, in some cases, an error code associated with the interrupt or exception.

The RET or IRET control-transfer instructions reverse the operation of CALLs, interrupts, and exceptions. These return instructions pop the return pointer off the stack and transfer control back to the calling program. If the calling program's stack pointer was pushed, it is restored by popping the saved values off the stack and into the SS and rSP registers.

3.7.3.1 Stack Alignment

Control-transfer performance can degrade significantly when the stack pointer is not aligned properly. Stack pointers should be word aligned in 16-bit segments, doubleword aligned in 32-bit segments, and quadword aligned in 64-bit mode.

3.7.3.2 Stack Operand-Size in 64-Bit Mode

In 64-bit mode, the stack pointer size is always 64 bits. The stack size is not controlled by the default-size (B) bit in the SS descriptor, as it is in compatibility and legacy modes, nor can it be overridden by an instruction prefix. Address-size overrides are ignored for implicit stack references.

Except for far branches, all instructions that implicitly reference the stack pointer default to 64-bit operand size in 64-bit mode. Table 3-8 on page 83 lists these instructions.

The default 64-bit operand size eliminates the need for a REX prefix with these instructions. However, a REX prefix is still required if R8–R15 (the extended set of eight GPRs) are used as operands, because the prefix is required to address the extended registers. Pushes and pops of 32-bit stack values are not possible in 64-bit mode with these instructions, because there is no 32-bit operand-size override prefix for 64-bit mode.

3.7.4 Jumps

Jump instructions provide a simple means for transferring program control from one location to another. Jumps do not affect the procedure stack, and return instructions cannot transfer control back to the instruction following a jump. Two general types of jump instruction are available: unconditional (JMP) and conditional (J*cc*).

There are two types of unconditional jumps (JMP):

- *Near Jumps*—When the target address is within the current code segment.
- *Far Jumps*—When the target address is outside the current code segment.

Although unconditional jumps can be used to change code segments, they cannot be used to change privilege levels.

Conditional jumps (J*cc*) test the state of various bits in the rFLAGS register (or rCX) and jump to a target location based on the results of that test. Only near forms of conditional jumps are available, so J*cc* cannot be used to transfer control to another code segment.

Table 3-8. Instructions that Implicitly Reference RSP in 64-Bit Mode

Mnemonic	Opcode (hex)	Description	Operand Size (bits)	
			Default	Possible Overrides[1]
CALL	E8, FF /2	Call Procedure Near	64	16
ENTER	C8	Create Procedure Stack Frame		
LEAVE	C9	Delete Procedure Stack Frame		
POP reg/mem	8F /0	Pop Stack (register or memory)		
POP reg	58 to 5F	Pop Stack (register)		
POP FS	0F A1	Pop Stack into FS Segment Register		
POP GS	0F A9	Pop Stack into GS Segment Register		
POPF POPFQ	9D	Pop to EFLAGS Word or Quadword		
PUSH imm32	68	Push onto Stack (sign-extended doubleword)		
PUSH imm8	6A	Push onto Stack (sign-extended byte)		
PUSH reg/mem	FF /6	Push onto Stack (register or memory)		
PUSH reg	50–57	Push onto Stack (register)		
PUSH FS	0F A0	Push FS Segment Register onto Stack		
PUSH GS	0F A8	Push GS Segment Register onto Stack		
PUSHF PUSHFQ	9C	Push rFLAGS Word or Quadword onto Stack		
RET	C2, C3	Return From Call (near)		

Note:
1. *There is no 32-bit operand-size override prefix in 64-bit mode.*

3.7.5 Procedure Calls

The CALL instruction transfers control unconditionally to a new address, but unlike jump instructions, it saves a return pointer (CS:rIP) on the stack. The called procedure can use the RET instruction to pop the return pointers to the calling procedure from the stack and continue execution with the instruction following the CALL.

There are four types of CALL:

- *Near Call*—When the target address is within the current code segment.
- *Far Call*—When the target address is outside the current code segment.
- *Interprivilege-Level Far Call*—A far call that changes privilege level.
- *Task Switch*—A call to a target address in another task.

3.7.5.1 Near Call

When a near CALL is executed, only the calling procedure's rIP (the return offset) is pushed onto the stack. After the rIP is pushed, control is transferred to the new rIP value specified by the CALL instruction. Parameters can be pushed onto the stack by the calling procedure prior to executing the CALL instruction. Figure 3-10 shows the stack pointer before (old rSP value) and after (new rSP value) the CALL. The stack segment (SS) is not changed.

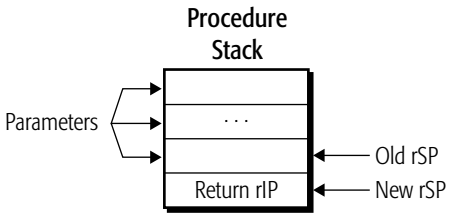

Figure 3-10. Procedure Stack, Near Call

When shadow stacks are enabled at the current privilege level, a near CALL pushes the calling procedure's LIP (CS base + rIP) onto the shadow stack, in addition to pushing the rIP onto the procedure stack.

3.7.5.2 Far Call, Same Privilege

A far CALL changes the code segment, so the full return pointer (CS:rIP) is pushed onto the stack. After the return pointer is pushed, control is transferred to the new CS:rIP value specified by the CALL instruction. Parameters can be pushed onto the stack by the calling procedure prior to executing the CALL instruction. Figure 3-11 shows the stack pointer before (old rSP value) and after (new rSP value) the CALL. The stack segment (SS) is not changed.

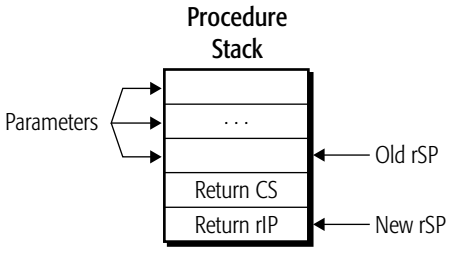

Figure 3-11. Procedure Stack, Far Call to Same Privilege

If the shadow stack feature is enabled at the current privilege level, a far CALL to the same privilege pushes the calling procedure's CS and LIP (CS.base + rIP) onto the shadow stack, in addition to

pushing the CS:rIP onto the procedure stack. For a detailed description of shadow stack operations, see "Shadow Stacks" in Volume 2.

3.7.5.3 Far Call, Greater Privilege

A far CALL to a more-privileged procedure performs a stack switch prior to transferring control to the called procedure. Switching stacks isolates the more-privileged procedure's stack from the less-privileged procedure's stack, and it provides a mechanism for saving the return pointer back to the procedure that initiated the call.

Calls to more-privileged software can only take place through a system descriptor called a *call-gate descriptor*. Call-gate descriptors are created and maintained by system software. In 64-bit mode, only indirect far calls (those whose target memory address is in a register or other memory location) are supported. Absolute far calls (those that reference the base of the code segment) are not supported in 64-bit mode.

When a call to a more-privileged procedure occurs, the processor locates the new procedure's stack pointer from its task-state segment (TSS). The old stack pointer (SS:rSP) is pushed onto the new stack, and (in legacy mode only) any parameters specified by the count field in the call-gate descriptor are copied from the old stack to the new stack (long mode does not support this automatic parameter copying). The return pointer (CS:rIP) is then pushed, and control is transferred to the new procedure. Figure 3-12 shows an example of a stack switch resulting from a call to a more-privileged procedure. "Segmented Virtual Memory" in Volume 2 provides additional information on privilege-changing CALLs.

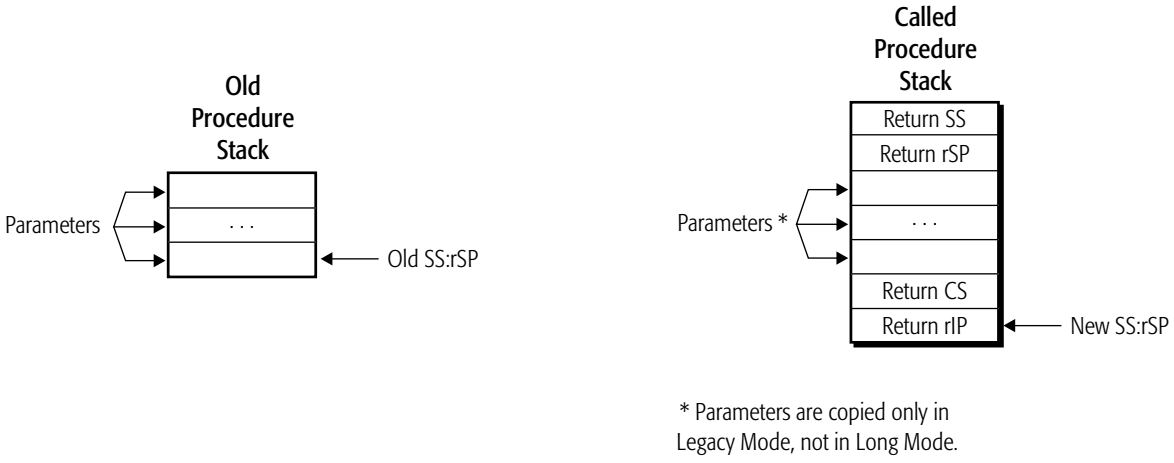

Figure 3-12. Procedure Stack, Far Call to Greater Privilege

If the shadow stack feature is enabled at the target CPL, a far call to a more-privileged level also switches to a new shadow stack. Depending on the target CPL, the old SSP and the CS and LIP may be pushed onto the new shadow stack.

If starting at CPL=3:

- the current SSP is saved to MSR PL3_SSP.
- a new SSP is loaded from PLn_SSP MSR (where n = the target CPL 0, 1 or 2).
- the CS and LIP are not pushed onto the new shadow stack.

If starting at CPL =1 or 2:

- the new SSP is loaded from MSR PLn_SSP, (where n = the target CPL 0 or 1).
- the CS, LIP and old SSP are pushed onto the new shadow stack.

For a detailed description of shadow stack operations, see “Shadow Stacks” in Volume 2.

3.7.5.4 Task Switch

In legacy mode, when a call to a new task occurs, the processor suspends the currently-executing task and stores the processor-state information at the point of suspension in the current task’s task-state segment (TSS). The new task’s state information is loaded from its TSS, and the processor resumes execution within the new task.

In long mode, hardware task switching is disabled. Task switching is fully described in “Segmented Virtual Memory” in Volume 2.

3.7.6 Returning from Procedures

The RET instruction reverses the effect of a CALL instruction. The return address is popped off the procedure stack, transferring control unconditionally back to the calling procedure at the instruction following the CALL. A return that changes privilege levels also switches stacks.

The three types of RET are:

- *Near Return*—Transfers control back to the calling procedure within the current code segment.
- *Far Return*—Transfers control back to the calling procedure outside the current code segment.
- *Interprivilege-Level Far Return*—A far return that changes privilege levels.

All of the RET instruction types can be used with an immediate operand indicating the number of parameter bytes present on the stack. These parameters are *released* from the stack—that is, the stack pointer is adjusted by the value of the immediate operand—but the parameter bytes are not actually popped off of the stack (i.e., read into a register or memory location).

3.7.6.1 Near Return

When a near RET is executed, the calling procedure's return offset is popped off of the stack and into the rIP register. Execution begins from the newly-loaded offset. If an immediate operand is included with the RET instruction, the stack pointer is adjusted by the number of bytes indicated. Figure 3-13 shows the stack pointer before (old rSP value) and after (new rSP value) the RET. The stack segment (SS) is not changed.

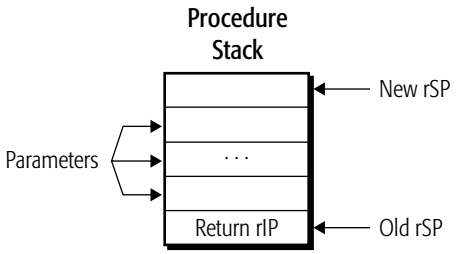

Figure 3-13. Procedure Stack, Near Return

If the shadow stack feature is enabled at the current CPL, a near RET pops the return LIP from the shadow stack and compares it to the return address read from the procedure stack. If the comparison fails, a control-protection (#CP fault) is generated. For a detailed description of shadow stack operations, see "Shadow Stacks" in Volume 2.

3.7.6.2 Far Return, Same Privilege

A far RET changes the code segment, so the full return pointer is popped off the stack and into the CS and rIP registers. Execution begins from the newly-loaded segment and offset. If an immediate operand is included with the RET instruction, the stack pointer is adjusted by the number of bytes indicated. Figure 3-14 on page 87 shows the stack pointer before (old rSP value) and after (new rSP value) the RET. The stack segment (SS) is not changed.

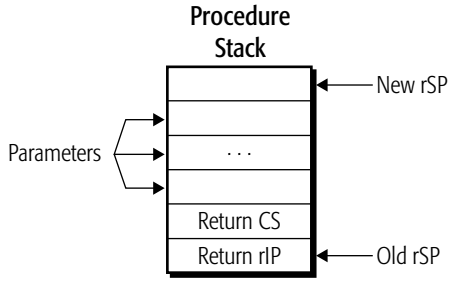

Figure 3-14. Procedure Stack, Far Return from Same Privilege

If the shadow stacks feature is enabled at the current CPL, a far RET to the same CPL pops the old SSP and the return LIP from the shadow stack. The return address is compared with the return address read from the procedure stack. If the comparison fails, a control-protection (#CP fault) is generated. For a detailed description of shadow stack operations, see “Shadow Stacks” in Volume 2.

3.7.6.3 Far Return, Less Privilege

Privilege-changing far RETs can only return to less-privileged code segments, otherwise a general-protection exception occurs. The full return pointer is popped off the stack and into the CS and rIP registers, and execution begins from the newly-loaded segment and offset. A far RET that changes privilege levels also switches stacks. The return procedure’s stack pointer is popped off the stack and into the SS and rSP registers. If an immediate operand is included with the RET instruction, the newly-loaded stack pointer is adjusted by the number of bytes indicated. Figure 3-15 shows the stack pointer before (old SS:rSP value) and after (new SS:rSP value) the RET. “Segmented Virtual Memory” in Volume 2 provides additional information on privilege-changing RETs.

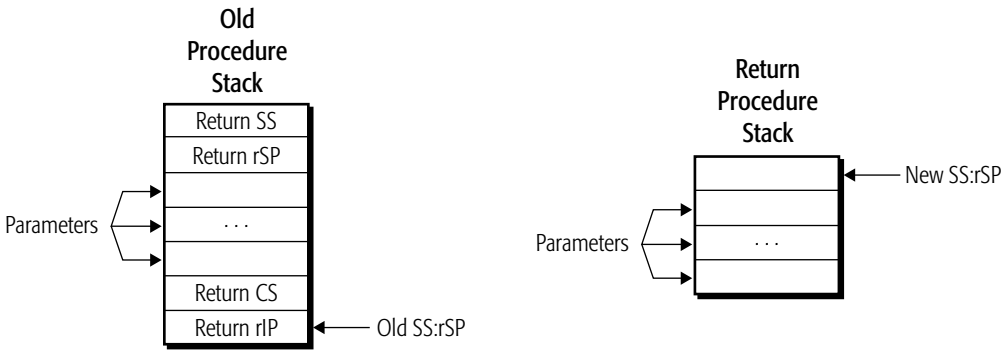

Figure 3-15. Procedure Stack, Far Return from Less Privilege

If the shadow stack feature is enabled, the operation of the shadow stack for a far return from a less-privileged level depends on the target CPL.

If returning to CPL 3:

- the old SSP is restored from PL3_SSP.
- the return address is not checked against the shadow stack.

If returning to CPL 1 or 2:

- the old SSP is popped and restored from the current shadow stack.

- the return CS and LIP are popped from the current shadow stack and compared with the return address read from the procedure stack. If the comparison fails, a control-protection (#CP fault) is generated.

For a detailed description of shadow stack operations, see “Shadow Stacks” in Volume 2.

3.7.7 System Calls

A disadvantage of far CALLs and far RETs is that they use segment-based protection and privilege-checking. This involves significant overhead associated with loading new segment selectors and their corresponding descriptors into the segment registers. The overhead includes not only the time required to load the descriptors from memory but also the time required to perform the privilege, type, and limit checks. Privilege-changing CALLs to the operating system are slowed further by the control transfer through a gate descriptor.

3.7.7.1 SYSCALL and SYSRET

SYSCALL and SYSRET are low-latency system-call and system-return control-transfer instructions. They can be used in protected mode. These instructions eliminate segment-based privilege checking by using pre-determined target and return code segments and stack segments. The operating system sets up and maintains the predetermined segments using special registers within the processor, so the segment descriptors do not need to be fetched from memory when the instructions are used. The simplifications made to privilege checking allow SYSCALL and SYSRET to complete in far fewer processor clock cycles than CALL and RET.

SYSRET can only be used to return from CPL = 0 procedures and is not available to application software. SYSCALL can be used by applications to call operating system service routines running at CPL = 0. The SYSCALL instruction does not take operands. Linkage conventions are initialized and maintained by the operating system. “System-Management Instructions” in Volume 2 contains detailed information on the operation of SYSCALL and SYSRET.

Because SYSCALL and SYSRET do not use the program stack for return address linkage, the shadow stack mechanism is not used to validate their return addresses. However, when the shadow stacks feature is enabled, SYSCALL and SYSRET save and restore the current SSP. See "SYSCALL and SYSRET" section 6.1.1, Volume 2 for more information.

3.7.7.2 SYSENTER and SYSEXIT

The SYSENTER and SYSEXIT instructions provide similar capabilities to SYSCALL and SYSRET. However, these instructions can be used only in legacy mode and are not supported in long mode. SYSCALL and SYSRET are the preferred instructions for calling privileged software. See “System-Management Instructions” in Volume 2 for further information on SYSENTER and SYSEXIT.

3.7.8 General Considerations for Branching

Branching causes delays which are a function of the hardware-implementation's branch-prediction capabilities. Sequential flow avoids the delays caused by branching but is still exposed to delays caused by cache misses, memory bus bandwidth, and other factors.

In general, branching code should be replaced with sequential code whenever practical. This is especially important if the branch body is small (resulting in frequent branching) and when branches depend on random data (resulting in frequent mispredictions of the branch target). In certain hardware implementations, far branches (as opposed to near branches) may not be predictable by the hardware, and recursive functions (those that call themselves) may overflow a return-address stack.

All calls and returns should be paired for optimal performance. Hardware implementations that include a return-address stack can lose stack synchronization if calls and returns are not paired.

3.7.9 Branching in 64-Bit Mode

3.7.9.1 Near Branches in 64-Bit Mode

The long-mode architecture expands the near-branch mechanisms to accommodate branches in the full 64-bit virtual-address space. In 64-bit mode, the operand size for all near branches defaults to 64 bits, so these instructions update the full 64-bit RIP.

Table 3-9 lists the near-branch instructions.

Table 3-9. Near Branches in 64-Bit Mode

Mnemonic	Opcode (hex)	Description	Operand Size (bits)	
			Default	Possible Overrides[1]
CALL	E8, FF /2	Call Procedure Near	64	16
J*cc*	70 to 7F, 0F 80 to 0F 8F	Jump Conditional		
JCXZ JECXZ JRCXZ	E3	Jump on CX/ECX/RCX Zero		
JMP	EB, E9, FF /4	Jump Near		
LOOP	E2	Loop		
LOOP*cc*	E0, E1	Loop if Zero/Equal or Not Zero/Equal		
RET	C2, C3	Return From Call (near)		

Note:
1. *There is no 32-bit operand-size override prefix in 64-bit mode.*

The default 64-bit operand size eliminates the need for a REX prefix with these instructions when registers RAX–RSP (the first set of eight GPRs) are used as operands. A REX prefix is still required if

R8–R15 (the extended set of eight GPRs) are used as operands, because the prefix is required to address the extended registers.

The following aspects of near branches are controlled by the effective operand size:

- Truncation of the instruction pointer.
- Size of a stack pop or push, resulting from a CALL or RET.
- Size of a stack-pointer increment or decrement, resulting from a CALL or RET.
- Indirect-branch operand size.

In 64-bit mode, all of the above actions are forced to 64 bits. However, the size of the displacement field for relative branches is still limited to 32 bits.

The operand size of near branches is fixed at 64 bits without the need for a REX prefix. However, the address size of near branches is not forced in 64-bit mode. Such addresses are 64 bits by default, but they can be overridden to 32 bits by a prefix.

3.7.9.2 Branches to 64-Bit Offsets

Because immediates are generally limited to 32 bits, the only way a full 64-bit absolute RIP can be specified in 64-bit mode is with an indirect branch. For this reason, direct forms of far branches are invalid in 64-bit mode.

3.7.10 Interrupts and Exceptions

Interrupts and exceptions are a form of control transfer operation. They are used to call special system-service routines, called interrupt handlers, which are designed to respond to the interrupt or exception condition. Pointers to the interrupt handlers are stored by the operating system in an *interrupt-descriptor table*, or IDT. In legacy real mode, the IDT contains an array of 4-byte far pointers to interrupt handlers. In legacy protected mode, the IDT contains an array of 8-byte gate descriptors. In long mode, the gate descriptors are 16 bytes. Interrupt gates, task gates, and trap gates can be stored in the IDT, but not call gates.

Interrupt handlers are usually privileged software because they typically require access to restricted system resources. System software is responsible for creating the interrupt gates and storing them in the IDT. “Exceptions and Interrupts” in Volume 2 contains detailed information on the interrupt mechanism and the requirements on system software for managing the mechanism.

The IDT is indexed using the interrupt number, or *vector*. How the vector is specified depends on the source, as described below. The first 32 of the available 256 interrupt vectors are reserved for internal use by the processor—for exceptions (as described below) and other purposes.

Interrupts are caused either by software or hardware. The INT, INT3, and INTO instructions implement a *software interrupt* by calling an interrupt handler directly. These are general-purpose (privilege-level-3) instructions. The operand of the INT instruction is an immediate byte value specifying the interrupt vector used to index the IDT. INT3 and INTO are specific forms of software interrupts used to call interrupt 3 and interrupt 4, respectively. *External interrupts* are produced by

system logic which passes the IDT index to the processor via input signals. External interrupts can be either *maskable* or *non-maskable*.

Exceptions usually occur as a result of software execution errors or other internal-processor errors. Exceptions can also occur in non-error situations, such as debug-program single-stepping or address-breakpoint detection. In the case of exceptions, the processor produces the IDT index based on the detected condition. The handlers for interrupts and exceptions are identical for a given vector.

The processor's response to an exception depends on the type of the exception. For all exceptions except SSE and x87 floating-point exceptions, control automatically transfers to the handler (or service routine) for that exception, as defined by the exceptions vector. For 128-bit-media and x87 floating-point exceptions, there is both a masked and unmasked response. When unmasked, these exceptions invoke their exception handler. When masked, a default masked response is provided instead of invoking the exception handler.

Exceptions and software-initiated interrupts occur synchronously with respect to the processor clock. There are three types of exceptions:

- *Faults*—A fault is a precise exception that is reported on the boundary before the interrupted instruction. Generally, faults are caused by an undesirable error condition involving the interrupted instruction, although some faults (such as page faults) are common and normal occurrences. After the service routine completes, the machine state prior to the faulting instruction is restored, and the instruction is retried.
- *Traps*—A trap is a precise exception that is reported on the boundary following the interrupted instruction. The instruction causing the exception finishes before the service routine is invoked. Software interrupts and certain breakpoint exceptions used in debugging are traps.
- *Aborts*—Aborts are imprecise exceptions. The instruction causing the exception, and possibly an indeterminate additional number of instructions, complete execution before the service routine is invoked. Because they are imprecise, aborts typically do not allow reliable program restart.

Table 3-10 shows the interrupts and exceptions that can occur, together with their vector numbers, mnemonics, source, and causes. For a detailed description of interrupts and exceptions, see "Exceptions and Interrupts" in Volume 2.

Control transfers to interrupt handlers are similar to far calls, except that for the former, the rFLAGS register is pushed onto the stack before the return address. Interrupts and exceptions to several of the first 32 interrupts can also push an error code onto the stack. No parameters are passed by an interrupt. As with CALLs, interrupts that cause a privilege change also perform a stack switch.

Table 3-10. Interrupts and Exceptions

Vector	Interrupt (Exception)	Mnemonic	Source	Cause	Generated By General-Purpose Instructions
0	Divide-By-Zero-Error	#DE	Software	DIV, IDIV instructions	yes
1	Debug	#DB	Internal	Instruction accesses and data accesses	yes
2	Non-Maskable-Interrupt	NMI	External	External $\overline{\text{NMI}}$ signal	no
3	Breakpoint	#BP	Software	INT3 instruction	yes
4	Overflow	#OF	Software	INTO instruction	yes
5	Bound-Range	#BR	Software	BOUND instruction	yes
6	Invalid-Opcode	#UD	Internal	Invalid instructions	yes
7	Device-Not-Available	#NM	Internal	x87 instructions	no
8	Double-Fault	#DF	Internal	Exception during an interrupt/exception transfer	indirectly
9	Coprocessor-Segment-Overrun	—	External	Unsupported (reserved)	
10	Invalid-TSS	#TS	Internal	Task-state segment access and task switch	yes
11	Segment-Not-Present	#NP	Internal	Segment access through a descriptor	yes
12	Stack	#SS	Internal	SS register loads and stack references	yes
13	General-Protection	#GP	Internal	Memory accesses and protection checks	yes
14	Page-Fault	#PF	Internal	Memory accesses when paging enabled	yes
15	Reserved	—			
16	x87 Floating-Point Exception-Pending	#MF	Software	x87 floating-point and 64-bit media floating-point instructions	no
17	Alignment-Check	#AC	Internal	Memory accesses	yes
18	Machine-Check	#MC	Internal External	Model specific	yes
19	SIMD Floating-Point	#XF	Internal	128-bit media floating-point instructions	no
20	Reserved	—			
21	Control-Protection	#CP	Internal	Control transfers	yes
22—31	Reserved (Internal and External)	—			

Table 3-10. Interrupts and Exceptions (continued)

Vector	Interrupt (Exception)	Mnemonic	Source	Cause	Generated By General-Purpose Instructions
30	Security	#SX	External	Security exception	no
31	Reserved	—			
0–255	External Interrupts (Maskable)	—	External	External interrupt signaling	no
0–255	Software Interrupts	—	Software	INT instruction	yes

3.7.10.1 Interrupt to Same Privilege in Legacy Mode

When an interrupt to a handler running at the same privilege occurs, the processor pushes a copy of the rFLAGS register, followed by the return pointer (CS:rIP), onto the stack. If the interrupt generates an error code, it is pushed onto the stack as the last item. Control is then transferred to the interrupt handler. Figure 3-16 on page 94 shows the stack pointer before (old rSP value) and after (new rSP value) the interrupt. The stack segment (SS) is not changed.

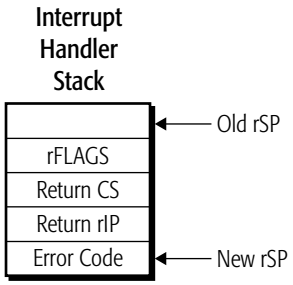

Figure 3-16. Procedure Stack, Interrupt to Same Privilege

If the shadow stack feature is enabled for the current CPL, an interrupt to a handler at the same privilege pushes the interrupted procedure's CS and LIP (linear return IP) onto the shadow stack, in addition to pushing the CS:rIP onto the procedure stack stack. For a detailed description of shadow stack operations, see "Shadow Stacks" in Volume 2.

3.7.10.2 Interrupt to More Privilege or in Long Mode

When an interrupt to a more-privileged handler occurs or the processor is operating in long mode the processor locates the handler's stack pointer from the TSS. The old stack pointer (SS:rSP) is pushed onto the new stack, along with a copy of the rFLAGS register. The return pointer (CS:rIP) to the interrupted program is then copied to the stack. If the interrupt generates an error code, it is pushed onto the stack as the last item. Control is then transferred to the interrupt handler. Figure 3-17 shows an example of a stack switch resulting from an interrupt with a change in privilege.

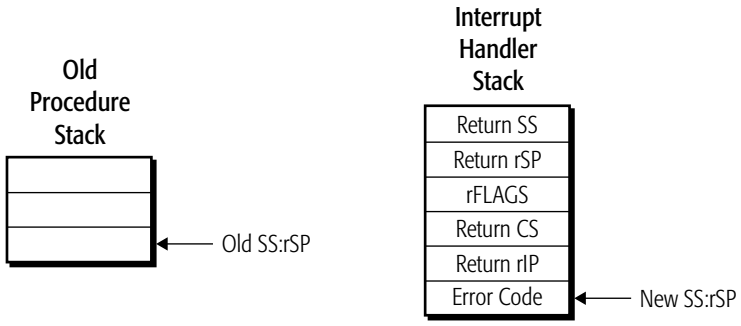

Figure 3-17. Procedure Stack, Interrupt to Higher Privilege

If the shadow stack feature is enabled at the target CPL, an interrupt to a more-privileged level also switches to a new shadow stack. Depending on the CPL of the interrupt procedure, the old SSP and the CS and LIP may be pushed onto the new shadow stack. For a detailed description of shadow stack operations, see "Shadow Stacks" in Volume 2.

3.7.10.3 Interrupt Returns

The IRET, IRETD, and IRETQ instructions are used to return from an interrupt handler. Prior to executing an IRET, the interrupt handler must pop the error code off of the stack if one was pushed by the interrupt or exception. IRET restores the interrupted program's rIP, CS, and rFLAGS by popping their saved values off of the stack and into their respective registers. If a privilege change occurs or IRET is executed in 64-bit mode, the interrupted program's stack pointer (SS:rSP) is also popped off of the stack. Control is then transferred back to the interrupted program.

If the shadow stack feature is enabled at the current CPL, an IRET to the same CPL pops the old SSP, return CS and return LIP from the shadow stack. The CS and return address are compared with the values read from the procedure stack. If the comparison fails, a control-protection (#CP) fault is generated. If IRET is returning to a different CPL, the operation of the shadow stack depends on the CPL of the procedure to which IRET is returning. If the return CPL is 1 or 2, the old SSP, return CS and return LIP are popped from the shadow stack. The CS and return address are compared with the values read from the procedure stack. If the comparison fails, a control-protection (#CP) fault is generated. If the return CPL is 3, the old SSP is restored from PL3_SSP and the return address is not checked against the shadow stack. For a detailed description of shadow stack operations, see "Shadow Stacks" in Volume 2.

3.8 Input/Output

I/O devices allow the processor to communicate with the outside world, usually to a human or to another system. In fact, a system without I/O has little utility. Typical I/O devices include a keyboard, mouse, LAN connection, printer, storage devices, and monitor. The speeds these devices must operate

at vary greatly, and usually depend on whether the communication is to a human (slow) or to another machine (fast). There are exceptions. For example, humans can consume graphics data at very high rates.

There are two methods for communicating with I/O devices in AMD64 processor implementations. One method involves accessing I/O through ports located in I/O-address space (“I/O Addressing” on page 96), and the other method involves accessing I/O devices located in the memory-address space (“Memory Organization” on page 9). The address spaces are separate and independent of each other.

I/O-address space was originally introduced as an optimized means for accessing I/O-device control ports. Then, systems usually had few I/O devices, devices tended to be relatively low-speed, device accesses needed to be strongly ordered to guarantee proper operation, and device protection requirements were minimal or non-existent. Memory-mapped I/O has largely supplanted I/O-address space access as the preferred means for modern operating systems to interface with I/O devices. Memory-mapped I/O offers greater flexibility in protection, vastly more I/O ports, higher speeds, and strong or weak ordering to suit the device requirements.

3.8.1 I/O Addressing

Access to I/O-address space is provided by the IN and OUT instructions, and the string variants of these instructions, INS and OUTS. The operation of these instructions are described in “Input/Output” on page 68. Although not required, processor implementations generally transmit I/O-port addresses and I/O data over the same external signals used for memory addressing and memory data. Different bus-cycles generated by the processor differentiate I/O-address space accesses from memory-address space accesses.

3.8.1.1 I/O-Address Space

Figure 3-18 on page 96 shows the 64 Kbyte I/O-address space. I/O ports can be addressed as bytes, words, or doublewords. As with memory addressing, word-I/O and doubleword-I/O ports are simply two or four consecutively-addressed byte-I/O ports. Word and doubleword I/O ports can be aligned on any byte boundary, but there is typically a performance penalty for unaligned accesses. Performance is optimized by aligning word-I/O ports on word boundaries, and doubleword-I/O ports on doubleword boundaries.

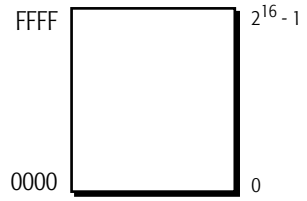

Figure 3-18. I/O Address Space

3.8.1.2 Memory-Mapped I/O

Memory-mapped I/O devices are attached to the system memory bus and respond to memory transactions as if they were memory devices, such as DRAM. Access to memory-mapped I/O devices can be performed using any instruction that accesses memory, but typically MOV instructions are used to transfer data between the processor and the device. Some I/O devices may have restrictions on read-modify-write accesses.

Any location in memory can be used as a memory-mapped I/O address. System software can use the paging facilities to virtualize memory devices and protect them from unauthorized access. See "System-Management Instructions" in Volume 2 for a discussion of memory virtualization and paging.

3.8.2 I/O Ordering

The order of read and write accesses between the processor and an I/O device is usually important for properly controlling device operation. Accesses to I/O-address space and memory-address space differ in the default ordering enforced by the processor and the ability of software to control ordering.

3.8.2.1 I/O-Address Space

The processor always orders I/O-address space operations strongly, with respect to other I/O and memory operations. Software cannot modify the I/O ordering enforced by the processor. IN instructions are not executed until all previous writes to I/O space and memory have completed. OUT instructions delay execution of the *following* instruction until all writes—including the write performed by the OUT—have completed. Unlike memory writes, writes to I/O addresses are never buffered by the processor.

The processor can use more than one bus transaction to access an unaligned, multi-byte I/O port. Unaligned accesses to I/O-address space do not have a defined bus transaction ordering, and that ordering can change from one implementation to another. If the use of an unaligned I/O port is required, and the order of bus transactions to that port is important, software should decompose the access into multiple, smaller aligned accesses.

3.8.2.2 Memory-Mapped I/O

To maximize software performance, processor implementations can execute instructions out of program order. This can cause the sequence of memory accesses to also be out of program order, called *weakly ordered*. As described in "Accessing Memory" on page 99, the processor can perform memory reads in any order, it can perform reads without knowing whether it requires the result (speculation), and it can reorder reads ahead of writes. In the case of writes, multiple writes to memory locations in close proximity to each other can be combined into a single write or a burst of multiple writes. Writes can also be delayed, or buffered, by the processor.

Application software that needs to force memory ordering to memory-mapped I/O devices can do so using the read/write barrier instructions: LFENCE, SFENCE, and MFENCE. These instructions are described in "Forcing Memory Order" on page 100. Serializing instructions, I/O instructions, and

locked instructions can also be used as read/write barriers, but they modify program state and are an inferior method for enforcing strong-memory ordering.

Typically, the operating system controls access to memory-mapped I/O devices. The AMD64 architecture provides facilities for system software to specify the types of accesses and their ordering for entire regions of memory. These facilities are also used to manage the cacheability of memory regions. See “System-Management Instructions” in Volume 2 for further information.

3.8.3 Protected-Mode I/O

In protected mode, access to the I/O-address space is governed by the I/O privilege level (IOPL) field in the rFLAGS register, and the I/O-permission bitmap in the current task-state segment (TSS).

3.8.3.1 I/O-Privilege Level

RFLAGS.IOPL governs access to *IOPL-sensitive* instructions. All of the I/O instructions (IN, INS, OUT, and OUTS) are IOPL-sensitive. IOPL-sensitive instructions cannot be executed by a program unless the program’s current-privilege level (CPL) is numerically less (more privileged) than or equal to the RFLAGS.IOPL field, otherwise a general-protection exception (#GP) occurs.

Only software running at CPL = 0 can change the RFLAGS.IOPL field. Two instructions, POPF and IRET, can be used to change the field. If application software (or any software running at CPL>0) attempts to change RFLAGS.IOPL, the attempt is ignored.

System software uses RFLAGS.IOPL to control the privilege level required to access I/O-address space devices. Access can be granted on a program-by-program basis using different copies of RFLAGS for every program, each with a different IOPL. RFLAGS.IOPL acts as a global control over a program’s access to I/O-address space devices. System software can grant less-privileged programs access to individual I/O devices (overriding RFLAGS.IOPL) by using the I/O-permission bitmap stored in a program’s TSS. For details about the I/O-permission bitmap, see “I/O-Permission Bitmap” in Volume 2.

3.9 Memory Optimization

Generally, application software is unaware of the memory hierarchy implemented within a particular system design. The application simply sees a homogenous address space within a single level of memory. In reality, both system and processor implementations can use any number of techniques to speed up accesses into memory, doing so in a manner that is transparent to applications. Application software can be written to maximize this speed-up even though the methods used by the hardware are not visible to the application. This section gives an overview of the memory hierarchy and access techniques that can be implemented within a system design, and how applications can optimize their use.

3.9.1 Accessing Memory

Implementations of the AMD64 architecture *commit* the results of each instruction—that is, store the result of the executed instruction in software-visible resources, such as a register (including flags), the data cache, an internal write buffer, or memory—in program order, which is the order specified by the instruction sequence in a program. Transparent to the application, implementations can execute instructions in any order and temporarily hold out-of-order results until the instructions are committed. Implementations can also *speculatively* execute instructions—executing instructions before knowing their results will be used (for example, executing both sides of a branch). By executing instructions out-of-order and speculatively, a processor can boost application performance by executing instructions that are ready, rather than delaying them behind instructions that are waiting for data. However, the processor commits results in program order (the order expected by software).

When executing instructions out-of-order and speculatively, processor implementations often find it useful to also allow out-of-order and speculative memory accesses. However, such memory accesses are potentially visible to software and system devices. The following sections describe the architectural rules for memory accesses. See “Memory System” in Volume 2 for information on how system software can further specify the flexibility of memory accesses.

3.9.1.1 Read Ordering

The ordering of memory reads does not usually affect program execution because the ordering does not usually affect the state of software-visible resources. The rules governing read ordering are:

- *Out-of-order reads are allowed.* Out-of-order reads can occur as a result of out-of-order instruction execution. The processor can read memory out-of-order to prevent stalling instructions that are executed out-of-order.
- *Speculative reads are allowed.* A speculative read occurs when the processor begins executing a memory-read instruction before it knows whether the instruction’s result will actually be needed. For example, the processor can predict a branch to occur and begin executing instructions following the predicted branch, before it knows whether the prediction is valid. When one of the speculative instructions reads data from memory, the read itself is speculative.
- *Reads can usually be reordered ahead of writes.* Reads are generally given a higher priority by the processor than writes because instruction execution stalls if the read data required by an instruction is not immediately available. Allowing reads ahead of writes usually maximizes software performance.

  Reads can be reordered ahead of writes, except that a read *cannot* be reordered ahead of a prior write if the read is from the same location as the prior write. In this case, the read instruction stalls until the write instruction is committed. This is because the result of the write instruction is required by the read instruction for software to operate correctly.

Some system devices might be sensitive to reads. Normally, applications do not have direct access to system devices, but instead call an operating-system service routine to perform the access on the application’s behalf. In this case, it is system software’s responsibility to enforce strong read-ordering.

3.9.1.2 Write Ordering

Writes affect program order because they affect the state of software-visible resources. The rules governing write ordering are restrictive:

- *Generally, out-of-order writes are not allowed.* Write instructions executed out-of-order cannot *commit* (write) their result to memory until all previous instructions have completed in program order. The processor can, however, hold the result of an out-of-order write instruction in a private buffer (not visible to software) until that result can be committed to memory.

  System software can create non-cacheable *write-combining* regions in memory when the order of writes is known to not affect system devices. When writes are performed to write-combining memory, they can appear to complete out of order relative to other writes. See “Memory System” in Volume 2 for additional information.
- *Speculative writes are not allowed.* As with out-of-order writes, speculative write instructions cannot commit their result to memory until all previous instructions have completed in program order. Processors can hold the result in a private buffer (not visible to software) until the result can be committed.

3.9.1.3 Atomicity of accesses.

Single load or store operations (from instructions that do just a single load or store) are naturally atomic on any AMD64 processor as long as they do not cross an aligned 8-byte boundary. Accesses up to eight bytes in size which do cross such a boundary may be performed atomically using certain instructions with a lock prefix, such as XCHG, CMPXCHG or CMPXCHG8B, as long as all such accesses are done using the same technique. (Note that misaligned locked accesses may be subject to heavy performance penalties.) CMPXCHG16B can be used to perform 16-byte atomic accesses in 64-bit mode (with certain alignment restrictions).

3.9.2 Forcing Memory Order

Special instructions are provided for application software to force memory ordering in situations where such ordering is important. These instructions are:

- *Load Fence*—The LFENCE instruction forces ordering of memory loads (reads). All memory loads preceding the LFENCE (in program order) are completed prior to completing memory loads following the LFENCE. Memory loads cannot be reordered around an LFENCE instruction, but other non-serializing instructions (such as memory writes) can be reordered around the LFENCE.
- *Store Fence*—The SFENCE instruction forces ordering of memory stores (writes). All memory stores preceding the SFENCE (in program order) are completed prior to completing memory stores following the SFENCE. Memory stores cannot be reordered around an SFENCE instruction, but other non-serializing instructions (such as memory loads) can be reordered around the SFENCE.
- *Memory Fence*—The MFENCE instruction forces ordering of all memory accesses (reads and writes). All memory accesses preceding the MFENCE (in program order) are completed prior to completing any memory access following the MFENCE. Memory accesses cannot be reordered

around an MFENCE instruction. Additionally in AMD64 processors, MFENCE is a serializing instruction (see below).

Although they serve different purposes, other instructions can be used as read/write barriers when the order of memory accesses must be strictly enforced. These read/write barrier instructions force all prior reads and writes to complete before subsequent reads or writes are executed. Unlike the fence instructions listed above, these other instructions alter the software-visible state. This makes these instructions less general and more difficult to use as read/write barriers than the fence instructions, although their use may reduce the total number of instructions executed. The following instructions are usable as read/write barriers:

- *Serializing instructions*—Serializing instructions force the processor to commit the serializing instruction and all previous instructions, then restart instruction fetching at the next instruction. This flushes any speculatively fetched instructions that may be in execution behind the serializing instruction. The serializing instructions available to applications (aside from MFENCE; see above) are CPUID and IRET. A serializing instruction is committed when the following operations are complete:
  - The instruction has executed.
  - All registers modified by the instruction are updated.
  - All memory updates performed by the instruction are complete.
  - All data held in the write buffers have been written to memory. (Write buffers are described in “Write Buffering” on page 103).
- *I/O instructions*—Reads from and writes to I/O-address space use the IN and OUT instructions, respectively. When the processor executes an I/O instruction, it orders it with respect to other loads and stores, depending on the instruction:
  - IN instructions (IN, INS, and REP INS) are not executed until all previous stores to memory and I/O-address space are complete.
  - Instructions *following* an OUT instruction (OUT, OUTS, or REP OUTS) are not executed until all previous stores to memory and I/O-address space are complete, including the store performed by the OUT.
- *Locked instructions*—A locked instruction is one that contains the LOCK instruction prefix. A locked instruction is used to perform an atomic read-modify-write operation on a memory operand, so it needs exclusive access to the memory location for the duration of the operation. Locked instructions order memory accesses in the following way:
  - All previous loads and stores (in program order) are completed prior to executing the locked instruction.
  - The locked instruction is completed before allowing loads and stores for subsequent instructions (in program order) to occur.

Only certain instructions can be locked. See “Lock Prefix” in Volume 3 for a list of instructions that can use the LOCK prefix.

3.9.3 Caches

Depending on the instruction, operands can be encoded in the instruction opcode or located in registers, I/O ports, or memory locations. An operand that is located in memory can actually be physically present in one or more locations within a system's *memory hierarchy*.

3.9.3.1 Memory Hierarchy

A system's memory hierarchy may have some or all of the following levels:

- *Main Memory*—Main memory is external to the processor chip and is the memory-hierarchy level farthest from the processor's execution units. All physical-memory addresses are present in main memory, which is implemented using relatively slow, but high-density memory devices.
- *External Caches*—External caches are external to the processor chip, but are implemented using lower-capacity, higher-performance memory devices than system memory. The system uses external caches to hold copies of frequently-used instructions and data found in main memory. A subset of the physical-memory addresses can be present in the external caches at any time. A system can contain any number of external caches, or none at all.
- *Internal Caches*—Internal caches are present on the processor chip itself, and are the closest memory-hierarchy level to the processor's execution units. Because of their presence on the processor chip, access to internal caches is very fast. Internal caches contain copies of the most frequently-used instructions and data found in main memory *and* external caches, and their capacities are relatively small in comparison to external caches. A processor implementation can contain any number of internal caches, or none at all. Implementations often contain a first-level instruction cache and first-level data (operand) cache, and they may also contain a higher-capacity (and slower) second- and even third-level internal cache for storing both instructions and data.

Figure 3-19 on page 103 shows an example of a four-level memory hierarchy that combines main memory, external third-level (L3) cache, and internal second-level (L2) and two first-level (L1) caches. As the figure shows, the first-level and second-level caches are implemented on the processor chip, and the third-level cache is external to the processor. The first-level cache is a split cache, with separate caches used for instructions and data. The second-level and third-level caches are unified (they contain both instructions and data). Memory at the highest levels of the hierarchy have greater capacity (larger size), but have slower access, than memory at the lowest levels.

Using caches to store frequently used instructions and data can result in significantly improved software performance by avoiding accesses to the slower main memory. Applications function identically on systems without caches and on systems with caches, although cacheless systems typically execute applications more slowly. Application software can, however, be optimized to make efficient use of caches when they are present, as described later in this section.

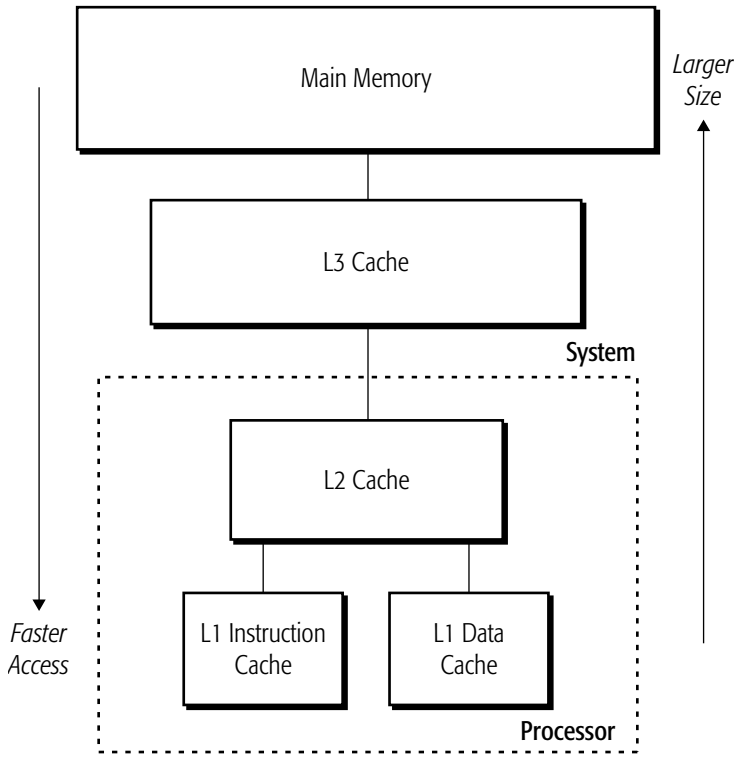

Figure 3-19. Memory Hierarchy Example

3.9.3.2 Write Buffering

Processor implementations can contain write-buffers attached to the internal caches. Write buffers can also be present on the interface used to communicate with the external portions of the memory hierarchy. Write buffers temporarily hold data writes when main memory or the caches are busy responding to other memory-system accesses. The existence of write buffers is transparent to software. However, some of the instructions used to optimize memory-hierarchy performance can affect the write buffers, as described in “Forcing Memory Order” on page 100.

3.9.4 Cache Operation

Although the existence of caches is transparent to application software, a simple understanding how caches are accessed can assist application developers in optimizing their code to run efficiently when caches are present.

Caches are divided into fixed-size blocks, called *cache lines*. Typically, implementations have either 32-byte or 64-byte cache lines. The processor *allocates* a cache line to correspond to an identically-sized region in main memory. After a cache line is allocated, the addresses in the corresponding region of main memory are used as addresses into the cache line. It is the processor’s responsibility to keep the contents of the allocated cache line *coherent* with main memory. Should another system device

access a memory address that is cached, the processor maintains coherency by providing the correct data back to the device and main memory.

When a memory-read occurs as a result of an instruction fetch or operand access, the processor first checks the cache to see if the requested information is available. A *read hit* occurs if the information is available in the cache, and a *read miss* occurs if the information is not available. Likewise, a *write hit* occurs if a memory write can be stored in the cache, and a *write miss* occurs if it cannot be stored in the cache.

A read miss or write miss can result in the allocation of a cache line, followed by a *cache-line fill*. Even if only a single byte is needed, all bytes in a cache line are loaded from memory by a cache-line fill. Typically, a cache-line fill must write over an existing cache line in a process called a *cache-line replacement*. In this case, if the existing cache line is modified, the processor performs a cache-line *writeback* to main memory prior to performing the cache-line fill.

Cache-line writebacks help maintain coherency between the caches and main memory. Internally, the processor can also maintain cache coherency by *internally probing* (checking) the other caches and write buffers for a more recent version of the requested data. External devices can also check a processor's caches and write buffers for more recent versions of data by *externally probing* the processor. All coherency operations are performed in hardware and are completely transparent to applications.

3.9.4.1 Cache Coherency and MOESI

Implementations of the AMD64 architecture maintain coherency between memory and caches using a five-state protocol known as MOESI. The five MOESI states are *modified*, *owned*, *exclusive*, *shared*, and *invalid*. See "Memory System" in Volume 2 for additional information on MOESI and cache coherency.

3.9.4.2 Instruction Cache Coherency

Instruction caches in AMD64 processors do not support in-cache updates. Any stores that hit a line in an instruction cache will cause that line to be invalidated by hardware to maintain coherency of the cache contents. The line may then be re-fetched and loaded into the cache as needed by the instruction fetch logic, reflecting the update. Special considerations for self-modifying code (code which writes into its own pending instruction stream) and cross-modifying code (code which writes into the active instruction stream of anotherthread) may be found in Volume 2, Section 7.6.1.

3.9.5 Cache Pollution

Because cache sizes are limited, caches should be filled only with data that is frequently used by an application. Data that is used infrequently, or not at all, is said to *pollute* the cache because it occupies otherwise useful cache lines. Ideally, the best data to cache is data that adheres to the *principle of locality*. This principle has two components: *temporal locality* and *spatial locality*.

- *Temporal locality* refers to data that is likely to be used more than once in a short period of time. It is useful to cache temporal data because subsequent accesses can retrieve the data quickly. Non-

temporal data is assumed to be used once, and then not used again for a long period of time, or ever. Caching of non-temporal data pollutes the cache and should be avoided.

Cache-control instructions (“Cache-Control Instructions” on page 105) are available to applications to minimize cache pollution caused by non-temporal data.

- *Spatial locality* refers to data that resides at addresses adjacent to or very close to the data being referenced. Typically, when data is accessed, it is likely the data at nearby addresses will be accessed in a short period of time. Caches perform cache-line fills in order to take advantage of spatial locality. During a cache-line fill, the referenced data and nearest neighbors are loaded into the cache. If the characteristics of spacial locality do not fit the data used by an application, then the cache becomes polluted with a large amount of unreferenced data.

  Applications can avoid problems with this type of cache pollution by using data structures with good spatial-locality characteristics.

Another form of cache pollution is *stale data*. Data that adheres to the principle of locality can become stale when it is no longer used by the program, or won’t be used again for a long time. Applications can use the CLFLUSH instruction to remove stale data from the cache.

3.9.6 Cache-Control Instructions

General control and management of the caches is performed by system software and not application software. System software uses special registers to assign *memory types* to physical-address ranges, and page-attribute tables are used to assign memory types to virtual address ranges. Memory types define the cacheability characteristics of memory regions and how coherency is maintained with main memory. See “Memory System” in Volume 2 for additional information on memory typing.

Instructions are available that allow application software to control the cacheability of data it uses on a more limited basis. These instructions can be used to boost an application’s performance by prefetching data into the cache, and by avoiding cache pollution. Run-time analysis tools and compilers may be able to suggest the use of cache-control instructions for critical sections of application code.

3.9.6.1 Cache Prefetching

Applications can prefetch entire cache lines into the caching hierarchy using one of the prefetch instructions. The prefetch should be performed in advance, so that the data is available in the cache when needed. Although load instructions can mimic the prefetch function, they do not offer the same performance advantage, because a load instruction may cause a subsequent instruction to stall until the load completes, but a prefetch instruction will never cause such a stall. Load instructions also unnecessarily require the use of a register, but prefetch instructions do not.

The instructions available in the AMD64 architecture for cache-line prefetching include one SSE instruction and two 3DNow! instructions:

- *PREFETCHlevel*—(an SSE instruction) Prefetches read/write data into a specific level of the cache hierarchy. If the requested data is already in the desired cache level or closer to the processor (lower cache-hierarchy level), the data is not prefetched. If the operand specifies an invalid

memory address, no exception occurs, and the instruction has no effect. Attempts to prefetch data from non-cacheable memory, such as video frame buffers, or data from write-combining memory, are also ignored. The exact actions performed by the PREFETCH*level* instructions depend on the processor implementation. Current AMD processor families map all PREFETCH*level* instructions to a PREFETCH. Refer to the *Optimization Guide for AMD Athlon™ 64 and AMD Opteron™ Processors*, order# 25112, for details relating to a particular processor family, brand or model.

- PREFETCHT0—Prefetches temporal data into the entire cache hierarchy.
- PREFETCHT1—Prefetches temporal data into the second-level (L2) and higher-level caches, but not into the L1 cache.
- PREFETCHT2—Prefetches temporal data into the third-level (L3) and higher-level caches, but not into the L1 or L2 cache.
- PREFETCHNTA—Prefetches non-temporal data into the processor, minimizing cache pollution. The specific technique for minimizing cache pollution is implementation-dependent and can include such techniques as allocating space in a software-invisible buffer, allocating a cache line in a single cache or a specific way of a cache, etc.

- *PREFETCH*—(a 3DNow! instruction) Prefetches read data into the L1 data cache. Data can be written to such a cache line, but doing so can result in additional delay because the processor must signal externally to negotiate the right to change the cache line's cache-coherency state for the purpose of writing to it.
- *PREFETCHW*—(a 3DNow! instruction) Prefetches write data into the L1 data cache. Data can be written to the cache line without additional delay, because the data is already prefetched in the *modified* cache-coherency state. Data can also be read from the cache line without additional delay. However, prefetching write data takes longer than prefetching read data if the processor must wait for another caching master to first write-back its modified copy of the requested data to memory before the prefetch request is satisfied.

The PREFETCHW instruction provides a hint to the processor that the cache line is to be modified, and is intended for use when the cache line will be written to shortly after the prefetch is performed. The processor can place the cache line in the modified state when it is prefetched, but before it is actually written. Doing so can save time compared to a PREFETCH instruction, followed by a subsequent cache-state change due to a write.

To prevent a false-store dependency from stalling a prefetch instruction, prefetched data should be located at least one cache-line away from the address of any surrounding data write. For example, if the cache-line size is 32 bytes, avoid prefetching from data addresses within 32 bytes of the data address in a preceding write instruction.

3.9.6.2 Non-Temporal Stores

Non-temporal store instructions are provided to prevent memory writes from being stored in the cache, thereby reducing cache pollution. These non-temporal store instructions are specific to the type of register they write:

- *GPR Non-temporal Stores*—MOVNTI.

- *YMM/XMM Non-temporal Stores*—(V)MASKMOVDQU, (V)MOVNTDQ, (V)MOVNTPD, and (V)MOVNTPS.
- *MMX Non-temporal Stores*—MASKMOVQ and MOVNTQ.

3.9.6.3 Removing Stale Cache Lines

When cache data becomes stale, it occupies space in the cache that could be used to store frequently-accessed data. Applications can use the CLFLUSH instruction to free a stale cache-line for use by other data. CLFLUSH writes the contents of a cache line to memory and then invalidates the line in the cache and in all other caches in the cache hierarchy that contain the line. Once invalidated, the line is available for use by the processor and can be filled with other data.

3.10 Performance Considerations

In addition to typical code optimization techniques, such as those affecting loops and the inlining of function calls, the following considerations may help improve the performance of application programs written with general-purpose instructions.

These are implementation-independent performance considerations. Other considerations depend on the hardware implementation. For information about such implementation-dependent considerations and for more information about application performance in general, see the data sheets and the software-optimization guides relating to particular hardware implementations.

3.10.1 Use Large Operand Sizes

Loading, storing, and moving data with the largest relevant operand size maximizes the memory bandwidth of these instructions.

3.10.2 Use Short Instructions

Use the shortest possible form of an instruction (the form with fewest opcode bytes). This increases the number of instructions that can be decoded at any one time, and it reduces overall code size.

3.10.3 Align Data

Data alignment directly affects memory-access performance. Data alignment is particularly important when accessing *streaming* (also called *non-temporal*) data—data that will not be reused and therefore should not be cached. Data alignment is also important in cases where data that is written by one instruction is subsequently read by a subsequent instruction soon after the write.

3.10.4 Avoid Branches

Branching can be very time-consuming. If the body of a branch is small, the branch may be replaceable with conditional move (CMOV*cc*) instructions, or with 128-bit or 64-bit media instructions that simulate predicated parallel execution or parallel conditional moves.

3.10.5 Prefetch Data

Memory latency can be substantially reduced—especially for data that will be used multiple times—by prefetching such data into various levels of the cache hierarchy. Software can use the PREFETCH*x* instructions very effectively in such cases. One PREFETCH*x* per cache line should be used.

Some of the best places to use prefetch instructions are inside loops that process large amounts of data. If the loop goes through less than one cache line of data per iteration, partially unroll the loop. Try to use virtually all of the prefetched data. This usually requires unit-stride memory accesses—those in which all accesses are to contiguous memory locations.

For data that will be used only once in a procedure, consider using non-temporal accesses. Such accesses are not burdened by the overhead of cache protocols.

3.10.6 Keep Common Operands in Registers

Keep frequently used values in registers rather than in memory. This avoids the comparatively long latencies for accessing memory.

3.10.7 Avoid True Dependencies

Spread out true dependencies (write-read or flow dependencies) to increase the opportunities for parallel execution. This spreading out is not necessary for anti-dependencies and output dependencies.

3.10.8 Avoid Store-to-Load Dependencies

Store-to-load dependencies occur when data is stored to memory, only to be read back shortly thereafter. Hardware implementations of the architecture may contain means of accelerating such store-to-load dependencies, allowing the load to obtain the store data before it has been written to memory. However, this acceleration might be available only when the addresses and operand sizes of the store and the dependent load are matched, and when both memory accesses are aligned. Performance is typically optimized by avoiding such dependencies altogether and keeping the data, including temporary variables, in registers.

3.10.9 Optimize Stack Allocation

When allocating space on the stack for local variables and/or outgoing parameters within a procedure, adjust the stack pointer and use moves rather than pushes. This method of allocation allows random access to the outgoing parameters, so that they can be set up when they are calculated instead of being held in a register or memory until the procedure call. This method also reduces stack-pointer dependencies.

3.10.10 Consider Repeat-Prefix Setup Time

The repeat instruction prefixes have a setup overhead. If the repeated count is variable, the overhead can sometimes be avoided by substituting a simple loop to move or store the data. Repeated string instructions can be expanded into equivalent sequences of inline loads and stores. For details, see “Repeat Prefixes” in Volume 3.

3.10.11 Replace GPR with Media Instructions

Some integer-based programs can be made to run faster by using 128-bit media or 64-bit media instructions. These instructions have their own register sets. Because of this, they relieve register pressure on the GPR registers. For loads, stores, adds, shifts, etc., media instructions may be good substitutes for general-purpose integer instructions. GPR registers are freed up, and the media instructions increase opportunities for parallel operations.

3.10.12 Organize Data in Memory Blocks

Organize frequently accessed constants and coefficients into cache-line-size blocks and prefetch them. Procedures that access data arranged in memory-bus-sized blocks, or memory-burst-sized blocks, can make optimum use of the available memory bandwidth.

4 Streaming SIMD Extensions Media and Scientific Programming

This chapter describes the programming model and instructions that make up the Streaming SIMD Extensions (SSE). SSE instructions perform integer and floating-point operations primarily on vector operands (a subset of the instructions take scalar operands) held in the YMM/XMM registers or loaded from memory. They can speed up certain types of procedures—typically high-performance media and scientific procedures—by substantial factors, depending on data element size and the regularity and locality of data accessed from memory.

4.1 Overview

Most of the SSE arithmetic instructions perform parallel operations on pairs of vectors. *Vector* operations are also called *packed* or *SIMD* (single-instruction, multiple-data) operations. They take vector operands consisting of multiple elements and all elements are operated on in parallel. Some SSE instructions operate on scalars instead of vectors.

4.1.1 Capabilities

The SSE instructions are designed to support media and scientific applications. Many physical and mathematical objects can be modeled as a set of numbers (elements) that quantify a fixed number of attributes related to that object. These elements are then aggregated together into what is called a vector. The SSE instructions allow applications to perform mathematical operations on vectors. In a vector instruction, each element of the one or more vector operands is operated upon in parallel using the same mathematical function. The elements can be integers (from bytes to octwords) or floating-point values (either single-precision or double-precision). Arithmetic operations produce signed, unsigned, and/or saturating results.

The availability of several types of vector move instructions and (in 64-bit mode) twice the number of YMM/XMM registers (a total of 16) can drastically reduce memory-access overhead, making a substantial difference in performance.

Types of Applications

Applications well-suited to the SSE programming model include a broad range of audio, video, and graphics programs. For example, music synthesis, speech synthesis, speech recognition, audio and video compression (encoding) and decompression (decoding), 2D and 3D graphics, streaming video (up to high-definition TV), and digital signal processing (DSP) kernels are all likely to experience higher performance using SSE instructions than using other types of instructions in AMD64 architecture.

Such applications commonly use small-sized integer or single-precision floating-point data elements in repetitive loops, in which the typical operations are inherently parallel. For example, 8-bit and 16-bit data elements are commonly used for pixel information in graphics applications, in which each of

the RGB pixel components (red, green, blue, and alpha) are represented by an 8-bit or 16-bit integer. 16-bit data elements are also commonly used for audio sampling.

The SSE instructions allow multiple data elements like these to be packed into 256-bit or 128-bit vector operands located in YMM/XMM registers or memory. The instructions operate in parallel on each of the elements in these vectors. For example, 32 elements of 8-bit data can be packed into a 256-bit vector operand, so that all 32 byte elements are operated on simultaneously, and in pairs of source operands, by a single instruction.

The SSE instructions also support a broad spectrum of scientific applications. For example, their ability to operate in parallel on double-precision floating-point vector elements makes them well-suited to computations like dense systems of linear equations, including matrix and vector-space operations with real and complex numbers. In professional CAD applications, for example, high-performance physical-modeling algorithms can be implemented to simulate processes such as heat transfer or fluid dynamics.

4.1.2 Origins

The SSE instruction set includes instructions originally introduced as the Streaming SIMD Extensions (Herein referred to as SSE1), and instructions added in subsequent extensions (SSE2, SSE3, SSSE3, SSE4.1, SSE4.2, SSE4A, AES, AVX, AVX2, CLMUL, FMA4, FMA, and XOP).

Collectively the SSE1, SSE2, SSE3, SSSE3, SSE4.1, SSE4.2, and SSE4A subsets are referred to as the *legacy* SSE instructions. All legacy SSE instructions support 128-bit vector operands. The *extended SSE* instructions include the AES, AVX, AVX2, CLMUL, FMA4, FMA, and XOP subsets. All extended SSE instructions provide support for 128-bit vector operands and most also support 256-bit operands.

Legacy SSE instructions support the specification of two vector operands, the AVX and AVX2 subsets support three, and AMD's FMA4 and XOP instruction sets support the specification of four 128-bit or 256-bit vector operands.

Each AVX instruction mirrors one of the legacy SSE instructions but presents different exception behavior. Most AVX instructions that operate on vector floating-point data types provide support for 256-bit vector widths. AVX2 adds support for 256-bit widths to most vector integer AVX instructions.

AVX, AVX2, FMA4, FMA, and XOP support the specification of a distinct destination register. This is called a non-destructive operation because none of the source operands is overwritten as a result of the execution of the instruction.

The assembler mnemonic for each AVX and AVX2 instruction is distinguished from the corresponding legacy form by prepending the letter *V* . In the discussion below, mnemonics for instructions which have both and a legacy SSE and an AVX form will be written (V)*mnemonic* (for example, (V)ADDPD). The mnemonics for the other extended SSE instructions also begin with the letter *V*.

4.1.3 Compatibility

The SSE instructions can be executed in any of the architecture's operating modes. Existing SSE binary programs run in legacy and compatibility modes without modification. The support provided by the AMD64 architecture for such binaries is identical to that provided by legacy x86 architectures.

To run in 64-bit mode, legacy SSE programs must be recompiled. The recompilation has no side effects on such programs, other than to provide access to the following additional resources:

- Eight additional YMM/XMM registers (for a total of 16).
- Eight additional general-purpose registers (for a total of 16 GPRs).
- Extended 64-bit width of all GPRs.
- 64-bit virtual address space.
- RIP-relative addressing mode.

The SSE instructions use data registers, a control and status register (MXCSR), rounding control, and an exception reporting and response mechanism that are distinct from and functionally independent of those used by the x87 floating-point instructions. Because of this, SSE programming support usually requires exception handlers that are distinct from those used for x87 exceptions. This support is provided by virtually all legacy operating systems for the x86 architecture.

4.2 Registers

The SSE programming model introduced the 128-bit XMM registers. In the extended SSE programming model these registers double in width to 256 bits and are designated YMM0–15. Rather than defining a separate array of registers, the extended SSE model overlays the YMM registers on the XMM registers, with each XMM register occupying the lower 128 bits of the corresponding YMM register. When referring to these registers in general, they are designated YMM/XMM0–15.

4.2.1 SSE Registers

The YMM/XMM registers are diagrammed in Figure 4-1 below. Most SSE instructions read operands from these registers or memory and store results in these registers. Operation of the SSE instructions is supported by the Media eXtension Control and Status Register (MXCSR) described below. A few SSE instructions—those that perform data conversion or move operations—can have operands located in MMX registers or general-purpose registers (GPRs).

Sixteen 256-bit YMM data registers, YMM0–YMM15, support the 256-bit media instructions. Sixteen 128-bit XMM data registers, XMM0–XMM15, support the 128-bit media instructions. They can hold operands for both vector and scalar operations utilizing the 128-bit and 256-bit integer and floating-point data types. The high eight YMM/XMM registers, YMM/XMM8–15, are available to software running in 64-bit mode for instructions that use a REX, VEX, or XOP prefix. For a discussion of the REX prefix, see "REX Prefixes" on page 79. For a discussion of VEX and XOP, see "VEX and XOP Prefixes" on page 79).

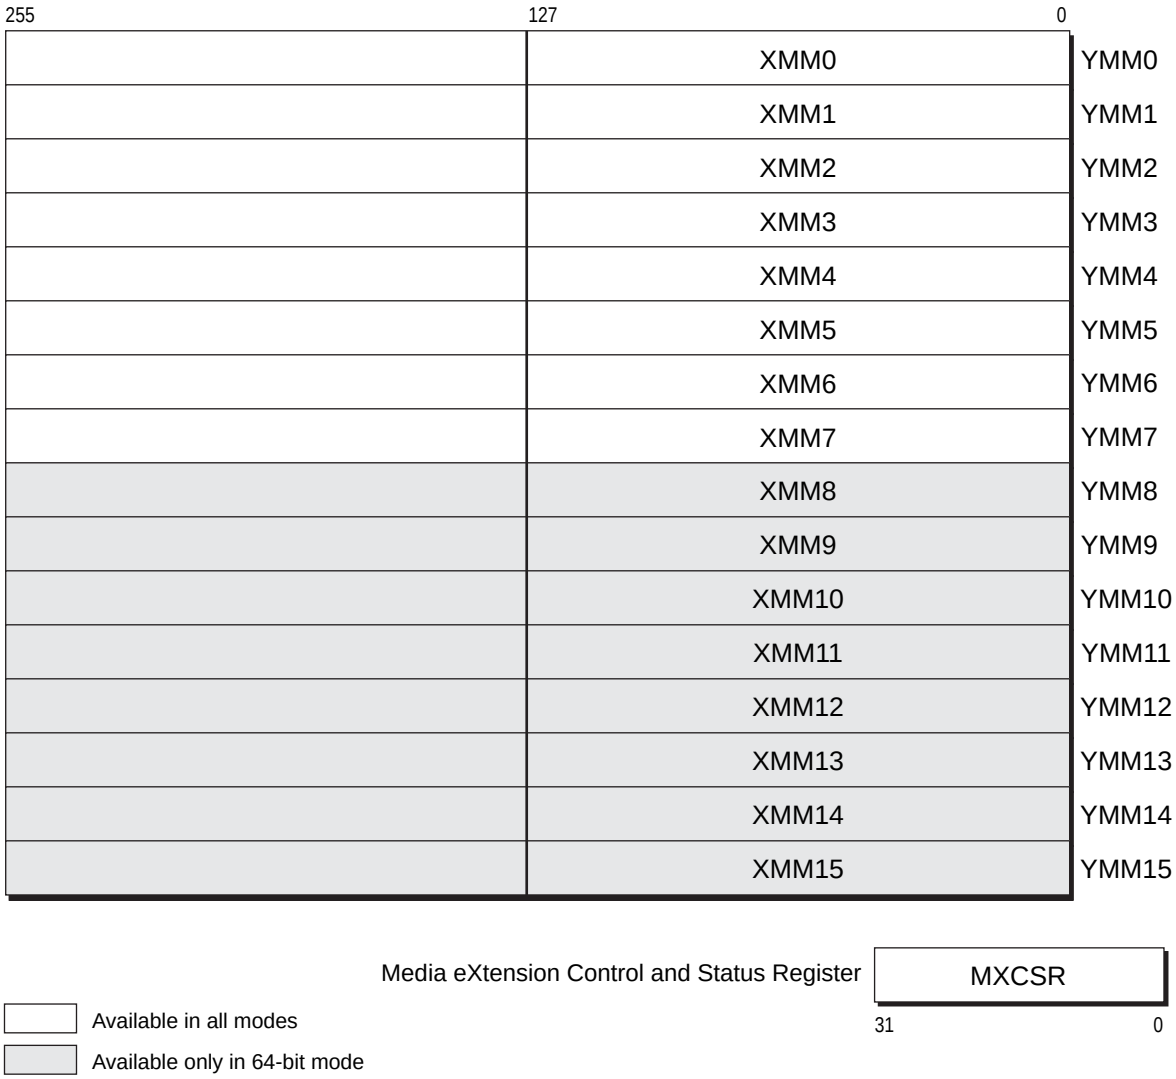

Figure 4-1. SSE Registers

Upon power-on reset, all 16 YMM/XMM registers are cleared to +0.0. However, initialization by means of the #INIT external input signal does not change the state of the YMM/XMM registers.

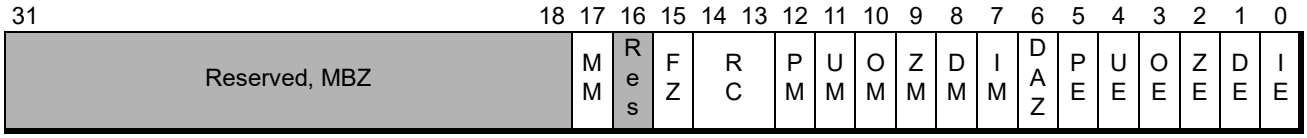
Handling of Upper Octword

128-bit media instructions read source operands from and write results to XMM registers, while the 256-bit media instructions use the 256-bit YMM registers. This raises the question—what is the disposition of the upper octword of a YMM register when the result of a 128-bit media instruction is written into the lower octword (the XMM register)? The answer differs depending on whether the instruction is a legacy SSE instruction or an extended SSE instruction. When a legacy SSE instruction writes a 128-bit result to an XMM register, the upper octword of the corresponding YMM register

remains unchanged. However, when the 128-bit form of an extended SSE instruction writes its result, the upper octword of the YMM register is cleared.

4.2.2 MXCSR Register

Figure 4-2 below shows a detailed view of the Media eXtension Control and Status Register (MXCSR). All defined fields in this register are read/write. The fields within the MXCSR apply only to operations performed by 256-bit and 128-bit media instructions. Software can load the register from memory using the XRSTOR, XRSTORS, FXRSTOR or LDMXCSR instructions, and it can store the register to memory using the XSAVE, XSAVEOPT, XSAVEC, XSAVES, FXSAVE or STMXCSR instructions.



Bits	Mnemonic	Description	Reset Bit-Value
31:18	–	Reserved, MBZ	
17	MM	Misaligned Exception Mask	0
16	–	Reserved, MBZ	
15	FZ	Flush-to-Zero for Masked Underflow	0
14:13	RC	Floating-Point Rounding Control	00
		Exception Masks	
12	PM	Precision Exception Mask	1
11	UM	Underflow Exception Mask	1
10	OM	Overflow Exception Mask	1
9	ZM	Zero-Divide Exception Mask	1
8	DM	Denormalized-Operand Exception Mask	1
7	IM	Invalid-Operation Exception Mask	1
6	DAZ	Denormals Are Zeros	0
		Exception Flags	
5	PE	Precision Exception	0
4	UE	Underflow Exception	0
3	OE	Overflow Exception	0
2	ZE	Zero-Divide Exception	0
1	DE	Denormalized-Operand Exception	0
0	IE	Invalid-Operation Exception	0

Figure 4-2. Media eXtension Control and Status Register (MXCSR)

On power-on reset, all bits are initialized to the values indicated above. However, initialization by means of the #INIT external input signal does not change the state of the MXCSR.

The six exception flags (IE, DE, ZE, OE, UE, PE) are sticky bits. (Once set by the processor, such a bit remains set until software clears it.) For details about the causes of SIMD floating-point exceptions

indicated by bits 5:0, see "SIMD Floating-Point Exception Causes" on page 220. For details about the masking of these exceptions, see "SIMD Floating-Point Exception Masking" on page 226.

Invalid-Operation Exception (IE). Bit 0. The processor sets this bit to 1 when an invalid-operation exception occurs. These exceptions are caused by many types of errors, such as an invalid operand.

Denormalized-Operand Exception (DE). Bit 1. The processor sets this bit to 1 when one of the source operands of an instruction is in denormalized form, except that if software has set the denormals are zeros (DAZ) bit, the processor does not set the DE bit. (See "Denormalized (Tiny) Numbers" on page 125.)

Zero-Divide Exception (ZE). Bit 2. The processor sets this bit to 1 when a non-zero number is divided by zero.

Overflow Exception (OE). Bit 3. The processor sets this bit to 1 when the absolute value of a rounded result is larger than the largest representable normalized floating-point number for the destination format. (See "Normalized Numbers" on page 125.)

Underflow Exception (UE). Bit 4. The processor sets this bit to 1 when the absolute value of a rounded non-zero result is too small to be represented as a normalized floating-point number for the destination format. (See "Normalized Numbers" on page 125.)

When masked by the UM bit, the processor reports a UE exception only if the UE occurs *together with* a precision exception (PE). Also, see bit 15, the flush-to-zero (FZ) bit.

Precision Exception (PE). Bit 5. The processor sets this bit to 1 when a floating-point result, after rounding, differs from the infinitely precise result and thus cannot be represented exactly in the specified destination format. The PE exception is also called the *inexact-result* exception.

Denormals Are Zeros (DAZ). Bit 6. Software can set this bit to 1 to enable the DAZ mode, if the hardware implementation supports this mode. In the DAZ mode, when the processor encounters source operands in the denormalized format it converts them to signed zero values, with the sign of the denormalized source operand, before operating on them, and the processor does not set the denormalized-operand exception (DE) bit, regardless of whether such exceptions are masked or unmasked. DAZ mode does not comply with the *IEEE Standard for Binary Floating-Point Arithmetic* (ANSI/IEEE Std 754).

Support for the DAZ bit is indicated by the MXCSR_MASK field in the FXSAVE memory save area or the low 512 bytes of the XSAVE extended save area. See "Saving Media and x87 State" in Volume 2.

Exception Masks (PM, UM, OM, ZM, DM, IM). Bits 12:7. Software can set these bits to mask, or clear this bits to unmask, the corresponding six types of SIMD floating-point exceptions (PE, UE, OE, ZE, DE, IE). A bit masks its exception type when set to 1, and unmasks it when cleared to 0.

In general, masking a type of exception causes the processor to handle all subsequent instances of the exception type in a default way (the UE exception has an unusual behavior). Unmasking the exception

type causes the processor to branch to the SIMD floating-point exception service routine when an exception occurs. For details about the processor's responses to masked and unmasked exceptions, see "SIMD Floating-Point Exception Masking" on page 226.

Floating-Point Rounding Control (RC). Bits 14:13. Software uses these bits to specify the rounding method for SSE floating-point operations. The choices are:

- 00 = round to nearest (default)
- 01 = round down
- 10 = round up
- 11 = round toward zero

For details, see "Floating-Point Rounding" on page 129.

Flush-to-Zero (FZ). Bit 15. If the rounded result is tiny and the underflow mask is set, the FTZ bit causes the result to be flushed to zero. This naturally causes the result to be inexact, which causes both PE and UE to be set. The sign returned with the zero is the sign of the true result. The FTZ bit does not have any effect if the underflow mask is 0.

This response does not comply with the IEEE 754 standard, but it may offer higher performance than can be achieved by responding to an underflow in this circumstance. The FZ bit is only effective if the UM bit is set to 1. If the UM bit is cleared to 0, the FZ bit is ignored. For details, see Table 4-16 on page 227.

Misaligned Exception Mask (MM). Bit 17. This bit is applicable to processors that support Misaligned SSE Mode. For these processors, MM controls the exception behavior triggered by an attempt to access a misaligned vector memory operand. If the misaligned exception mask (MM) is set to 1, an attempt to access a non-aligned vector memory operand does not cause a #GP exception, but is instead subject to alignment checking. When MM is set and alignment checking is enabled, a #AC exception is generated, if the memory operand is not aligned. When MM is set and alignment checking is not enabled, no exception is triggered by accessing a non-aligned vector operand.

Support for Misaligned SSE Mode is indicated by CPUID Fn8000_0001_ECX[MisAlignSse] = 1. For details on alignment requirements, see "Data Alignment" on page 120.

The corresponding MXCSR_MASK bit (17) is 1, regardless of whether MM is set or not. For details on MXCSR and MXCSR_MASK, see "SSE, MMX, and x87 Programming" in Volume 2 of this manual.

4.2.3 Other Data Registers

Some SSE instructions that perform data transfer, data conversion or data reordering operations ("Data Transfer" on page 150, "Data Conversion" on page 155, and "Data Reordering" on page 157) can access operands in the MMX or general-purpose registers (GPRs). When addressing GPRs registers in 64-bit mode, the REX instruction prefix can be used to access the extended GPRs, as described in "REX Prefixes" on page 79.

For a description of the GPR registers, see “Registers” on page 23. For a description of the MMX registers, see “MMX™ Registers” on page 246.

4.2.4 Effect on rFLAGS Register

The execution of most SSE instructions have no effect on the rFLAGS register. However, some SSE instructions, such as COMISS and PTEST, do write flag bits based on the results of a comparison. For a description of the rFLAGS register, see “Flags Register” on page 34.

4.3 Operands

Operands for most SSE instructions are held in the YMM/XMM registers, sourced from memory, or encoded in the instruction as an immediate value. Instructions operate on two distinct operand widths — either 256 bits or 128 bits. 256-bit operands may be held in one or more of the YMM registers. 128-bit operands may be held in one or more of the XMM registers. As shown in Figure 4-1 on page 114, the 128-bit XMM registers overlay the lower octword of the 256-bit YMM registers. The data types of these operands include scalar integers, integer vectors, and scalar and floating-point vectors.

4.3.1 Operand Addressing

Depending on the instruction, referenced operands may be in registers or memory.

4.3.1.1 Register Operands

Most SSE instructions can access source and destination operands in YMM or XMM registers. A few of these instructions access the MMX registers, GPR registers, rFLAGS register, or MXCSR register. The type of register addressed is specified in the instruction syntax. When addressing a GPR or YMM/XMM register, the REX instruction prefix can be used to access the eight additional GPR or YMM/XMM registers, as described in “Instruction Prefixes” on page 217. Instructions encoded with the VEX/XOP prefix can utilize an immediate byte to provide the specification of additional operands.

4.3.1.2 Memory Operands

Most SSE instructions can read memory for source operands, and some of the instructions can write results to memory. Figure 4-3 below illustrates how a vector operand is stored in memory relative to its arrangement in an SSE register.

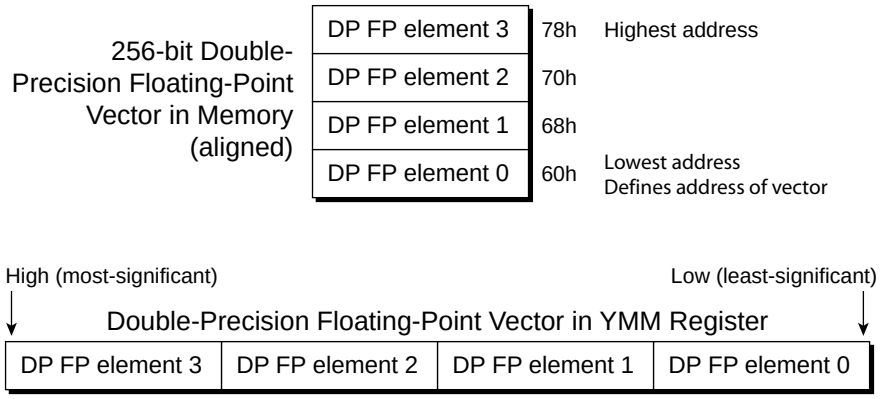


Figure 4-3. Vector (Packed) Data in Memory

This specific example shows a 256-bit double-precision floating-point vector.

This particular data type is composed of four 64-bit double-precision floating-point values (abbreviated “DP FP”, in the figure) packed into 256 bits. The four values comprise the four elements of the vector. Elements are numbered right to left. Element 0 is defined to occupy the least significant (right-most) position. Element 1 is in the next most significant position and 2 the next. Element 3 occupies the most significant (left-most) position. When held in a YMM register the elements are laid out as shown in the figure.

When stored in memory, element 0 is stored at the lowest address (60h in this example). Element 1 is stored at that address incremented by the element size in bytes (each double-precision floating-point value is 8 bytes long). Element 2 is located at the initial address plus 16 (10h) and element 3 is stored at the initial address plus 24 (18h). Each element is stored based on the rules for the fundament data type of the element (double-precision floating-point in this example). See Section 4.3.3.3 “Floating-Point Data Types” on page 123 for details on how double-precision floating-point values are represented in registers and memory.

The address of a vector is the same as the address of element 0 (60h in this example). This vector is said to be *naturally aligned* (or, simply, *aligned*) because it is located at an address that is an integer multiple of its size in bytes (32, in this case). Alignment of vector operands is not required. See “Data Alignment” below.

Other vector data types are stored in memory in an analogous fashion with the lowest indexed element placed at the lowest address.

4.3.1.3 Immediate Operands

Immediate operands are used in certain data-conversion, vector-shift, and vector-compare instructions. Such instructions take 8-bit immediates, which provide control for the operation.

4.3.1.4 I/O Ports

I/O ports in the I/O address space cannot be directly addressed by SSE instructions, and although memory-mapped I/O ports can be addressed by such instructions, doing so may produce unpredictable results, depending on the hardware implementation of the architecture.

4.3.2 Data Alignment

Generally, legacy SSE instructions that attempt to access a vector operand in memory that is not naturally aligned trigger a general-protection exception (#GP).

AMD processors that support Misaligned SSE Mode may be programmed to disable this exception behavior for legacy load/execute SSE instructions. For these processors, exception behavior on misaligned memory access for vector operands of load/execute instructions is controlled by the MXCSR.MM bit. If MM is not set, the default behavior occurs (a #GP results).

If MXCSR.MM is set, the #GP is inhibited and the exception behavior depends on the alignment checking mechanism. If alignment checking is enabled (CR0.AM = 1 and rFLAGS.AC = 1), a misaligned memory access to a vector operand will trigger an #AC exception. On the other hand, if alignment checking is disabled, no exception will be triggered.

Support for Misaligned SSE Mode is indicated by CPUID Fn8000_0001_ECX[MisAlignSse] = 1. For information on using the CPUID instruction to determine support for Misaligned SSE Mode, see the description of the CPUID instruction in Volume 3 and the definition of the MisAlignSse feature flag in Appendix E of Volume 3.

The FXSAVE, FXRSTOR, (V)MOVAPD, (V)MOVAPS, and (V)MOVDQA, (V)MOVNTDQ, (V)MOVNTPD and (V)MOVNTPS instructions do *not* support misaligned accesses. These instructions always generate an exception when attempting to access misaligned data. See individual instruction listings for specific alignment requirements.

Legacy SSE instructions that manipulate scalar operands never trigger a #GP due to data misalignment, nor do any of the following instructions:

- LDDQU—Load Unaligned Double Quadword
- MASKMOVDQU—Masked Move Double Quadword Unaligned.
- MOVDQU—Move Unaligned Double Quadword.
- MOVUPD—Move Unaligned Packed Double-Precision Floating-Point.
- MOVUPS—Move Unaligned Packed Single-Precision Floating-Point.
- PCMPESTRI—Packed Compare Explicit Length Strings Return Index
- PCMPESTRM—Packed Compare Explicit Length Strings Return Mask
- PCMPISTRI—Packed Compare Implicit Length Strings Return Index
- PCMPISTRM—Packed Compare Implicit Length Strings Return Mask

For extended SSE instructions, the MXCSR.MM bit does not control exception behavior. Only those extended SSE instructions that explicitly require aligned memory operands (VMOVAPS/PD, VMOVDQA, VMOVNTPS/PD, and VMOVNTDQ) will result in a general protection exception (#GP) when attempting to access unaligned memory operands.

For all other extended SSE instructions, unaligned memory accesses do not result in a #GP. However, software can enable alignment checking, where misaligned memory accesses cause an #AC exception, by the means specified above.

While the architecture does not impose data-alignment requirements for SSE instructions (except for those that explicitly demand it), the consequence of storing operands at unaligned locations is that accesses to those operands may require more processor and bus cycles than for aligned accesses. See “Data Alignment” on page 43 for details.

4.3.3 SSE Instruction Data Types

Most SSE instructions operate on packed (also called vector) data. These data types are aggregations of the fundamental data types—signed and unsigned integers and single- and double-precision floating-point numbers. The following sections describe the encoding and characteristics of these data types.

4.3.3.1 Integer Data Types

The architecture defines signed and unsigned integers in sizes from 8 to 128 bits. The characteristics of these data types are described below.

Sign. The sign bit is the most-significant bit—bit 7 for a byte, bit 15 for a word, bit 31 for a doubleword, bit 63 for a quadword, or bit 127 for a double quadword. Arithmetic instructions that are not specifically named as unsigned perform signed two’s-complement arithmetic.

Range of Representable Values. Table 4-1 below shows the range of representable values for the integer data types.

Table 4-1. Range of Values of Integer Data Types

Data-Type Interpretation		Byte	Word	Doubleword	Quadword	Double Quadword
Unsigned integers	Base-2 (exact)	0 to $+2^8-1$	0 to $+2^{16}-1$	0 to $+2^{32}-1$	0 to $+2^{64}-1$	0 to $+2^{128}-1$
	Base-10 (approx.)	0 to 255	0 to 65,535	0 to $4.29 * 10^9$	0 to $1.84 * 10^{19}$	0 to $3.40 * 10^{38}$
Signed integers[1]	Base-2 (exact)	-2^7 to $+(2^7-1)$	-2^{15} to $+(2^{15}-1)$	-2^{31} to $+(2^{31}-1)$	-2^{63} to $+(2^{63}-1)$	-2^{127} to $+(2^{127}-1)$
	Base-10 (approx.)	-128 to +127	-32,768 to +32,767	$-2.14 * 10^9$ to $+2.14 * 10^9$	$-9.22 * 10^{18}$ to $+9.22 * 10^{18}$	$-1.70 * 10^{38}$ to $+1.70 * 10^{38}$

Note:
1. *The sign bit is the most-significant bit (bit 7 for a byte, bit 15 for a word, bit 31 for doubleword, bit 63 for quadword, bit 127 for double quadword.).*

Saturation. Saturating (also called limiting or clamping) instructions limit the value of a result to the maximum or minimum value representable by the applicable data type. Saturating versions of integer vector-arithmetic instructions operate on byte-sized and word-sized elements. These instructions—for example, (V)PACKx, (V)PADDSx, (V)PADDUSx, (V)PSUBSx, and (V)PSUBUSx—saturate signed or unsigned data at the vector-element level when the element reaches its maximum or minimum representable value. Saturation avoids overflow or underflow errors. Many of the integer multiply and accumulate instructions saturate the cumulative results of the multiplication and addition (accumulation) operations before writing the final results to the destination (accumulator) register.

Note, however, that not all multiply and accumulate instructions saturate results.

The examples in Table 4-2 below illustrate saturating and non-saturating results with word operands. Saturation for other data-type sizes follows similar rules. Once saturated, the saturated value is treated like any other value of its type. For example, if 0001h is subtracted from the saturated value, 7FFFh, the result is 7FFEh.

Table 4-2. Saturation Examples

Operation	Non-Saturated Infinitely Precise Result	Saturated Signed Result	Saturated Unsigned Result
7000h + 2000h	9000h	7FFFh	9000h
7000h + 7000h	E000h	7FFFh	E000h
F000h + F000h	1E000h	E000h	FFFFh
9000h + 9000h	12000h	8000h	FFFFh
7FFFh + 0100h	80FFh	7FFFh	80FFh
7FFFh + FF00h	17EFFh	7EFFh	FFFFh

Arithmetic instructions not specifically designated as saturating perform non-saturating, twos-complement arithmetic.

4.3.3.2 Other Fixed-Point Operands

The architecture provides specific support only for integer fixed-point operands—those in which an implied binary point is always located to the right of bit 0. Nevertheless, software may use fixed-point operands in which the implied binary point is located in any position. In such cases, software is responsible for managing the interpretation of such implied binary points, as well as any redundant sign bits that may occur during multiplication.

4.3.3.3 Floating-Point Data Types

The floating-point data types, shown in Figure 4-4 below, include 32-bit single precision and 64-bit double precision. Both formats are fully compatible with the *IEEE Standard for Binary Floating-Point Arithmetic* (ANSI/IEEE Std 754). The SSE instructions operate internally on floating-point data types in the precision specified by each instruction.

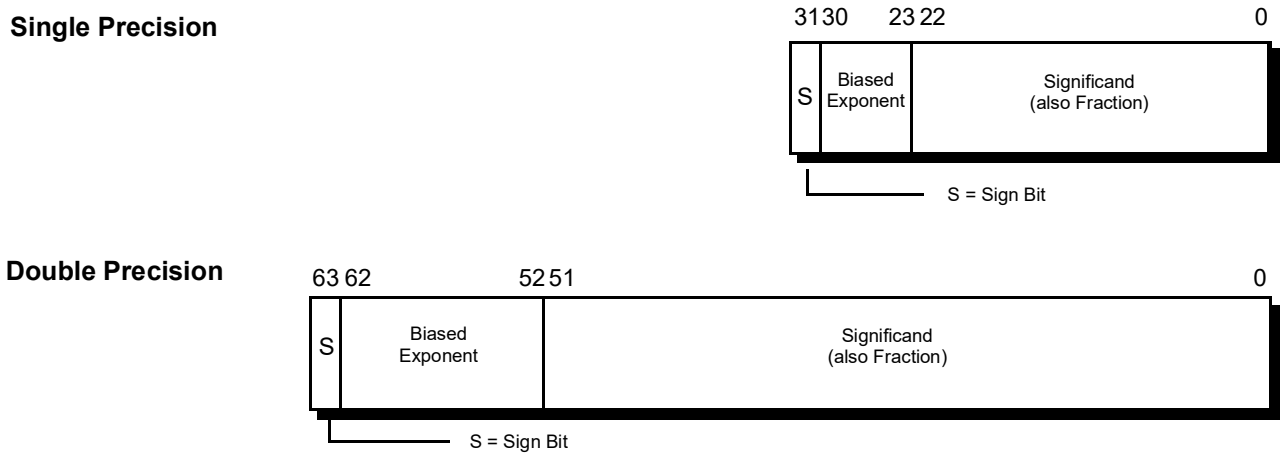

Figure 4-4. Floating-Point Data Types

Both of the floating-point data types consist of a sign (0 = positive, 1 = negative), a biased exponent (base-2), and a significand, which represents the integer and fractional parts of the number. The integer bit (also called the *J bit)* is implied (called a *hidden integer bit*). The value of an implied integer bit can be inferred from number encodings, as described in Section "Floating-Point Number Encodings" on page 127. The bias of the exponent is a constant that makes the exponent always positive and allows reciprocation, without overflow, of the smallest normalized number representable by that data type.

Specifically, the data types are formatted as follows:

- *Single-Precision Format*—This format includes a 1-bit sign, an 8-bit biased exponent whose value is 127, and a 23-bit significand. The integer bit is implied, making a total of 24 bits in the significand.
- *Double-Precision Format*—This format includes a 1-bit sign, an 11-bit biased exponent whose value is 1023, and a 52-bit significand. The integer bit is implied, making a total of 53 bits in the significand.

Table 4-3 shows the range of finite values representable by the two floating-point data types.

Table 4-3. Range of Values in Normalized Floating-Point Data Types

Data Type	Range of Normalized[1] Values	
	Base 2 (exact)	Base 10 (approximate)
Single Precision	2^{-126} to $2^{127} * (2 - 2^{-23})$	$1.17 * 10^{-38}$ to $+3.40 * 10^{38}$
Double Precision	2^{-1022} to $2^{1023} * (2 - 2^{-52})$	$2.23 * 10^{-308}$ to $+1.79 * 10^{308}$

Note:
1. See "Normalized Numbers" on page 125 for a definition of "normalized".

For example, in the single-precision format, the largest normal number representable has an exponent of FEh and a significand of 7FFFFFh, with a numerical value of $2^{127} * (2 - 2^{-23})$. Results that overflow above the maximum representable value return either the maximum representable normalized number (see "Normalized Numbers" on page 125) or infinity, with the sign of the true result, depending on the rounding mode specified in the rounding control (RC) field of the MXCSR register. Results that underflow below the minimum representable value return either the minimum representable normalized number or a denormalized number (see "Denormalized (Tiny) Numbers" on page 125), with the sign of the true result, or a result determined by the SIMD floating-point exception handler, depending on the rounding mode and the underflow-exception mask (UM) in the MXCSR register (see "Unmasked Responses" on page 229).

Compatibility with x87 Floating-Point Data Types

The results produced by SSE floating-point instructions comply fully with the *IEEE Standard for Binary Floating-Point Arithmetic* (ANSI/IEEE Std 754), because these instructions represent data in the single-precision or double-precision data types throughout their operations. The x87 floating-point instructions, however, by default perform operations in the double-extended-precision format. Because of this, x87 instructions operating on the same source operands as SSE floating-point instructions may return results that are slightly different in their least-significant bits.

Floating-Point Number Types

A SSE floating-point value can be one of five types, as follows:

- Normal
- Denormal (Tiny)
- Zero

- Infinity
- Not a Number (NaN)

In common engineering and scientific usage, floating-point numbers—also called *real numbers*—are represented in base (radix) 10. A non-zero number consists of a *sign*, a normalized *significand*, and a signed *exponent*, as in:

```
+2.71828 e0
```

Both large and small numbers are representable in this notation, subject to the limits of data-type precision. For example, a million in base-10 notation appears as +1.00000 e6 and -0.0000383 is represented as -3.83000 e-5. A non-zero number can always be written in *normalized form*—that is, with a leading non-zero digit immediately before the decimal point. Thus, a normalized significand in base-10 notation is a number in the range [1,10). The signed exponent specifies the number of positions that the decimal point is shifted.

Unlike the common engineering and scientific usage described above, SSE floating-point numbers are represented in base (radix) 2. Like its base-10 counterpart, a normalized base-2 significand is written with its leading non-zero digit immediately to the left of the radix point. In base-2 arithmetic, a non-zero digit is always a one, so the range of a binary significand is [1,2):

```
+1.fraction ±exponent
```

The leading non-zero digit is called the *integer bit*. As shown in Figure 4-4 on page 123, the integer bit is omitted (and called the *hidden integer bit)* in the single-precision and the double-precision floating-point formats, because its implied value is always 1 in a normalized significand (0 in a denormalized significand), and the omission allows an extra bit of precision.

Floating-Point Representations

The following sections describe the number representations.

Normalized Numbers. Normalized floating-point numbers are the most frequent operands for SSE instructions. These are finite, non-zero, positive or negative numbers in which the integer bit is 1, the biased exponent is non-zero and non-maximum, and the fraction is any representable value. Thus, the significand is within the range of [1, 2). Whenever possible, the processor represents a floating-point result as a normalized number.

Denormalized (Tiny) Numbers. Denormalized numbers (also called *tiny* numbers) are smaller than the smallest representable normalized numbers. They arise through an underflow condition, when the exponent of a result lies below the representable minimum exponent. These are finite, non-zero, positive or negative numbers in which the integer bit is 0, the biased exponent is 0, and the fraction is non-zero.

The processor generates a denormalized-operand exception (DE) when an instruction uses a denormalized *source operand*. The processor may generate an underflow exception (UE) when an instruction produces a rounded, non-zero *result* that is too small to be represented as a normalized floating-point number in the destination format, and thus is represented as a denormalized number. If a

result, after rounding, is too small to be represented as the minimum denormalized number, it is represented as zero. (See “Exceptions” on page 218 for specific details.)

Denormalization may correct the exponent by placing leading zeros in the significand. This may cause a loss of precision, because the number of significant bits in the fraction is reduced by the leading zeros. In the single-precision floating-point format, for example, normalized numbers have biased exponents ranging from 1 to 254 (the unbiased exponent range is from –126 to +127). A true result with an exponent of, say, –130, undergoes denormalization by right-shifting the significand by the difference between the normalized exponent and the minimum exponent, as shown in Table 4-4 below.

Table 4-4. Example of Denormalization

Significand (base 2)	Exponent	Result Type
1.0011010000000000	–130	True result
0.0001001101000000	–126	Denormalized result

Zero. The floating-point zero is a finite, positive or negative number in which the integer bit is 0, the biased exponent is 0, and the fraction is 0. The sign of a zero result depends on the operation being performed and the selected rounding mode. It may indicate the direction from which an underflow occurred, or it may reflect the result of a division by +∞ or –∞.

Infinity. Infinity is a positive or negative number, +∞ and –∞, in which the integer bit is 1, the biased exponent is maximum, and the fraction is 0. The infinities are the maximum numbers that can be represented in floating-point format. Negative infinity is less than any finite number and positive infinity is greater than any finite number (i.e., the affine sense).

An infinite result is produced when a non-zero, non-infinite number is divided by 0 or multiplied by infinity, or when infinity is added to infinity or to 0. Arithmetic on infinities is exact. For example, adding any floating-point number to +∞ gives a result of +∞. Arithmetic comparisons work correctly on infinities. Exceptions occur only when the use of an infinity as a source operand constitutes an invalid operation.

Not a Number (NaN). NaNs are non-numbers, lying outside the range of representable floating-point values. The integer bit is 1, the biased exponent is maximum, and the fraction is non-zero. NaNs are of two types:

- *Signaling NaN (SNaN)*
- *Quiet NaN (QNaN)*

A QNaN is a NaN with the most-significant fraction bit set to 1, and an SNaN is a NaN with the most-significant fraction bit cleared to 0. When the processor encounters an SNaN as a source operand for an instruction, an invalid-operation exception (IE) occurs and a QNaN is produced as the result, if the exception is masked. In general, when the processor encounters a QNaN as a source operand for an instruction, the processor does not generate an exception but generates a QNaN as the result.

The processor never generates an SNaN as a result of a floating-point operation. When an invalid-operation exception (IE) occurs due to an SNaN operand, the invalid-operation exception mask (IM) bit determines the processor's response, as described in "SIMD Floating-Point Exception Masking" on page 226.

When a floating-point operation or exception produces a QNaN result, its value is determined by the rules in Table 4-5 below.

Table 4-5. NaN Results

Source Operands (in either order)		NaN Result[1]
QNaN	Any non-NaN floating-point value, or single-operand instructions	Value of QNaN
SNaN	Any non-NaN floating-point value, or single-operand instructions	Value of SNaN converted to a QNaN[2]
QNaN	QNaN	Value of operand 1
QNaN	SNaN	
SNaN	QNaN	Value of operand 1 converted to a QNaN, if necessary[2]
SNaN	SNaN	
Invalid-Operation Exception (IE) occurs without QNaN or SNaN source operands		Floating-point indefinite value[3] (a special form of QNaN)

Note:
1. *The NaN result is produced when the floating-point invalid-operation exception is masked.*
2. *The conversion is done by changing the most-significant fraction bit to 1.*
3. *See "Indefinite Values" on page 128.*

Floating-Point Number Encodings

Supported Encodings. Table 4-6 below shows the floating-point encodings of supported numbers and non-numbers. The number categories are ordered from large to small. In this affine ordering, positive infinity is larger than any positive normalized number, which in turn is larger than any positive denormalized number, which is larger than positive zero, and so forth. Thus, the ordinary rules of comparison apply between categories as well as within categories, so that comparison of any two numbers is well-defined.

The actual exponent field length is 8 or 11 bits, and the fraction field length is 23 or 52 bits, depending on operand precision. The single-precision and double-precision formats do not include the integer bit in the significand (the value of the integer bit can be inferred from number encodings). Exponents of both types are encoded in biased format, with respective biasing constants of 127 and 1023.

Table 4-6. Supported Floating-Point Encodings

Classification		Sign	Biased Exponent[1]	Significand[2]
Positive Non-Numbers	SNaN	0	111 ... 111	1.011 ... 111 to 1.000 ... 001
	QNaN	0	111 ... 111	1.111 ... 111 to 1.100 ... 000
Positive Floating-Point Numbers	Positive Infinity (+∞)	0	111 ... 111	1.000 ... 000
	Positive Normal	0	111 ... 110 to 000 ... 001	1.111 ... 111 to 1.000 ... 000
	Positive Denormal	0	000 ... 000	0.111 ... 111 to 0.000 ... 001
	Positive Zero	0	000 ... 000	0.000 ... 000
Negative Floating-Point Numbers	Negative Zero	1	000 ... 000	0.000 ... 000
	Negative Denormal	1	000 ... 000	0.000 ... 001 to 0.111 ... 111
	Negative Normal	1	000 ... 001 to 111 ... 110	1.000 ... 000 to 1.111 ... 111
	Negative Infinity (–∞)	1	111 ... 111	1.000 ... 000
Negative Non-Numbers	SNaN	1	111 ... 111	1.000 ... 001 to 1.011 ... 111
	QNaN[3]	1	111 ... 111	1.100 ... 000 to 1.111 ... 111

Note:

1. *The actual exponent field length is 8 or 11 bits, depending on operand precision.*
2. *The "1." and "0." prefixes represent the implicit integer bit. The actual fraction field length is 23 or 52 bits, depending on operand precision.*
3. *The floating-point indefinite value is a QNaN with a negative sign and a significand whose value is 1.100 ... 000.*

Indefinite Values. Floating-point and integer data type each have a unique encoding that represents an *indefinite value*. The processor returns an indefinite value when a masked invalid-operation exception (IE) occurs.

For example, if a floating-point division operation is attempted using source operands that are both zero, and IE exceptions are masked, the floating-point indefinite value is returned as the result. Or, if a

floating-point-to-integer data conversion overflows its destination integer data type, and IE exceptions are masked, the integer indefinite value is returned as the result.

Table 4-7 shows the encodings of the indefinite values for each data type. For floating-point numbers, the indefinite value is a special form of QNaN. For integers, the indefinite value is the largest representable negative twos-complement number, 80...00h. (This value is the largest representable negative number, except when a masked IE exception occurs, in which case it is generated as the indefinite value.)

Table 4-7. Indefinite-Value Encodings

Data Type	Indefinite Encoding
Single-Precision Floating-Point	FFC0_0000h
Double-Precision Floating-Point	FFF8_0000_0000_0000h
16-Bit Integer	8000h
32-Bit Integer	8000_0000h
64-Bit Integer	8000_0000_0000_0000h

Floating-Point Rounding

The floating-point rounding control (RC) field comprises bits [14:13] of the MXCSR. This field which specifies how the results of floating-point computations are rounded. Rounding modes apply to most arithmetic operations. When rounding occurs, the processor generates a precision exception (PE). Rounding is not applied to operations that produce NaN results.

The IEEE 754 standard defines the four rounding modes as shown in Table 4-8 below.

Table 4-8. Types of Rounding

RC Value	Mode	Type of Rounding
00 (default)	Round to nearest	The rounded result is the representable value closest to the infinitely precise result. If equally close, the even value (with least-significant bit 0) is taken.
01	Round down	The rounded result is closest to, but no greater than, the infinitely precise result.
10	Round up	The rounded result is closest to, but no less than, the infinitely precise result.
11	Round toward zero	The rounded result is closest to, but no greater in absolute value than, the infinitely precise result.

Round to nearest is the default rounding mode. It provides a statistically unbiased estimate of the true result, and is suitable for most applications. The other rounding modes are directed roundings: round up (toward +∞), round down (toward –∞), and round toward zero. Round up and round down are used in interval arithmetic, in which upper and lower bounds bracket the true result of a computation. Round toward zero takes the smaller in magnitude, that is, always truncates.

The processor produces a floating-point result defined by the IEEE standard to be infinitely precise. This result may not be representable exactly in the destination format, because only a subset of the continuum of real numbers finds exact representation in any particular floating-point format. Rounding modifies such a result to conform to the destination format, thereby making the result inexact and also generating a precision exception (PE), as described in “SIMD Floating-Point Exception Causes” on page 220.

Suppose, for example, the following 24-bit result is to be represented in single-precision format, where “E_2 1010” represents the biased exponent:

$$1.0011\ 0101\ 0000\ 0001\ 0010\ 0111\ E_2\ 1010$$

This result has no exact representation, because the least-significant 1 does not fit into the single-precision format, which allows for only 23 bits of fraction. The rounding control field determines the direction of rounding. Rounding introduces an error in a result that is less than one *unit in the last place (ulp)*, that is, the least-significant bit position of the floating-point representation.

Half-Precision Floating-Point Data Type

The architecture supports a half-precision floating-point data type. This representation requires only 16 bits and is used primarily to save space when floating-point values are stored in memory. One instruction converts packed half-precision floating-point numbers loaded from memory to packed single-precision floating-point numbers and another converts packed single-precision numbers in a YMM/XMM register to packed half-precision numbers in preparation for storage. See Section 4.7.2.5 “Half-Precision Floating-Point Conversion” on page 193 for more information on these instructions.

The 16-bit floating-point data type, shown in Figure 4-5, includes a 1-bit sign, a 5-bit exponent with a bias of 15 and a 10-bit significand. The integer bit is implied, making a total of 11 bits in the significand. The value of the integer bit can be inferred from the number encoding. Table 4-9 on page 131 shows the floating-point encodings of supported numbers and non-numbers.

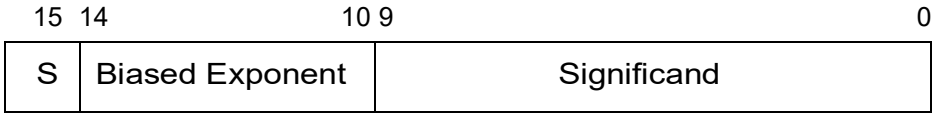

Figure 4-5. 16-Bit Floating-Point Data Type

Table 4-9. Supported 16-Bit Floating-Point Encodings

Sign	Bias Exponent	Significand[a]	Classification	
0	1 1111	1.00 0000 0000	Positive Floating-Point Numbers	Positive Infinity
0	1 1110 to 0 0001	1.11 1111 1111 to 1.00 0000 0000		Positive Normal
0	0 0000	0.11 1111 1111 to 0.00 0000 0001		Positive Denormal
0	0 0000	0.00 0000 0000		Positive Zero
1	0 0000	0.00 0000 0000	Negative Floating-Point Numbers	Negative Zero
1	0 0000	0.00 0000 0001 to 0.11 1111 1111		Negative Denormal
1	0 0001 to 1 1110	1.00 0000 0000 to 1.11 1111 1111		Negative Normal
1	1 1111	1.00 0000 0000		Negative Infinity
X	1 1111	1.00 0000 0001 to 1.01 1111 1111	Non-Number	SNaN
X	1 1111	1.10 0000 0000 to 1.11 1111 1111		QNaN

a. *The "1." and "0." prefixes represent the implicit integer bit.*

4.3.3.4 Vector and Scalar Data Types

Most SSE instructions accept vector or scalar operands. These data types are composites of the fundamental data types discussed above. The following data types are supported:

- Vector (packed) single-precision (32-bit) floating-point numbers
- Vector (packed) double-precision (64-bit) floating-point numbers
- Vector (packed) signed (two's-complement) integers
- Vector (packed) unsigned integers
- Scalar single- and double-precision floating-point numbers
- Scalar signed (two's-complement) integers
- Scalar unsigned integers

Hardware does not check or enforce the data types for instructions. Software is responsible for ensuring that each operand for an instruction is of the correct data type. If data produced by a previous instruction is of a type different from that used by the current instruction, and the current instruction

sources such data, the current instruction may incur a latency penalty, depending on the hardware implementation.

For the sake of identifying a specific element within a vector (packed) data type, the elements are numbered from right to left starting with 0 and ending with *(vector_size/element_size) −1*. Some instructions operate on even and odd pairs of elements. The even elements are (0, 2, 4 ...) and the odd elements are (1,3,5 ...).

Software can interpret data in ways other than those listed —such fixed-point or fractional numbers— but the SSE instructions do not directly support such interpretations and software must handle them entirely on its own.

128-bit Vector Data Types

Figure 4-6 below illustrates the 128-bit vector data types.

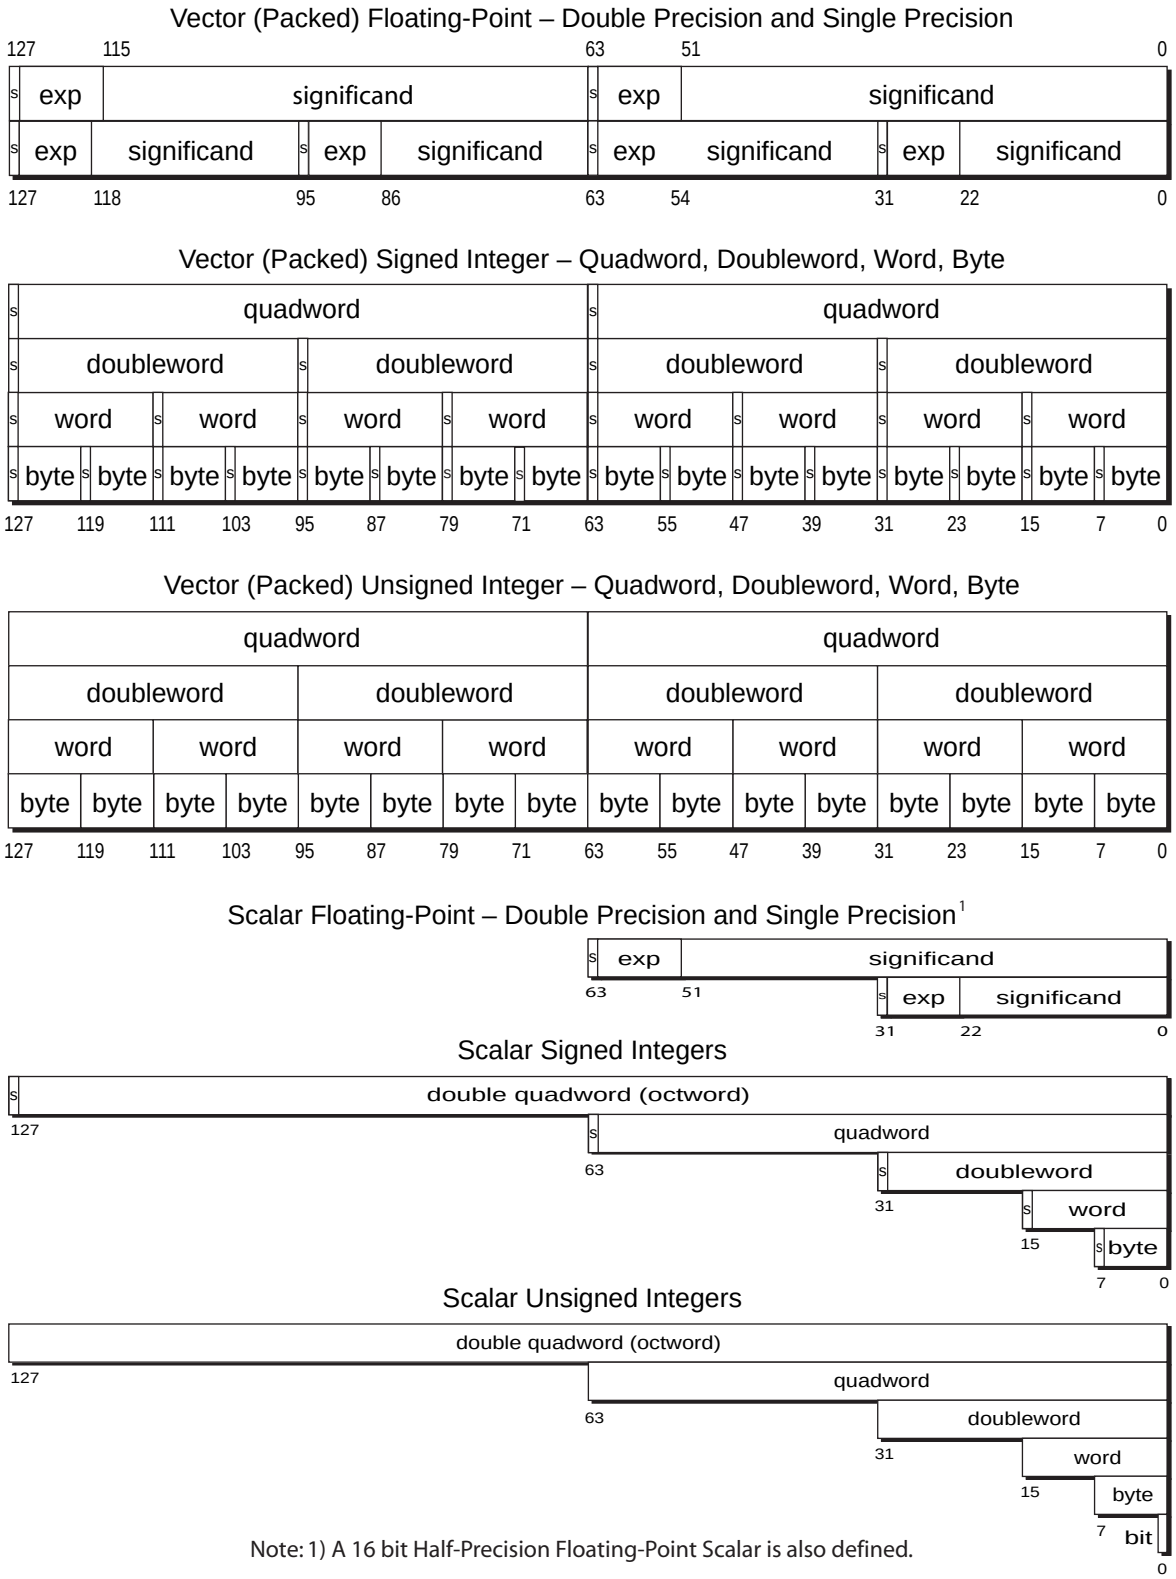

Figure 4-6. 128-Bit Media Data Types

256-bit Vector Data Types

Figure 4-7 and Figure 4-8 below illustrate the 256-bit vector data types.

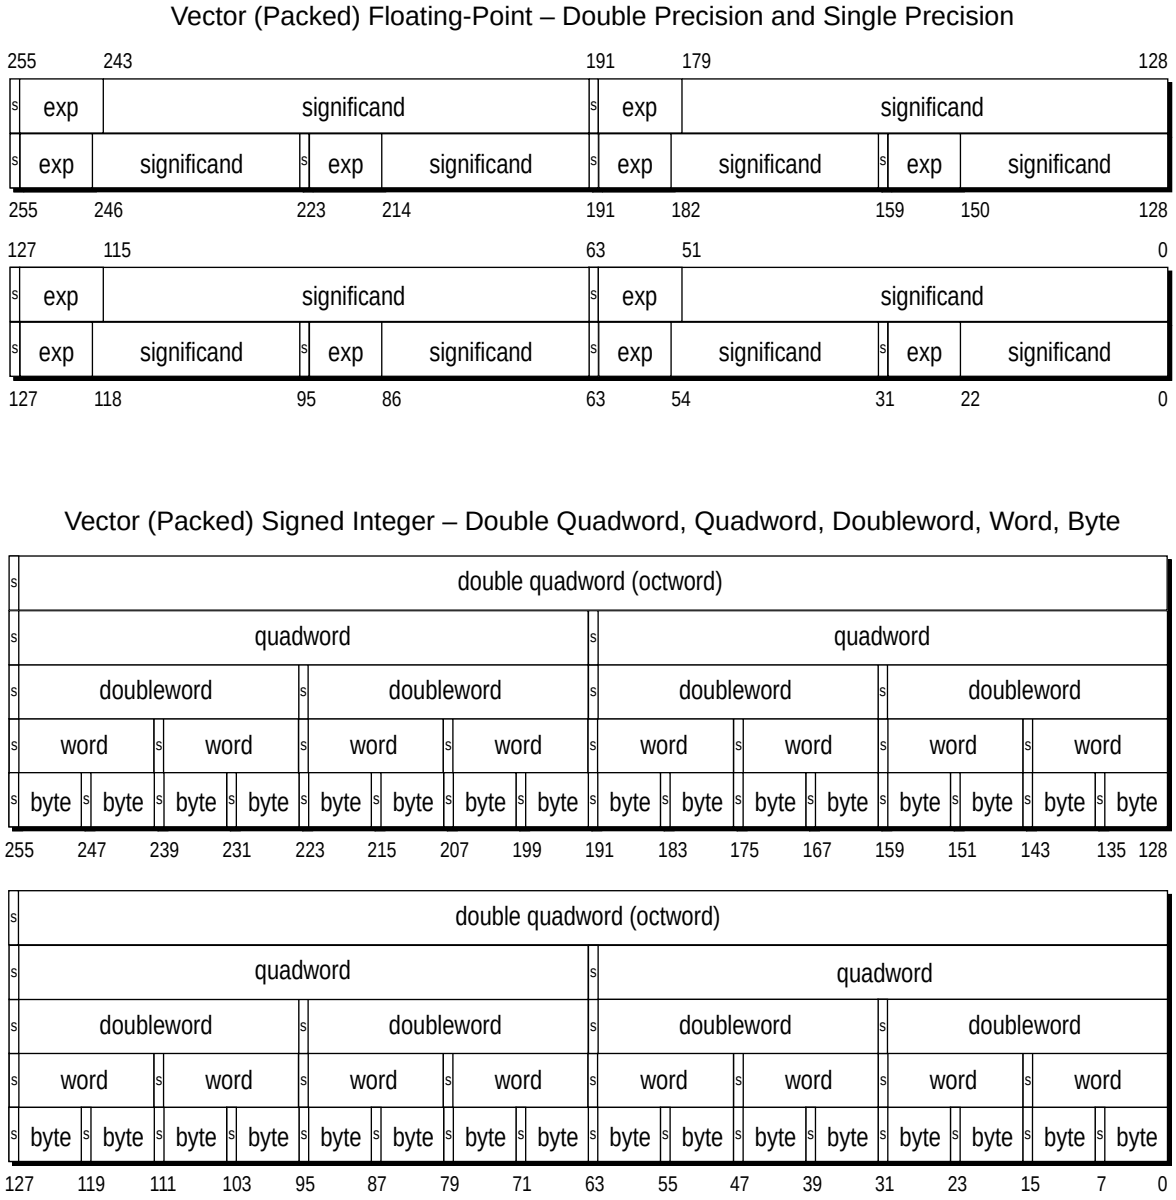

Figure 4-7. 256-Bit Media Data Types

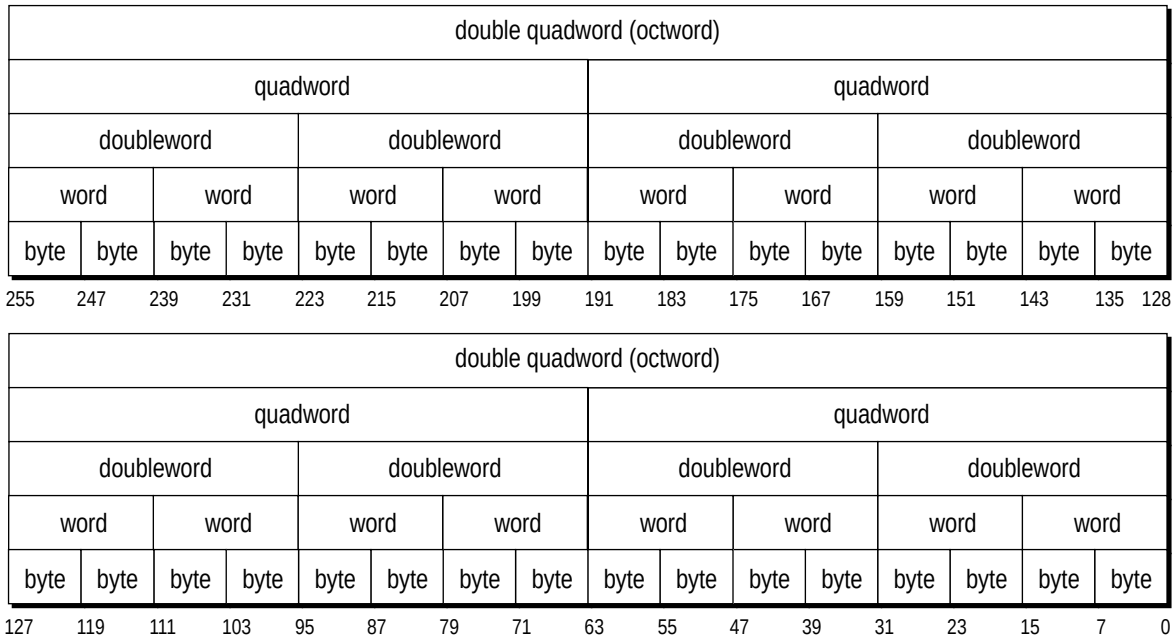
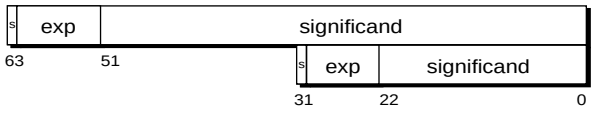
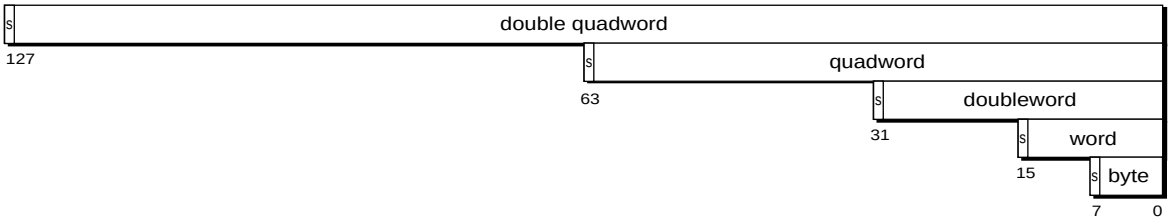
Vector (Packed) Unsigned Integer – Double Quadword, Quadword, Doubleword, Word, Byte



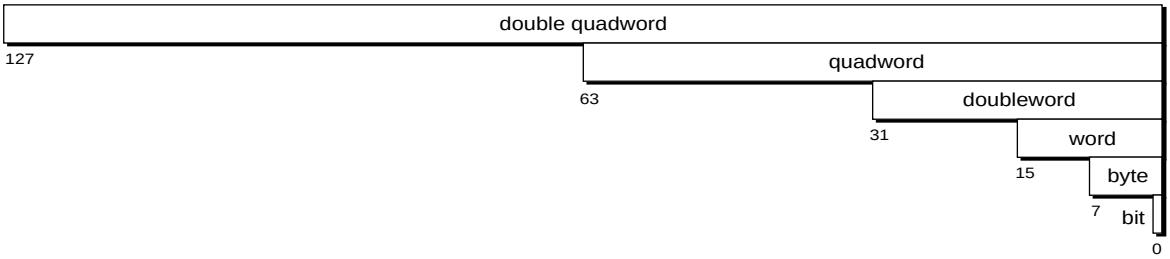
Scalar Floating-Point – Double Precision and Single Precision[1]



Scalar Signed Integers



Scalar Unsigned Integers



Note: 1) A 16 bit Half-Precision Floating-Point Scalar is also defined.

Figure 4-8. 256-Bit Media Data Types (Continued)

Software can interpret the data types in ways other than those shown—such as bit fields or fractional numbers—but the instructions do not directly support such interpretations and software must handle them entirely on its own.

4.3.4 Operand Sizes and Overrides

Operand sizes for SSE instructions are determined by instruction opcodes. Some of these opcodes include an operand-size override prefix, but this prefix acts in a special way to modify the opcode and is considered an integral part of the opcode. The general use of the 66h operand-size override prefix described in “Instruction Prefixes” on page 76 does not apply to SSE instructions.

For details on the use of operand-size override prefixes in SSE instructions, see “*Volume 4: 128-Bit and 256-Bit Media Instructions*”.

4.4 Vector Operations

4.4.1 Integer Vector Operations

Figure 4-9 below shows an example of a typical two operand integer vector operation. In this example, each n-bit wide vector contains 16 integer elements. Note that the same mathematical operation is performed on all 16 elements in parallel. The computation of one element of the result vector does not affect the computation of any of the other result elements. For example, a carry out that could occur as a result of computing a sum is not added into the sum of the next most significant element of the vector.

In general, the result of a vector operation is a vector of the same width as the operands with the same number of elements. (Although there are instructions which increase or decrease the width and number of elements in the result.) There are instructions that operate on vectors of words, doublewords, quadwords and octwords. Both 128-bit and 256-bit wide vectors are supported. See Section 4.6 “Instruction Summary—Integer Instructions” on page 149 for more information on the supported 128-bit and 256-bit integer data types.

Most legacy SSE instructions support the specification of two operands. For these instructions the result overwrites the first operand as shown. The extended SSE set includes instructions that support two, three, or four vector operands. In these instructions, the result is generally written to a destination register specified by the instruction encoding.

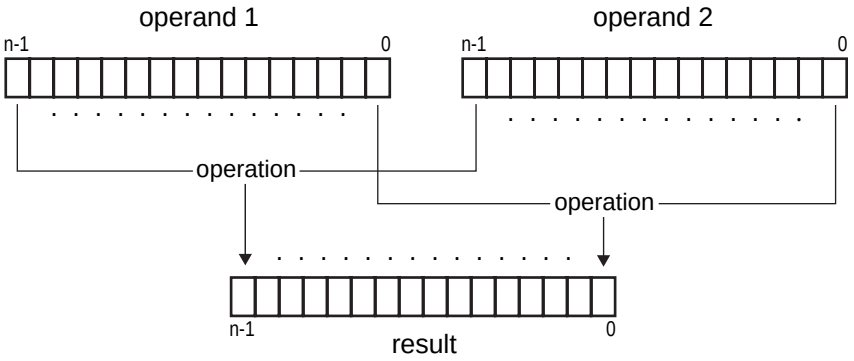


Figure 4-9. Mathematical Operations on Integer Vectors

The SSE instruction set also supports a vector form of the unary arithmetic operation *absolute value*. In these instructions the absolute value operation is applied independently to all the elements of the source operand to produce the result.

4.4.2 Floating-Point Vector Operations

The SSE instruction set supports vectors of both single-precision and double-precision floating-point values in both 128-bit and 256-bit vector widths. See Section 4.6 “Instruction Summary—Integer Instructions” on page 149 for more information on the supported 128-bit and 256-bit data types.

Figure 4-10 shows an example of a parallel operation on two 256-bit vectors, each containing four 64-bit double-precision floating-point values. As in the integer vector operation, each element of the vector result is the product of the mathematical operation applied to corresponding elements of the source operands. The number of elements and parallel operations is 2, 4, or 8 depending on vector and element size.

Some SSE floating-point instructions support the specification of only two operands. For most of these instructions the result overwrites the first operand. The extended SSE instructions include instructions that support three or four operands. In most three and four operand instructions, the result is written to a separate destination register specified by the instruction encoding.

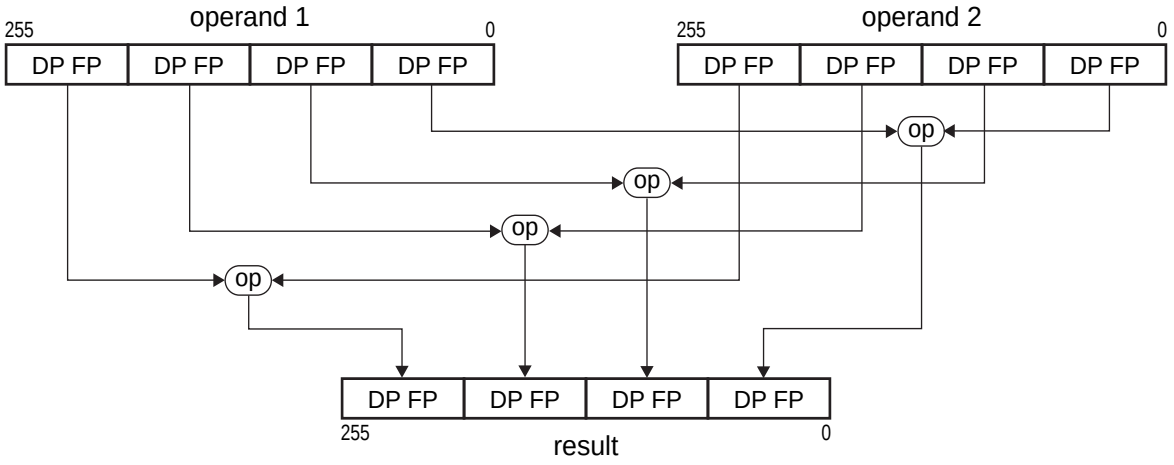

Figure 4-10. Mathematical Operations on Floating-Point Vectors

Integer and floating-point instructions can be freely intermixed in the same procedure. The floating-point instructions allow media applications such as 3D graphics to accelerate geometry, clipping, and lighting calculations. Pixel data are typically integer-based, although both integer and floating-point instructions are often required to operate completely on the data. For example, software can change the viewing perspective of a 3D scene through transformation matrices by using floating-point instructions in the same procedure that contains integer operations on other aspects of the graphics data.

For media and scientific programs that demand floating-point operations, it is often easier and more powerful to use SSE instructions. Such programs perform better than x87 floating-point programs, because the YMM/XMM register file is flat rather than stack-oriented, there are twice as many registers (in 64-bit mode), and SSE instructions can operate on four or eight times the number of floating-point operands as can x87 instructions. This ability to operate in parallel on multiple pairs of floating-point elements often makes it possible to remove local temporary variables that would otherwise be needed in x87 floating-point code.

4.5 Instruction Overview

4.5.1 Instruction Syntax

Each instruction has a *mnemonic syntax* used by assemblers to specify the operation and the operands to be used for source and destination (result) data.

Legacy SSE Instructions

The legacy SSE instructions accept two operands and generally have the following syntax:

```
MNEMONIC xmm1, xmm2/mem128
```

Figure 4-11 below shows an example of the mnemonic syntax for a packed add bytes (PADDB) instruction.

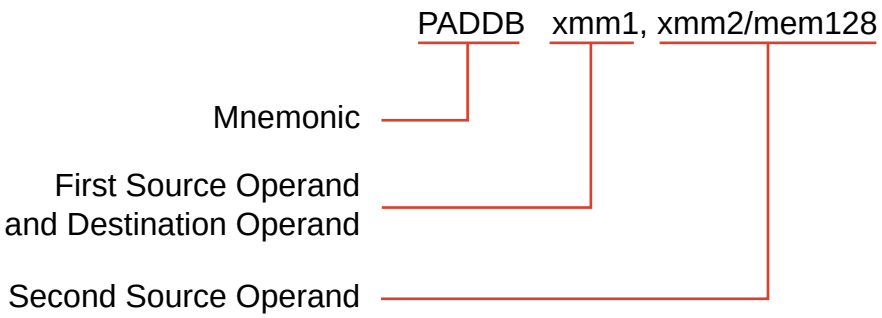

Figure 4-11. Mnemonic Syntax for Typical Legacy SSE Instruction

This example shows the PADDB mnemonic followed by two operands, a 128-bit XMM register operand and another 128-bit XMM register or 128-bit memory operand. In most instructions that take two operands, the first (left-most) operand is both a source operand and the destination operand. The second (right-most) operand serves only as a source. Some instructions can have one or more prefixes that modify default properties, as described in “Instruction Prefixes” on page 217.

Extended SSE Instructions

The extended SSE instructions support operands of either 128 bits or 256 bits. They also support the specification of two, three, four, or five operands sourced from YMM/XMM registers, memory or immediate bytes. A three-operand 128-bit extended SSE instruction has the following syntax:

```
MNEMONIC xmm1, xmm2, xmm3/mem128
```

A three-operand 256-bit extended SSE instruction has the following syntax:

```
MNEMONIC ymm1, ymm2, ymm3/mem256
```

Figure 4-12 below shows an example of the mnemonic syntax for the packed add bytes (VPADDB) instruction.

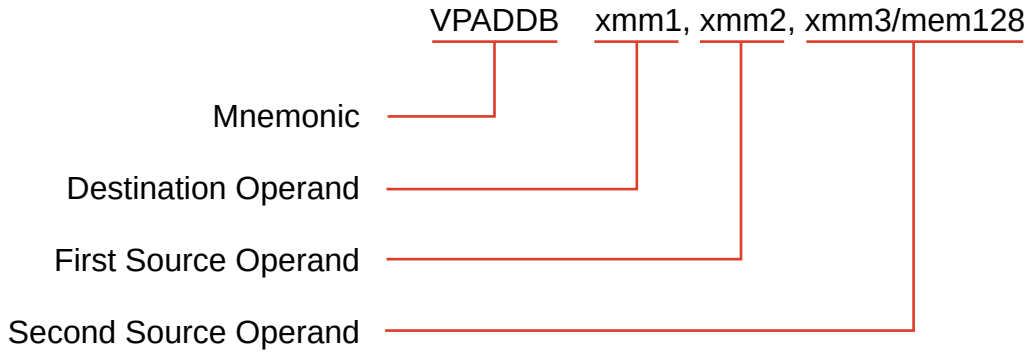

Figure 4-12. Mnemonic Syntax for Typical Extended SSE Instruction

This example shows the VPADDB mnemonic followed by three operands—a destination XMM register and two source operands. Instruction operand number 2 located in an XMM register is actually the first source operand and operand 3 is the second source operand. The second source operand may be located in an XMM register or in memory. The result of the vector add operation is placed in the specified destination register. Some instructions can have one or more prefixes that modify default properties, as described in “Instruction Prefixes” on page 217.

4.5.2 Mnemonics

Most mnemonics follow some general conventions:

As noted above, a **V** prepended to a mnemonic means that it is an extended SEE instruction.

The initial character string of the mnemonic (immediately after the possibly prepended **V)** represents the operation the instruction performs. An initial **P** in the string representing the operation stands for “Packed.” Subsequent character strings in various combinations either refer to operand types or indicate a variant of the basic operation. The following lists most of these conventions:

- **A**—Aligned
- **B**—Byte
- **D**—Doubleword
- **DQ**—Double quadword
- **HL**—High to low
- **LH**—Low to high
- **L**—Left
- **PD**—Packed double-precision floating-point
- **PI**—Packed integer
- **PS**—Packed single-precision floating-point
- **Q**—Quadword
- **R**—Right
- **S**—Signed, or Saturation, or Shift
- **SD**—Scalar double-precision floating-point
- **SI**—Signed integer
- **SS**—Scalar single-precision floating-point, or Signed saturation
- **U**—Unsigned, or Unordered, or Unaligned
- **US**—Unsigned saturation
- **V**—Intial letter designates an extended SSE instruction
- **W**—Word
- **2**—to. Used in data type conversion instruction mnemonics.

Consider the example VPMULHUW. The initial **V** indicates that the instruction is an extended SSE instruction (in this case, an AVX instruction). It is a packed (that is, vector) multiply (**P** for packed and **MUL** for multiply) of unsigned words (**U** for unsigned and **W** for Word). Finally, the **H** refers to the fact that the high word of each intermediate double word result is written to the destination vector element.

4.5.3 Move Operations

Move instructions—along with unpack instructions—are among the most frequently used instructions in media procedures.

When moving between XMM registers, or between an XMM register and memory, each integer move instruction can copy up to 16 bytes of data. When moving between an XMM register and an MMX or GPR register, an integer move instruction can move up to 8 bytes of data. The packed floating-point move instructions can copy vectors of four single-precision or two double-precision floating-point operands in parallel.

Figure 4-13 below provides an overview of the basic move operations involving the XMM registers. Crosshatching in the figure represents bits in the destination register which may either be zero-extended or left unchanged in the move operation based on the instruction or (for one instruction) the source of the data. Data written to memory is never zero-extended. The AVX subset provides a number of 3-operand variants of the basic move instructions that merge additional data from a XMM register into the destination register. These are not shown in this figure nor are those instructions that extend fields in the destination register by duplicating bits from the source register.

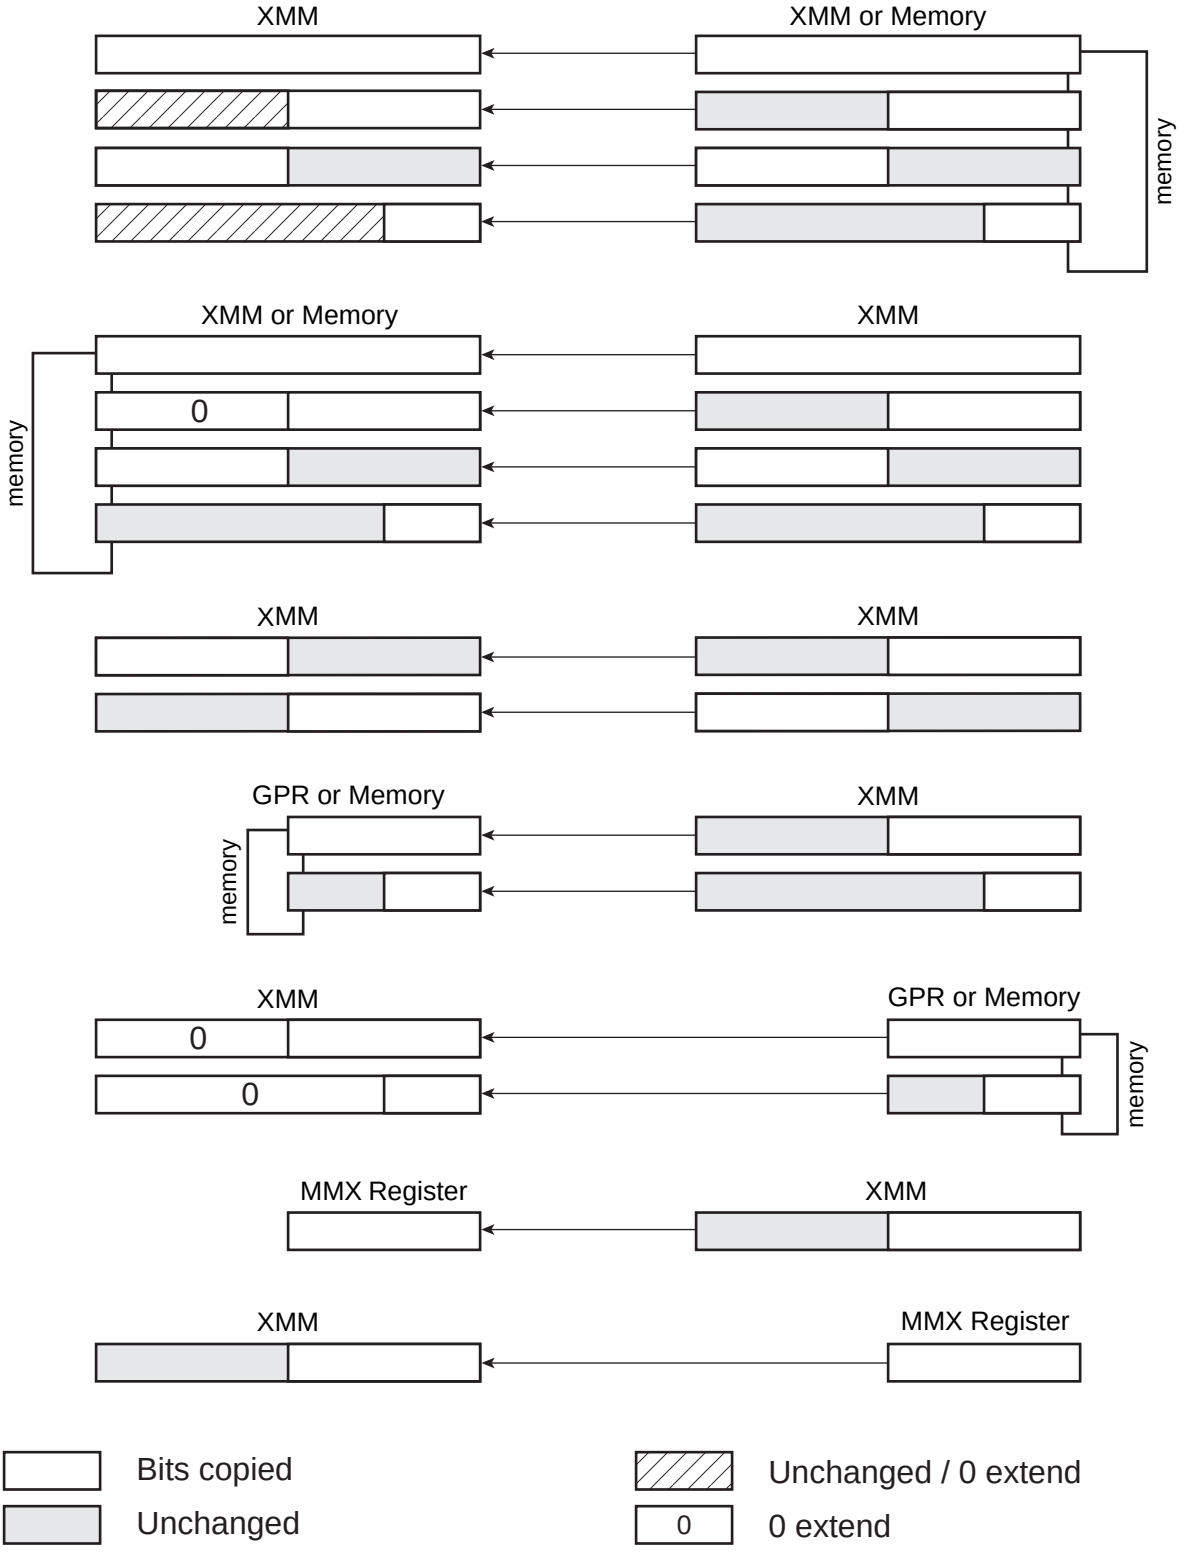

Figure 4-13. XMM Move Operations

The extended SSE instruction set provides instructions that load a YMM register from memory, store the contents of a YMM register to memory, or move 256 bits from one register to another. Figure 4-14 below provides a schematic representation of these operations.

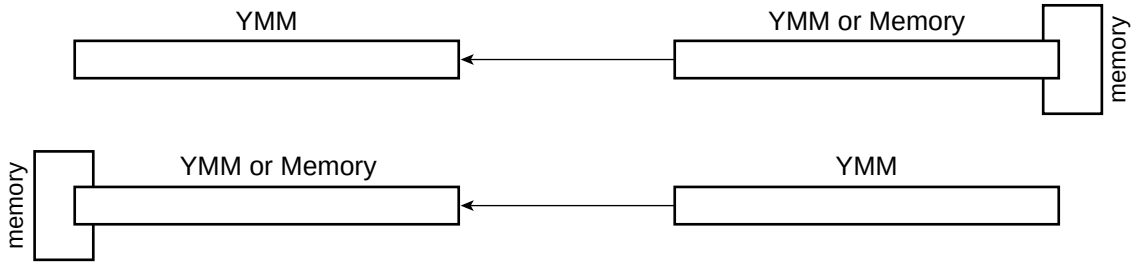

Figure 4-14. YMM Move Operations

Streaming-store versions of the move instructions (also known as non-temporal moves) bypass the cache when storing data that is accessed only once. This maximizes memory-bus utilization and minimizes cache pollution.

The move-mask instruction stores specific bytes from one vector, as selected by mask values in a second vector. Figure 4-15 below shows the (V)MASKMOVDQU operation. It can be used, for example, to handle end cases in block copies and block fills based on streaming stores.

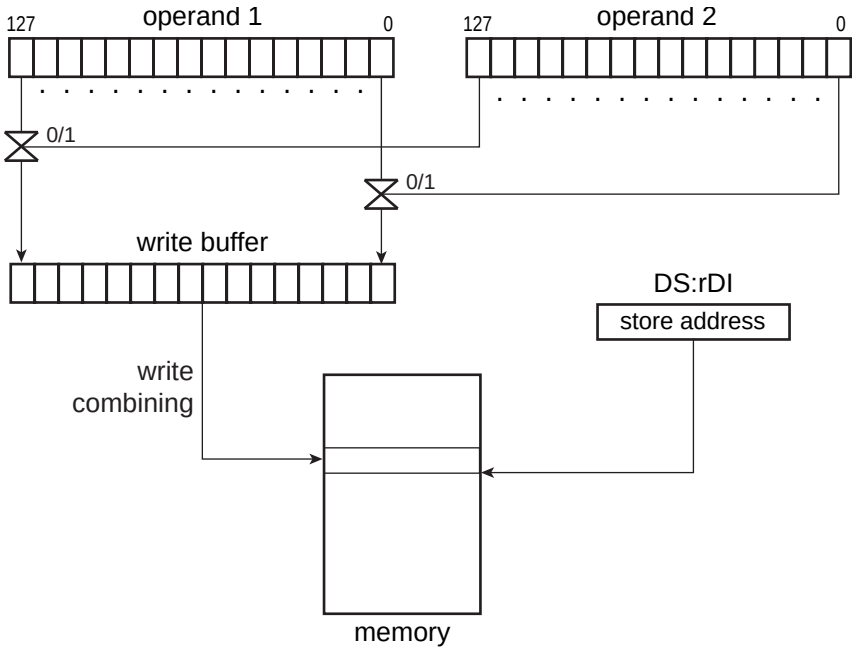

Figure 4-15. Move Mask Operation

4.5.4 Data Conversion and Reordering

SSE instructions support data conversion of vector elements, including conversions between integer and floating-point data types—located in YMM/XMM registers, MMX™ registers, GPR registers, or memory—and conversions of element-ordering or precision.

For example, the unpack instructions take two vector operands and interleave their low or high elements. Figure 4-16 shows an unpack and interleave operation on word-sized elements. This this case, (V)PUNPCKLWD. If operand 1 is a vector of unsigned integers and the left-hand source operand has elements whose value is zero, the operation converts each element in the low half of operand 1 to an integer data type of twice its original width. This would be a useful step prior to multiplying two integer vectors together to ensure that no overflow can occur during a vector multiply operation.

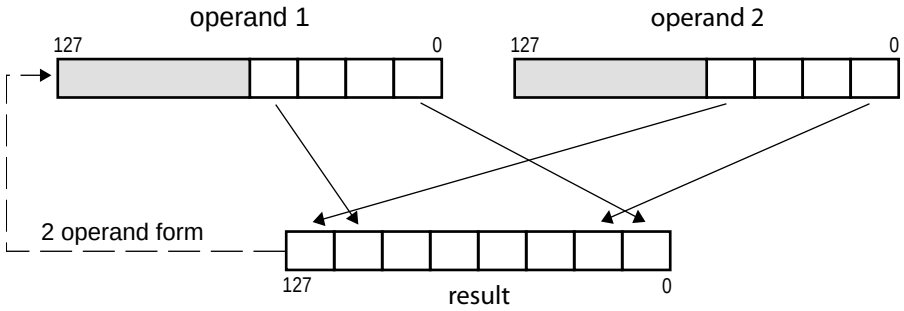

Figure 4-16. Unpack and Interleave Operation

There are also pack instructions, such as (V)PACKSSDW shown below in Figure 4-17, that convert each element in a pair of integer vectors to lower precision and pack them into the result vector.

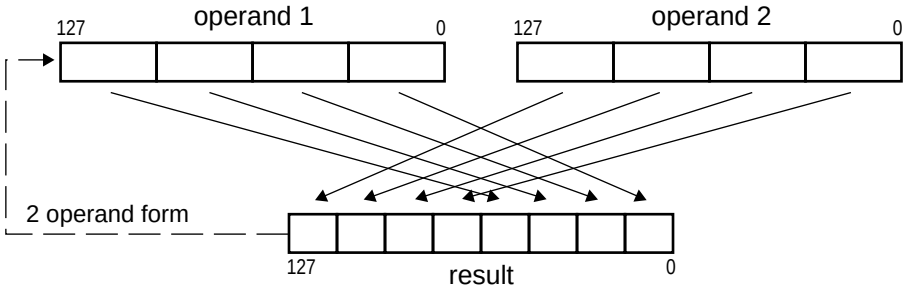

Figure 4-17. Pack Operation

Vector-shift instructions are also provided. These instructions may be used to scale each element in an integer vector up or down.

Figure 4-18 shows one of many types of shuffle operations; in this case, PSHUFD. Here the second operand is a vector containing doubleword elements, and an immediate byte provides shuffle control for up to 256 permutations of the elements. Shuffles are useful, for example, in color imaging when

computing alpha saturation of RGB values. In this case, a shuffle instruction can replicate an alpha value in a register so that parallel comparisons with three RGB values can be performed.

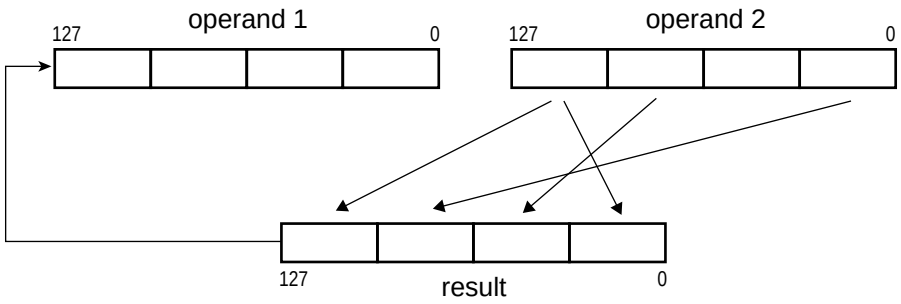

Figure 4-18. Shuffle Operation

The (V)PINSRB, (V)PINSRW, (V)PINSRD, and (V)PINSRQ instructions insert a byte, word, doubleword or quadword from a general-purpose register or memory into an XMM register, at a specified location. The legacy instructions leave the other elements in the XMM register unmodified. The extended instructions fill in the other elements from a second XMM source operand.

4.5.5 Matrix and Special Arithmetic Operations

The instruction set provides a broad assortment of vector add, subtract, multiply, divide, and square-root operations for use on matrices and other data structures common to media and scientific applications. It also provides special arithmetic operations including multiply-add, average, sum-of-absolute differences, reciprocal square-root, and reciprocal estimation.

SSE integer and floating-point instructions can perform several types of matrix-vector or matrix-matrix operations, such as addition, subtraction, multiplication, and accumulation. Efficient matrix multiplication is further supported with instructions that can first transpose the elements of matrix rows and columns. These transpositions can make subsequent accesses to memory or cache more efficient when performing arithmetic matrix operations.

Figure 4-19 on page 146 shows a Packed Multiply and Add instruction ((V)PMADDWD) which multiplies vectors of 16-bit integer elements to yield intermediate results of 32-bit elements, which are then summed pair-wise to yield four 32-bit elements. This operation can be used with one source operand (for example, a coefficient) taken from memory and the other source operand (for example, the data to be multiplied by that coefficient) taken from an XMM register. It can also be used together with a vector-add operation to accumulate *dot product* results (also called *inner* or *scalar products*), which are used in many media algorithms such as those required for finite impulse response (FIR) filters, one of the commonly used DSP algorithms.

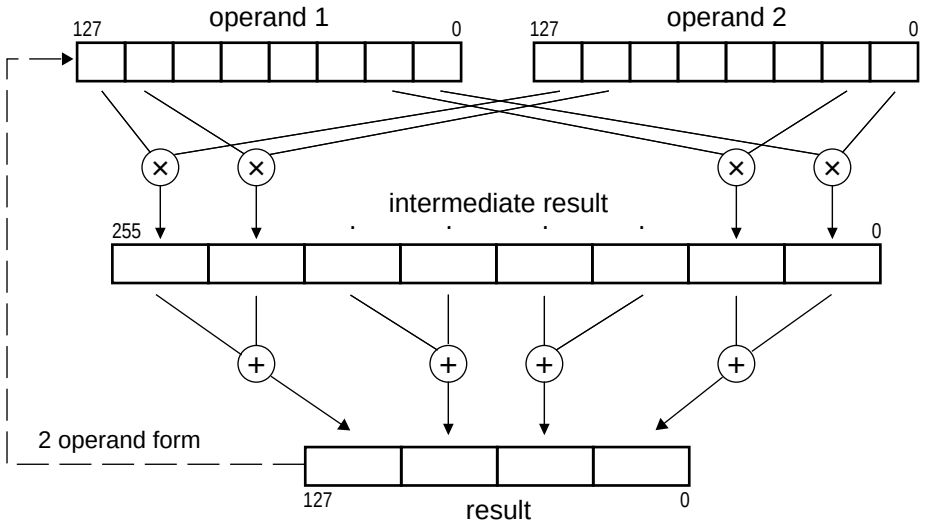

Figure 4-19. Multiply-Add Operation

See Section 4.7.5 “Fused Multiply-Add Instructions” on page 206 for a discussion of floating-point fused multiply-add instructions.

The sum-of-absolute-differences instruction ((V)PSADBW), shown in Figure 4-20 is useful, for example, in computing motion-estimation algorithms for video compression.

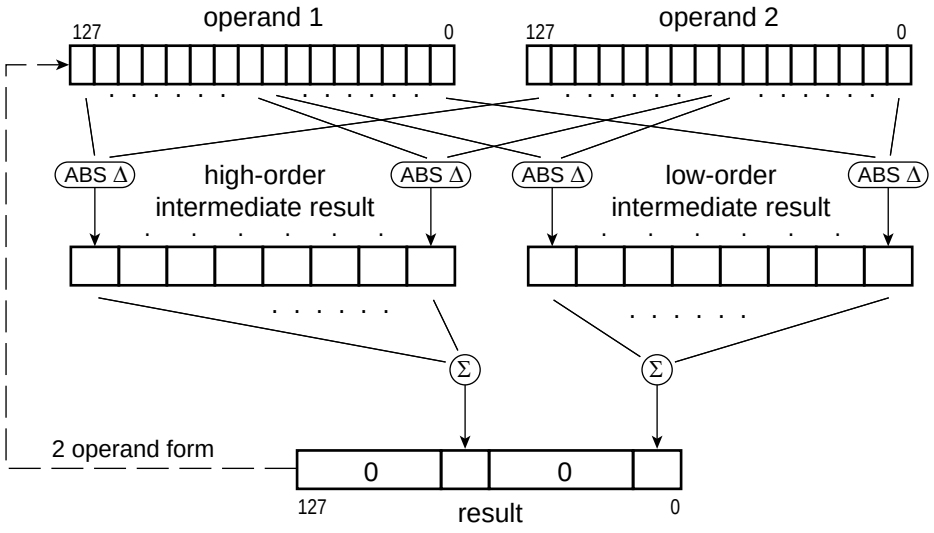

Figure 4-20. Sum-of-Absolute-Differences Operation

There is an instruction for computing the average of unsigned bytes or words. The instruction is useful for MPEG decoding, in which motion compensation involves many byte-averaging operations

between and within macroblocks. In addition to speeding up these operations, the instruction also frees up registers and makes it possible to unroll the averaging loops.

Some of the arithmetic and pack instructions produce vector results in which each element *saturates* independently of the other elements in the result vector. Such results are clamped (limited) to the maximum or minimum value representable by the destination data type when the true result exceeds that maximum or minimum representable value. Saturating data is useful for representing physical-world data, such as sound and color. It is used, for example, when combining values for pixel coloring.

4.5.6 Branch Removal

Branching is a time-consuming operation that, unlike most SSE vector operations, does not exhibit parallel behavior (there is only one branch target, not multiple targets, per branch instruction). In many media applications, a branch involves selecting between only a few (often only two) cases. Such branches can be replaced with SSE vector compare and vector logical instructions that simulate predicated execution or conditional moves.

Figure 4-21 shows an example of a non-branching sequence that implements a two-way multiplexer—one that is equivalent to the ternary operator "?:" in C and C++. The comparable code sequence is explained in "Compare and Write Mask" on page 177.

The sequence begins with a vector compare instruction that compares the elements of two source operands in parallel and produces a mask vector containing elements of all 1s or 0s. This mask vector is ANDed with one source operand and ANDed-Not with the other source operand to isolate the desired elements of both operands. These results are then ORed to select the relevant elements from each operand. A similar branch-removal operation can be done using floating-point source operands.

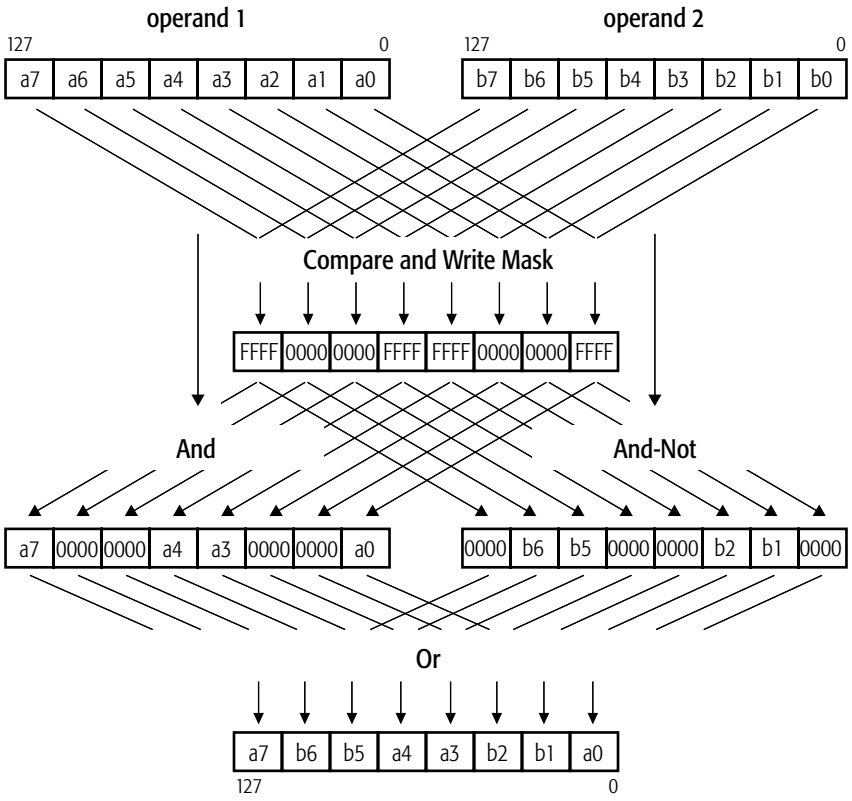

Figure 4-21. Branch-Removal Sequence

The min/max compare instructions, for example, are useful for clamping, such as color clamping in 3D graphics, without the need for branching. Figure 4-22 on page 148 illustrates a move-mask instruction ((V)PMOVMSKB) that copies sign bits to a general-purpose register (GPR). The instruction can extract bits from mask patterns, or zero values from quantized data, or sign bits—resulting in a byte that can be used for data-dependent branching.

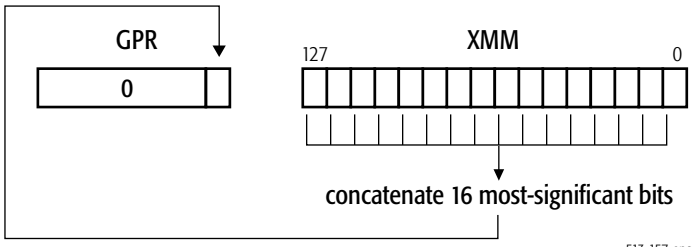

Figure 4-22. Move Mask Operation

4.6 Instruction Summary—Integer Instructions

This section summarizes the SSE instructions that operate on scalar and packed integers. Software running at any privilege level can use any of the instructions discussed below given that hardware and system software support is provided and the appropriate instruction subset is enabled. Detection and enablement of instruction subsets is normally handled by operating system software. Hardware support for each instruction subset is indicated by processor feature bits. These are accessed via the CPUID instruction. See Volume 3 for details on the CPUID instruction and the feature bits associated with the SSE instruction set.

The SSE instructions discussed below include those that use the YMM/XMM registers as well as instructions that convert data from integer to floating-point formats. For more detail on each instruction, see individual instruction reference pages in the Instruction Reference chapter of Volume 4, "*128-Bit and 256-Bit Media Instructions.*"

For a summary of the floating-point instructions including instructions that convert from floating-point to integer formats, see "Instruction Summary—Floating-Point Instructions" on page 184.

The following subsections are organized by functional groups. These are:

- Data Transfer
- Data Conversion
- Data Reordering
- Arithmetic
- Enhanced Media
- Shift and Rotate
- Compare
- Logical
- Save and Restore

Most of the instructions described below have both a legacy and an AVX form. Generally the AVX form is functionally equivalent to the legacy form except for the affect of the instruction on the upper octword of the destination YMM register. The legacy form of an instruction leaves the upper octword of the YMM register that overlays the destination XMM register unchanged, while the AVX form always clears the upper octword.

The descriptions that follow apply equally to the legacy instruction and its 128-bit AVX form. Many of the AVX instructions also support a 256-bit version of the instruction that operates on the 256-bit data types. For the instructions which accept vector operands, the only difference in functionality between the 128-bit form and the 256-bit form is the number of elements operated upon in parallel (that is, the number of elements doubles). Other differences will be noted at the end of the discussion.

4.6.1 Data Transfer

The data-transfer instructions copy data between a memory location, a YMM/XMM register, an MMX register, or a GPR. The MOV mnemonic, which stands for *move*, is a misnomer. A copy function is actually performed instead of a move. A new copy of the source value is created at the destination address, and the original copy remains unchanged at its source location.

4.6.1.1 Move

- (V)MOVD—Move Doubleword or Quadword
- (V)MOVQ—Move Quadword
- (V)MOVDQA—Move Aligned Double Quadword
- (V)MOVDQU—Move Unaligned Double Quadword
- MOVDQ2Q—Move Quadword to Quadword
- MOVQ2DQ—Move Quadword to Quadword
- (V)LDDQU—Load Double Quadword Unaligned

When copying between YMM registers, or between a YMM register and memory, a move instruction can copy up to 32 bytes of data. When copying between XMM registers, or between an XMM register and memory, a move instruction can copy up to 16 bytes of data. When copying between an XMM register and an MMX or GPR register, a move instruction can copy up to 8 bytes of data.

The (V)MOVD instruction copies a 32-bit or 64-bit value from a GPR register or memory location to the low-order 32 or 64 bits of an XMM register, or from the low-order 32 or 64 bits of an XMM register to a 32-bit or 64-bit GPR or memory location. If the source operand is a GPR or memory location, the source is zero-extended to 128 bits in the XMM register. If the source is an XMM register, only the low-order 32 or 64 bits of the source are copied to the destination.The 64-bit (long) form of (V)MOVD is aliased as (V)MOVQ.

The (V)MOVQ instruction copies a 64-bit value from memory to the low quadword of an XMM register, or from the low quadword of an XMM register to memory, or between the low quadwords of two XMM registers. If the source is in memory and the destination is an XMM register, the source is zero-extended to 128 bits in the XMM register.

The (V)MOVDQA instruction copies a 128-bit value from memory to an XMM register, or from an XMM register to memory, or between two XMM registers. If either the source or destination is a memory location, the memory address must be aligned. The (V)MOVDQU instruction does the same, except for unaligned operands. The (V)LDDQU instruction is virtually identical in operation to the (V)MOVDQU instruction. The (V)LDDQU instruction moves a double quadword of data from a 128-bit memory operand into a destination XMM register.

The VMOVDQA and VMOVDQU instructions have 256-bit forms which copy a 256-bit value from memory to a YMM register, or from a YMM register to memory, or between two YMM registers. VLDDQU has a 256-bit form that loads a 256-bit value from memory.

The MOVDQ2Q instruction copies the low-order 64-bit value in an XMM register to an MMX register. The MOVQ2DQ instruction copies a 64-bit value from an MMX register to the low-order 64 bits of an XMM register, with zero-extension to 128 bits.

Figure 4-23 below diagrams the capabilities of these instructions. (V)LDDQU and the 128-bit forms of the extended instructions are not shown.

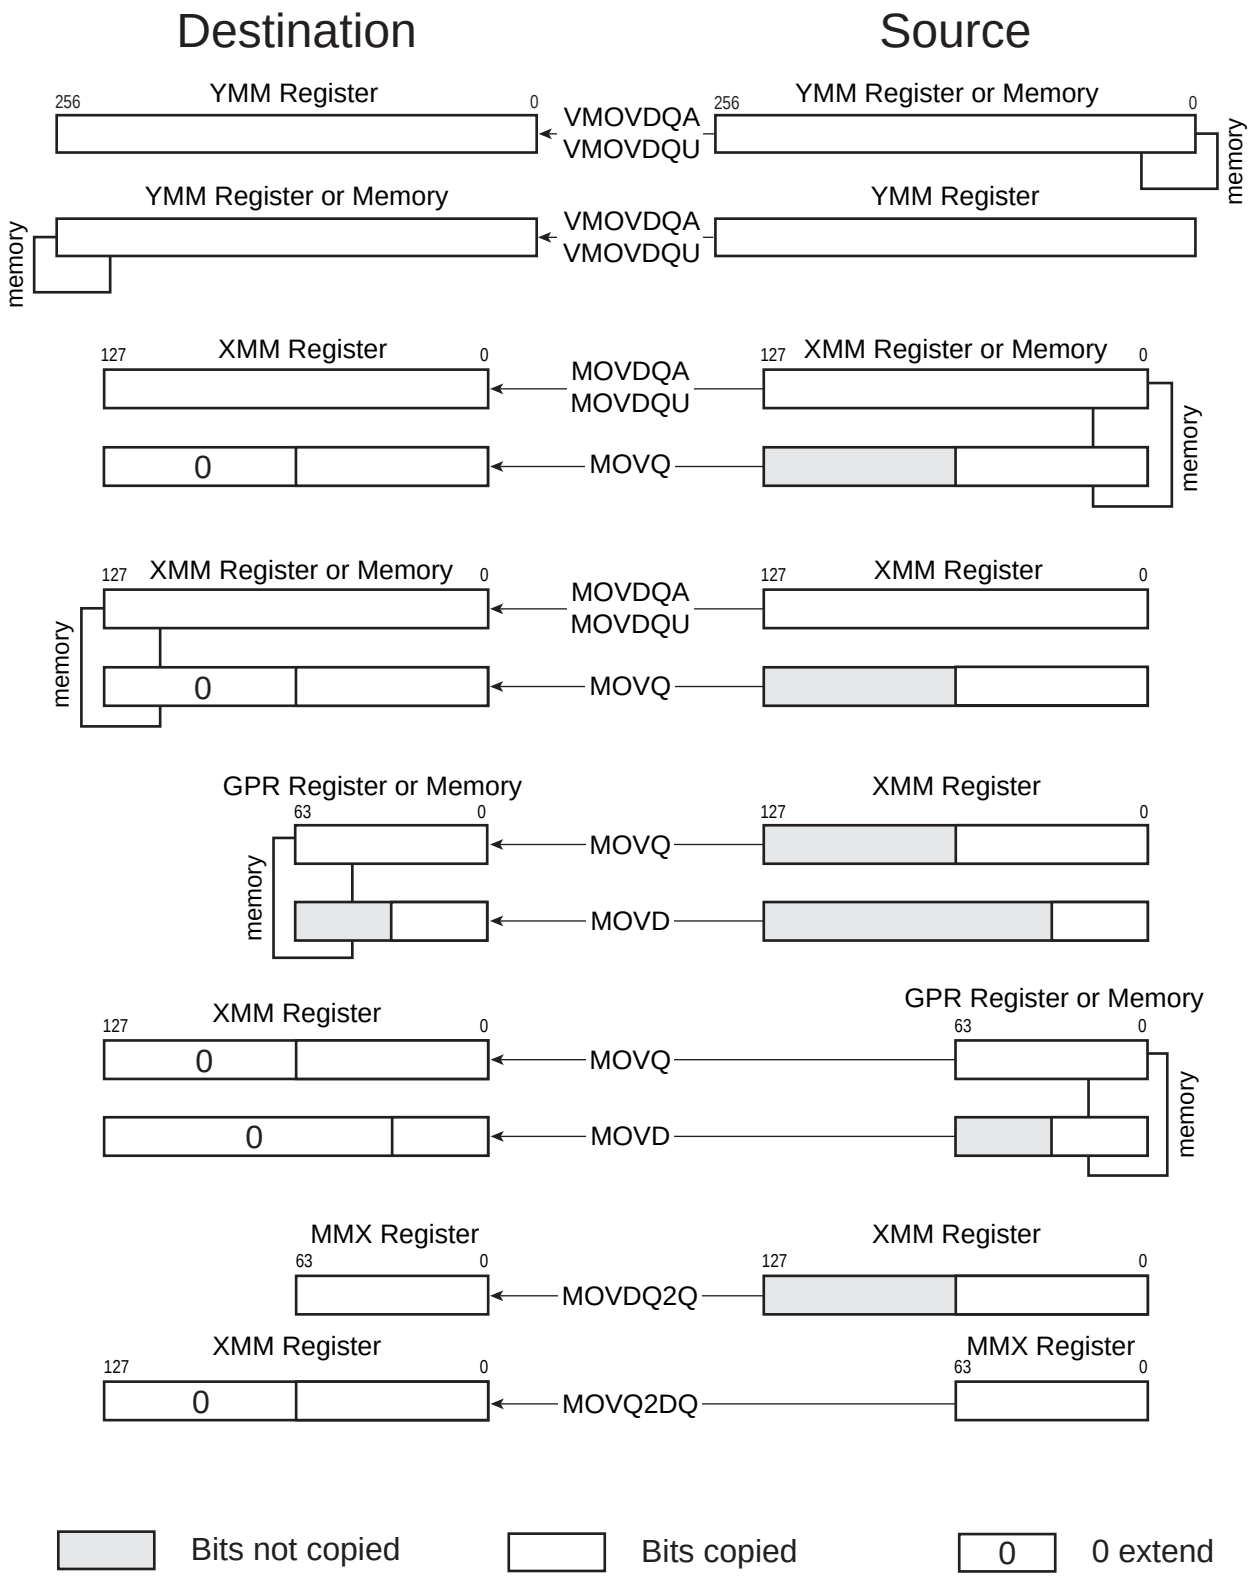

Figure 4-23. Integer Move Operations

The move instructions are in many respects similar to the assignment operator in high-level languages. The simplest example of their use is for initializing variables. To initialize a register to 0, however, rather than using a MOV*x* instruction it may be more efficient to use the (V)PXOR instruction with identical destination and source operands.

4.6.1.2 Move Non-Temporal

The move non-temporal instructions are *streaming-store* instructions. They minimize pollution of the cache.

- (V)MOVNTDQ—Move Non-temporal Double Quadword
- (V)MOVNTDQA—Move Non-temporal Double Quadword Aligned
- (V)MASKMOVDQU—Masked Move Double Quadword Unaligned

The (V)MOVNTDQ instruction stores its source operand (a 128-bit XMM register value or a 256-bit YMM register value) to a 128-bit or 256-bit memory location. (V)MOVNTDQ indicates to the processor that its data is *non-temporal*, which assumes that the referenced data will be used only once and is therefore not subject to cache-related overhead (as opposed to *temporal* data, which assumes that the data will be accessed again soon and should be cached). The non-temporal instructions use weakly-ordered, write-combining buffering of write data, and they minimize cache pollution. The exact method by which cache pollution is minimized depends on the hardware implementation of the instruction. For further information, see “Memory Optimization” on page 98 and “Use Streaming Loads and Stores” on page 233.

The MOVNTDQA instruction loads an XMM register from an aligned 128-bit memory location. VMOVNTDQA loads either an XMM or a YMM register from an aligned 128-bit or 256-bit memory location. An attempt by MOVNTDQA to read from an unaligned memory address causes a #GP or invokes the alignment checking mechanism depending on the setting of the MXCSR[MM] bit. An attempt by the VMOVNTDQA to read from an unaligned memory address causes a #GP.

(V)MASKMOVDQU is also a non-temporal instruction. It stores bytes from the first operand, as selected by the mask value in the second operand. Bytes are written to a memory location specified in the rDI and DS registers. The first and second operands are both XMM registers. The address may be unaligned. Figure 4-24 shows the (V)MASKMOVDQU operation. It is useful for the handling of end cases in block copies and block fills based on streaming stores.

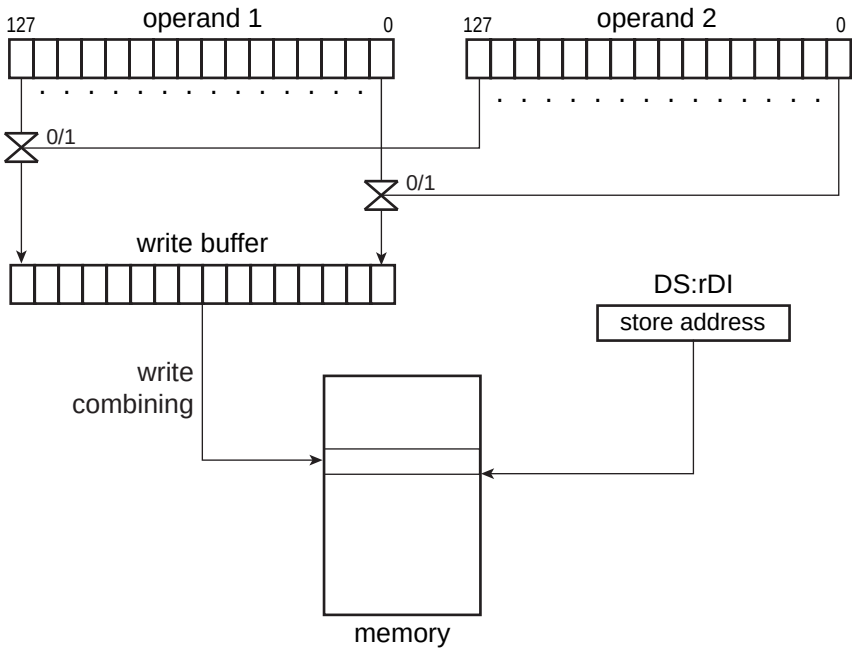

Figure 4-24. (V)MASKMOVDQU Move Mask Operation

4.6.1.3 Move Mask

- (V)PMOVMSKB—Packed Move Mask Byte

The (V)PMOVMSKB instruction moves the most-significant bit of each byte in an XMM register to the low-order word of a 32-bit or 64-bit general-purpose register, with zero-extension. The instruction is useful for extracting bits from mask patterns, or zero values from quantized data, or sign bits—resulting in a byte that can be used for data-dependent branching. Figure 4-25 below shows the (V)PMOVMSKB operation using the example of a 128-bit source operand held in an XMM register.

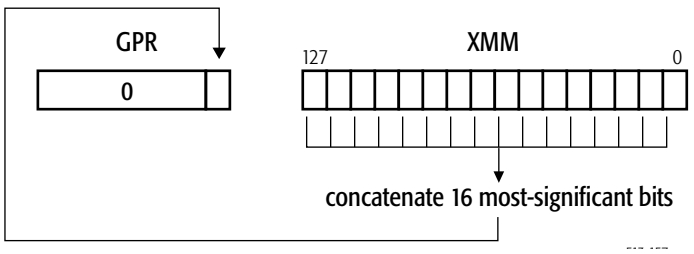

Figure 4-25. (V)PMOVMSKB Move Mask Operation

AVX2 adds support for a 256-bit source operand held in a YMM register. The 32-bit results is zero-extended to 64 bits.

4.6.1.4 Vector Conditional Moves

XOP instruction set includes the vector conditional move instructions:

- VPCMOV—Vector Conditional Moves
- VPPERM—Packed Permute Bytes

The VPCMOV instruction implements the C/C++ language ternary '?' operator a bit level. Each bit of the destination YMM/XMM register is copied from the corresponding bit of either the first or second source operand based on the value of the corresponding bit of a third source operand. This instruction has both 128-bit and 256-bit forms. The VPCMOV instruction allows either the second or the third operand to be source from memory, based on the XOP.W bit.

The VPPERM instruction performs vector permutation on a packed array of 32 bytes composed of two 16-byte input operands. The VPPERM instruction replaces each destination byte with 00h, FFh, or one of the 32 bytes of the packed array. A byte selected from the array may have an additional operation such as NOT or bit reversal applied to it, before it is written to the destination. The action for each destination byte is determined by a corresponding control byte. The VPPERM instruction allows either the second 16-byte input array or the control array to be memory based, per the XOP.W bit.

4.6.2 Data Conversion

The integer data-conversion instructions convert integer operands to floating-point operands. These instructions take integer source operands. For data-conversion instructions that take floating-point source operands, see "Data Conversion" on page 190. For data-conversion instructions that take 64-bit source operands, see Section 5.6.4 "Data Conversion" on page 257 and Section 5.7.2 "Data Conversion" on page 271.

4.6.2.1 Convert Integer to Floating-Point

These instructions convert integer data types in a YMM/XMM register or memory into floating-point data types in a YMM/XMM register.

- (V)CVTDQ2PS—Convert Packed Doubleword Integers to Packed Single-Precision Floating-Point
- (V)CVTDQ2PD—Convert Packed Doubleword Integers to Packed Double-Precision Floating-Point

The (V)CVTDQ2PS instruction converts four (eight, for 256-bit form) 32-bit signed integer values in the second operand to four (eight) single-precision floating-point values and writes the converted values to the specified XMM (YMM) register. If the result of the conversion is an inexact value, the value is rounded. The (V)CVTDQ2PD instruction is analogous to (V)CVTDQ2PS except that it converts two (four) 64-bit signed integer values to two (four) double-precision floating-point values.

4.6.2.2 Convert MMX Integer to Floating-Point

These instructions convert integer data types in MMX registers or memory into floating-point data types in XMM registers.

- CVTPI2PS—Convert Packed Doubleword Integers to Packed Single-Precision Floating-Point
- CVTPI2PD—Convert Packed Doubleword Integers to Packed Double-Precision Floating-Point

The CVTPI2PS instruction converts two 32-bit signed integer values in an MMX register or a 64-bit memory location to two single-precision floating-point values and writes the converted values in the low-order 64 bits of an XMM register. The high-order 64 bits of the XMM register are not modified.

The CVTPI2PD instruction is analogous to CVTPI2PS except that it converts two 32-bit signed integer values to two double-precision floating-point values and writes the converted values in the full 128 bits of an XMM register.

Before executing a CVTPI2*x* instruction, software should ensure that the MMX registers are properly initialized so as to prevent conflict with their aliased use by x87 floating-point instructions. This may require clearing the MMX state, as described in "Accessing Operands in MMX™ Registers" on page 232.

For a description of SSE instructions that convert in the opposite direction—floating-point to integer in MMX registers—see "Convert Floating-Point to MMX™ Integer" on page 192. For a summary of instructions that operate on MMX registers, see Chapter 5, "64-Bit Media Programming."

4.6.2.3 Convert GPR Integer to Floating-Point

These instructions convert integer data types in GPR registers or memory into floating-point data types in XMM registers.

- (V)CVTSI2SS—Convert Signed Doubleword or Quadword Integer to Scalar Single-Precision Floating-Point
- (V)CVTSI2SD—Convert Signed Doubleword or Quadword Integer to Scalar Double-Precision Floating-Point

The (V)CVTSI2SS instruction converts a 32-bit or 64-bit signed integer value in a general-purpose register or memory location to a single-precision floating-point value and writes the converted value to the low-order 32 bits of an XMM register. The legacy version of the instruction leaves the three high-order doublewords of the destination XMM register unmodified. The extended version of the instruction copies the three high-order doublewords of another XMM register (specified in the first source operand) to the destination.

The (V)CVTSI2SD instruction converts a 32-bit or 64-bit signed integer value in a general-purpose register or memory location to a double-precision floating-point value and writes the converted value to the low-order 64 bits of an XMM register. The legacy version of the instruction leaves the high-order 64 bits in the destination XMM register unmodified. The extended version of the instruction copies the upper 64 bits of another XMM register (specified in the first source operand) to the destination.

4.6.2.4 Convert Packed Integer Format

A common operation on packed integers is the conversion by zero or sign extension of packed integers into wider data types. These instructions convert from a smaller packed integer type to a larger integer type. Only the number of integers that will fit in the destination XMM or YMM register are converted starting with the least-significant integer in the source operand.

- (V)PMOVSXBW—Sign extend 8-bit integers in the source operand to 16 bits and pack into destination register.
- (V)PMOVZXBW—Zero extend 8-bit integers in the source operand to 16 bits and pack into destination register.
- (V)PMOVSXBD—Sign extend 8-bit integers in the source operand to 32 bits and pack into destination register.
- (V)PMOVZXBD—Zero extend 8-bit integers in the source operand to 32 bits and pack into destination register.
- (V)PMOVSXWD—Sign extend 16-bit integers in the source operand to 32 bits and pack into destination register.
- (V)PMOVZXWD—Zero extend 16-bit integers in the source operand to 32 bits and pack into destination register.
- (V)PMOVSXBQ—Sign extend 8-bit integers in the source operand to 64 bits and pack into destination register.
- (V)PMOVZXBQ—Zero extend 8-bit integers in the source operand to 64 bits and pack into destination register.
- (V)PMOVSXWQ—Sign extend 16-bit integers in the source operand to 64 bits and pack into destination register.
- (V)PMOVZXWQ—Zero extend 16-bit integers in the source operand to 64 bits and pack into destination register.
- (V)PMOVSXDQ—Sign extend 32-bit integers in the source operand to 64 bits and pack into destination register.
- (V)PMOVZXDQ—Zero extend 32-bit integers in the source operand to 64 bits and pack into destination register.

The source operand is an XMM/YMM register or a 128-bit or 256-bit memory location. The destination is an XMM/YMM register. When accessing memory, no alignment is required for any of the instructions unless alignment checking is enabled. In which case, all conversions must be aligned to the width of the memory reference. The legacy form of these instructions support 128-bit operands. AVX2 adds support for 256-bit operands to the extended forms.

4.6.3 Data Reordering

The integer data-reordering instructions pack, unpack, interleave, extract, insert, and shuffle the elements of vector operands.

4.6.3.1 Pack with Saturation

These instructions pack larger data types into smaller data types, thus halving the precision of each element in a vector operand.

- (V)PACKSSDW—Pack with Saturation Signed Doubleword to Word
- (V)PACKUSDW—Pack with Unsigned Saturation Doubleword to Word
- (V)PACKSSWB—Pack with Saturation Signed Word to Byte
- (V)PACKUSWB—Pack with Saturation Signed Word to Unsigned Byte

PACKSSDW and the 128-bit form of VPACKSSDW convert each of the four signed doubleword integers in two source operands (an XMM register, and another XMM register or 128-bit memory location) into signed word integers and packs the converted values into the destination register. The 256-bit form of VPACKSSDW performs this operation separately on the upper and lower 128 bits of its operands. The (V)PACKUSDW instruction does the same operation except that it converts signed doubleword integers into unsigned (rather than signed) word integers.

PACKSSWB and the 128-bit form of VPACKSSWB convert each of the eight signed word integers in two source operands (an XMM register, and another XMM register or 128-bit memory location) into signed 8-bit integers and packs the converted values into the destination register. The 256-bit form of VPACKSSDW performs this operation separately on the upper and lower 128 bits of its operands. The (V)PACKUSWB instruction does the same operation except that it converts signed word integers into unsigned (rather than signed) bytes.

Figure 4-26 shows an example of a (V)PACKSSDW instruction using the example of 128-bit vector operands. The operation merges vector elements of 2x size into vector elements of 1x size, thus reducing the precision of the vector-element data types. Any results that would otherwise overflow or underflow are saturated (clamped) at the maximum or minimum representable value, respectively, as described in “Saturation” on page 122.

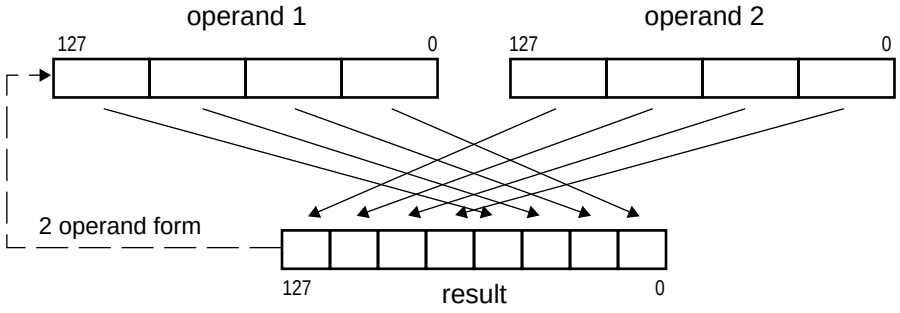

Figure 4-26. (V)PACKSSDW Pack Operation

Conversion from higher-to-lower precision is often needed, for example, by multiplication operations in which the higher-precision format is used for source operands in order to prevent possible overflow, and the lower-precision format is the desired format for the next operation.

4.6.3.2 Packed Blend

These instructions select vector elements from one of two source operands to be copied to the corresponding elements of the destination.

- (V)PBLENDVB—Variable Blend Packed Bytes
- (V)PBLENDW—Blend Packed Words

(V)PBLENDVB and (V)PBLENDW instructions copy bytes or words from either of two sources to the specified destination register based on selector bits in a mask. If the mask bit is a 0 the corresponding element is copied from the first source operand. If the mask bit is a 1, the element is copied from the second source operand.

For (V)PBLENDVB the mask is composed of the most significant bits of the elements of a third source operand. For the legacy instruction PBLENDVB, the mask is contained in the implicit operand register XMM0. For the extended form, the mask is contained in an XMM or YMM register specified via encoding in the instruction. For (V)PBLENDW the mask is specified via an immediate byte.

For the legacy form and the 128-bit extended form of these instructions, the first source operand is an XMM register and the second source operand is either an XMM register or a 128-bit memory location. For the 256-bit extended form, the first source operand is an YMM register and the second source operand is either an YMM register or a 256-bit memory location.

For the legacy instructions, the destination is also the first source operand. For the extended forms, the destination is a separately specified YMM/XMM register.

AVX2 adds support for 256-bit operands to the AVX forms of these instructions.

4.6.3.3 Unpack and Interleave

These instructions interleave vector elements from either the high or low halves of two source operands.

- (V)PUNPCKHBW—Unpack and Interleave High Bytes
- (V)PUNPCKHWD—Unpack and Interleave High Words
- (V)PUNPCKHDQ—Unpack and Interleave High Doublewords
- (V)PUNPCKHQDQ—Unpack and Interleave High Quadwords
- (V)PUNPCKLBW—Unpack and Interleave Low Bytes
- (V)PUNPCKLWD—Unpack and Interleave Low Words
- (V)PUNPCKLDQ—Unpack and Interleave Low Doublewords
- (V)PUNPCKLQDQ—Unpack and Interleave Low Quadwords

The (V)PUNPCKHBW instruction copies the eight high-order bytes from its two source operands and interleaves them into the destination register. The bytes in the low-order half of the source operands are ignored. The (V)PUNPCKHWD, (V)PUNPCKHDQ, and (V)PUNPCKHQDQ instructions perform analogous operations for words, doublewords, and quadwords in the source operands,

packing them into interleaved words, interleaved doublewords, and interleaved quadwords in the destination.

The (V)PUNPCKLBW, (V)PUNPCKLWD, (V)PUNPCKLDQ, and (V)PUNPCKLQDQ instructions are analogous to their high-element counterparts except that they take elements from the low quadword of each source vector and ignore elements in the high quadword.

Depending on the hardware implementation, if the second source operand is located in memory, the 64 bits of the operand not required to perform the operation may or may not be read.

Figure 4-27 shows an example of the (V)PUNPCKLWD instruction using the example of 128-bit vector operands. The elements are taken from the low half of the source operands. Elements from the second source operand are placed to the left of elements from first source operand.

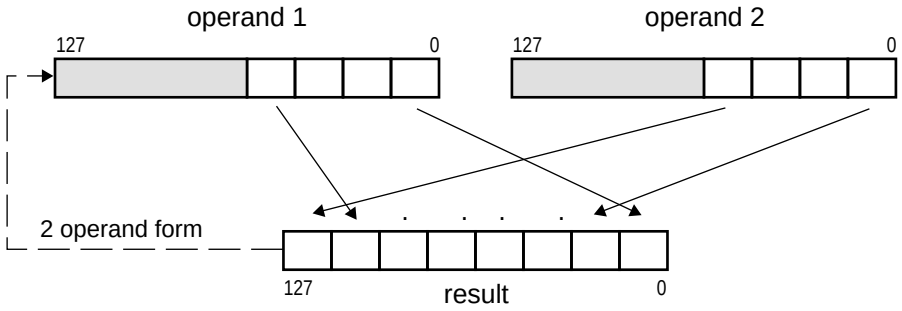

Figure 4-27. (V)PUNPCKLWD Unpack and Interleave Operation

If operand 2 is a vector consisting of all zero-valued elements, the unpack instructions perform the function of expanding vector elements of 1x size into vector elements of 2x size. Conversion from lower-to-higher precision is often needed, for example, prior to multiplication operations in which the higher-precision format is used for source operands in order to prevent possible overflow during multiplication.

If both source operands are of identical value, the unpack instructions can perform the function of duplicating adjacent elements in a vector.

The (V)PUNPCK*x* instructions can be used in a repeating sequence to transpose rows and columns of an array. For example, such a sequence could begin with (V)PUNPCK*x*WD and be followed by (V)PUNPCK*x*QD**.** These instructions can also be used to convert pixel representation from RGB format to color-plane format, or to interleave interpolation elements into a vector.

AVX2 adds support for 256-bit operands. When the operand size is 256 bits, the unpack and interleave operation is performed independently on the upper and lower halves of the source operands and the results written to the respective 128 bits of the destination YMM register.

4.6.3.4 Extract and Insert

These instructions copy a word element from a vector, in a manner specified by an immediate operand.

- EXTRQ—Extract Field from Register
- INSERTQ—Insert Field
- (V)PEXTRB—Extract Packed Byte
- (V)PEXTRW—Extract Packed Word
- (V)PEXTRD—Extract Packed Doubleword
- (V)PEXTRQ—Extract Packed Quadword
- (V)PINSRB—Packed Insert Byte
- (V)PINSRW—Packed Insert Word
- (V)PINSRD—Packed Insert Doubleword
- (V)PINSRQ—Packed Insert Quadword

The EXTRQ instruction extracts specified bits from the lower 64 bits of the destination XMM register. The extracted bits are saved in the least-significant bit positions of the destination and the remaining bits in the lower 64 bits of the destination register are cleared to 0. The upper 64 bits of the destination register are undefined.

The INSERTQ instruction inserts a specified number of bits from the lower 64 bits of the source operand into a specified bit position of the lower 64 bits of the destination operand. No other bits in the lower 64 bits of the destination are modified. The upper 64 bits of the destination are undefined.

The (V)PEXTRB, (V)PEXTRW, (V)PEXTRD, and (V)PEXTRQ instructions extract a single byte, word, doubleword, or quadword from an XMM register, as selected by the immediate-byte operand, and write it to memory or to the low-order bits of a general-purpose register with zero-extension to 32 bit or 64 bits as required. These instructions are useful for loading computed values, such as table-lookup indices, into general-purpose registers where the values can be used for addressing tables in memory.

The (V)PINSRB, (V)PINSRW, (V)PINSRD, and (V)PINSRQ instructions insert a byte, word, or doubleword value from the low-order bits of a general-purpose register or from a memory location into an XMM register. The location in the destination register is selected by the immediate-byte operand. For the legacy form, the other elements of the destination register are not modified. For the extended form, the other elements are filled in from a second source XMM register. As an example of these instructions, Figure 4-28 below provides a schematic the (V)PINSRD instruction.

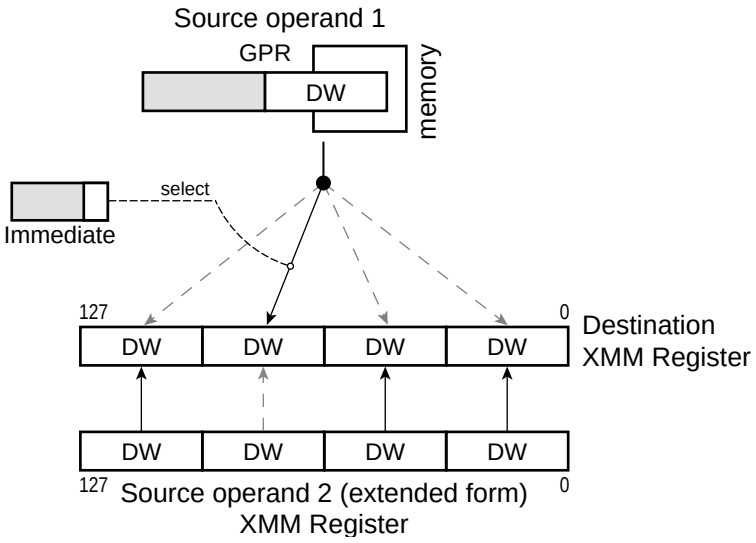

Figure 4-28. (V)PINSRD Operation

4.6.3.5 Shuffle

These instructions reorder the elements of a vector.

- (V)PSHUFB—Packed Shuffle Byte
- (V)PSHUFD—Packed Shuffle Doublewords
- (V)PSHUFHW—Packed Shuffle High Words
- (V)PSHUFLW—Packed Shuffle Low Words

The (V)PSHUFB instruction copies bytes from the first source operand to the destination or clears bytes in the destination as specified by control bytes in the second source operand. Each byte in the second operand controls how the corresponding byte is the destination is selected or cleared.

For PSHUFB and the 128-bit version of VPSHUFB, the first source operand is an XMM register and the second source operand is either an XMM register or a 128-bit memory location. For the 256-bit version of the extended form, the first source operand is a YMM register and the second source operand is either a YMM register or a 256-bit memory location. For the legacy form, the first source XMM register is also the destination. For the extended form, a separate destination register is specified in the instruction.

The (V)PSHUFD instruction fills each doubleword of the destination register by copying any one of the doublewords in the source operand . An immediate byte operand specifies for each double word of the destination which doubleword to copy. For the 256-bit version of the extended form, the immediate byte is reused to specify the shuffle operation for the upper four doublewords of the destination YMM register.

The ordering of the shuffle can occur in one of 256 possible ways for a 128-bit destination or for each half of a 256-bit destination.

Figure 4-29 below shows one of the 256 possible shuffle operations using the example of a 128-bit source and destination.

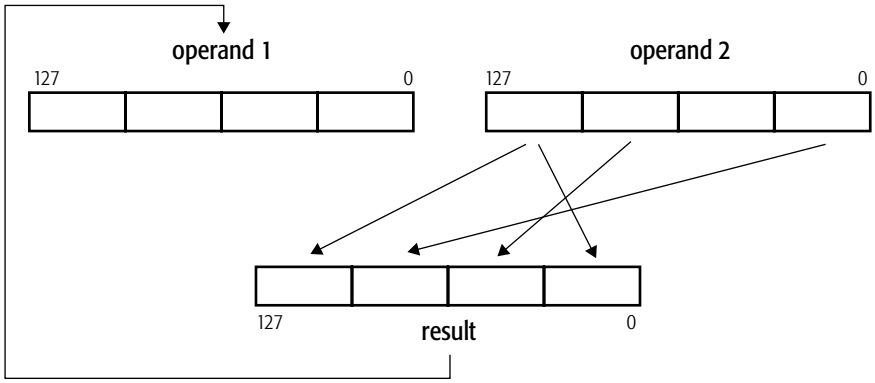

Figure 4-29. (V)PSHUFD Shuffle Operation

For the PSHUFD and the 128-bit version of VPSHUFD, the source operand is an XMM register or a 128-bit memory location and the destination is an XMM register. For the 256-bit version of VPSHUFD, the source operand is a YMM register or a 256-bit memory location and the destination is a YMM register.

The (V)PSHUFHW and (V)PSHUFLW instructions are analogous to (V)PSHUFD, except that they fill each word of the high or low quadword, respectively, of the destination register by copying any one of the four words in the high or low quadword of the source operand. The 256-bit version of the extended form of these instructions repeats the same operation on the high or low quadword, respectively, of the upper half of the destination YMM register using either the high or low quadword of the upper half of the source operand.

Figure 4-30 shows the (V)PSHUFHW operation using the example of a 128-bit source and destination.

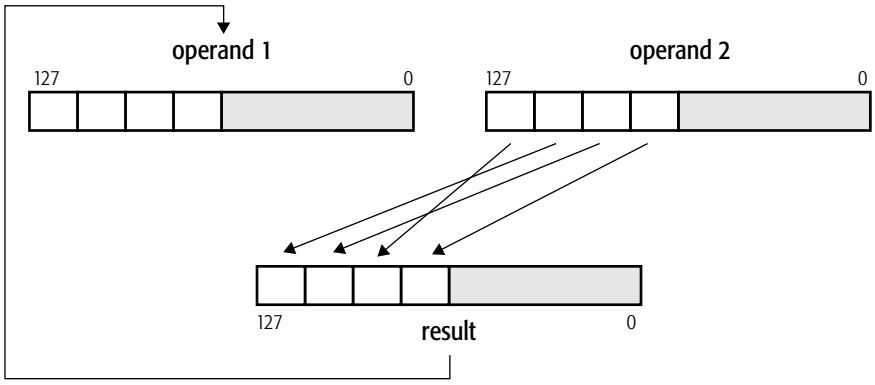

Figure 4-30. (V)PSHUFHW Shuffle Operation

(V)PSHUFHW and (V)PSHUFLW are useful, for example, in color imaging when computing alpha saturation of RGB values. In this case, (V)PSHUF*x*W can replicate an alpha value in a register so that parallel comparisons with three RGB values can be performed.

AVX2 adds support for 256-bit operands to the AVX forms of these instructions.

4.6.4 Arithmetic

Arithmetic operations can be unary or binary. A unary operation has a single operand and produces a single result. A binary operation has two operands that are combined arithmetically to produce a result. A vector arithmetic operation applies the same operation independently to all elements of a vector.

Figure 4-31 shows a typical unary vector operation. Figure 4-32 on page 165 shows a typical binary vector arithmetic operation.

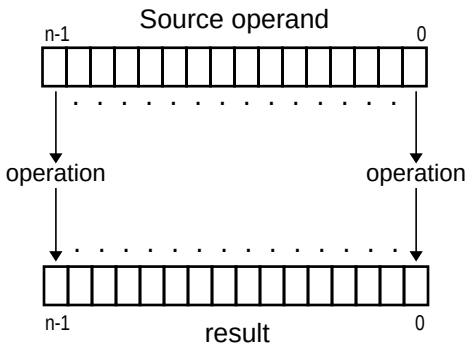

Figure 4-31. Unary Vector Arithmetic Operation

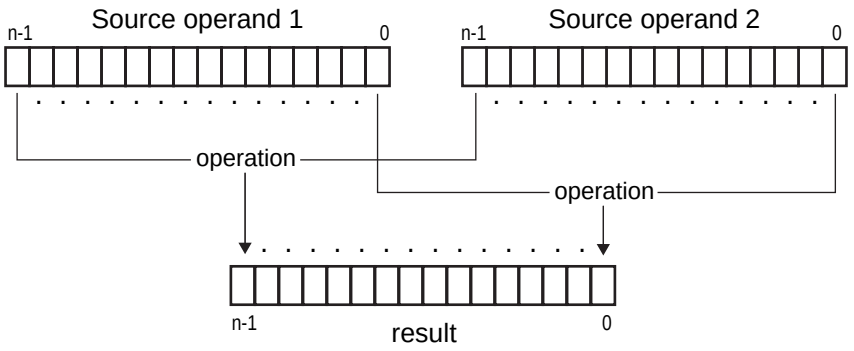

Figure 4-32. Binary Vector Arithmetic Operation

4.6.4.1 Absolute Value

- (V)PABSB—Packed Absolute Value Signed Byte
- (V)PABSW—Packed Absolute Value Signed Word
- (V)PABSD—Packed Absolute Value Signed Doubleword

These instructions operate on a vector of signed 8-bit, 16-bit, or 32-bit integers and produce a vector of unsigned integers of the same data width. Each element of the result is the absolute value of the corresponding element of the source operand. The AVX form of these instructions supports 128-bit operands and the AVX2 form supports 256-bit operands.

4.6.4.2 Addition

- (V)PADDB—Packed Add Bytes
- (V)PADDW—Packed Add Words
- (V)PADDD—Packed Add Doublewords
- (V)PADDQ—Packed Add Quadwords
- (V)PADDSB—Packed Add with Saturation Bytes
- (V)PADDSW—Packed Add with Saturation Words
- (V)PADDUSB—Packed Add Unsigned with Saturation Bytes
- (V)PADDUSW—Packed Add Unsigned with Saturation Words

The (V)PADDB, (V)PADDW, (V)PADDD, and (V)PADDQ instructions add each packed 8-bit ((V)PADDB), 16-bit ((V)PADDW), 32-bit ((V)PADDD), or 64-bit ((V)PADDQ) integer element in the second source operand to the corresponding same-sized integer element in the first source operand and write the integer result to the corresponding, same-sized element of the destination. Figure 4-32 diagrams a (V)PADDB operation (where the operation is addition). These instructions operate on both signed and unsigned integers. However, if the result overflows, the carry is ignored and only the low-order byte, word, doubleword, or quadword of each result is written to the destination. The

(V)PADDD instruction can be used together with (V)PMADDWD (page 169) to implement dot products.

The (V)PADDSB and (V)PADDSW instructions add each 8-bit ((V)PADDSB) or 16-bit ((V)PADDSW) signed integer element in the second source operand to the corresponding, same-sized signed integer element in the first source operand and write the signed integer result to the corresponding same-sized element of the destination. For each result in the destination, if the result is larger than the largest, or smaller than the smallest, representable 8-bit ((V)PADDSB) or 16-bit ((V)PADDSW) signed integer, the result is saturated to the largest or smallest representable value, respectively.

The (V)PADDUSB and (V)PADDUSW instructions perform saturating-add operations analogous to the (V)PADDSB and (V)PADDSW instructions, except on unsigned integer elements.

For the legacy form and 128-bit extended form of these instructions, the first source operand is an XMM register and the second source operand is either an XMM register or a 128-bit memory location. For the 256-bit extended form, the first source operand is a YMM register and the second source operand is either a YMM register or a 256-bit memory location. For the legacy form, the first source XMM register is also the destination. For the extended form, a separate destination register is specified in the instruction.

AVX2 adds support for 256-bit operands to the AVX forms of these instructions.

4.6.4.3 Subtraction

- (V)PSUBB—Packed Subtract Bytes
- (V)PSUBW—Packed Subtract Words
- (V)PSUBD—Packed Subtract Doublewords
- (V)PSUBQ—Packed Subtract Quadword
- (V)PSUBSB—Packed Subtract with Saturation Bytes
- (V)PSUBSW—Packed Subtract with Saturation Words
- (V)PSUBUSB—Packed Subtract Unsigned and Saturate Bytes
- (V)PSUBUSW—Packed Subtract Unsigned and Saturate Words

The subtraction instructions perform operations analogous to the addition instructions.

The (V)PSUBB, (V)PSUBW, (V)PSUBD, and (V)PSUBQ instructions subtract each 8-bit ((V)PSUBB), 16-bit ((V)PSUBW), 32-bit ((V)PSUBD), or 64-bit ((V)PSUBQ) integer element in the second operand from the corresponding, same-sized integer element in the first operand and write the integer result to the corresponding, same-sized element of the destination. For vectors of *n* number of elements, the operation is:

```
result[i] = operand1[i] - operand2[i]
```

where: i = 0 to n – 1

These instructions operate on both signed and unsigned integers. However, if the result underflows, the borrow is ignored and only the low-order byte, word, doubleword, or quadword of each result is written to the destination.

The (V)PSUBSB and (V)PSUBSW instructions subtract each 8-bit ((V)PSUBSB) or 16-bit ((V)PSUBSW) signed integer element in the second operand from the corresponding, same-sized signed integer element in the first operand and write the signed integer result to the corresponding, same-sized element of the destination. For each result in the destination, if the result is larger than the largest, or smaller than the smallest, representable 8-bit ((V)PSUBSB) or 16-bit ((V)PSUBSW) signed integer, the result is saturated to the largest or smallest representable value, respectively.

The (V)PSUBUSB and (V)PSUBUSW instructions perform saturating-add operations analogous to the (V)PSUBSB and (V)PSUBSW instructions, except on unsigned integer elements.

For the legacy form and 128-bit extended form of these instructions, the first source operand is an XMM register and the second source operand is either an XMM register or a 128-bit memory location. For the 256-bit extended form, the first source operand is a YMM register and the second source operand is either a YMM register or a 256-bit memory location. For the legacy form, the first source XMM register is also the destination. For the extended form, a separate destination register is specified in the instruction.

AVX2 adds support for 256-bit operands to the AVX forms of these instructions.

4.6.4.4 Multiplication

- (V)PMULHW—Packed Multiply High Signed Word
- (V)PMULHRSW—Packed Multiply High with Round and Scale Words
- (V)PMULLW—Packed Multiply Low Signed Word
- (V)PMULHUW—Packed Multiply High Unsigned Word
- (V)PMULUDQ—Packed Multiply Unsigned Doubleword to Quadword
- (V)PMULLD—Packed Multiply Low Signed Doubleword
- (V)PMULDQ—Packed Multiply Double Quadword

The (V)PMULHW instruction multiplies each 16-bit signed integer value in the first operand by the corresponding 16-bit integer in the second operand, producing a 32-bit intermediate result. The instruction then writes the high-order 16 bits of the 32-bit intermediate result of each multiplication to the corresponding word of the destination. The (V)PMULHRSW instruction performs the same multiplication as (V)PMULHW but rounds and scales the 32-bit intermediate result prior to truncating it to 16 bits. The (V)PMULLW instruction performs the same multiplication as (V)PMULHW but writes the low-order 16 bits of the 32-bit intermediate result to the corresponding word of the destination.

Figure 4-33 below shows the (V)PMULHW, (V)PMULLW, and (V)PMULHW instruction operations. The difference between the instructions is the manner in which the intermediate element result is reduced to 16 bits prior writing it to the destination.

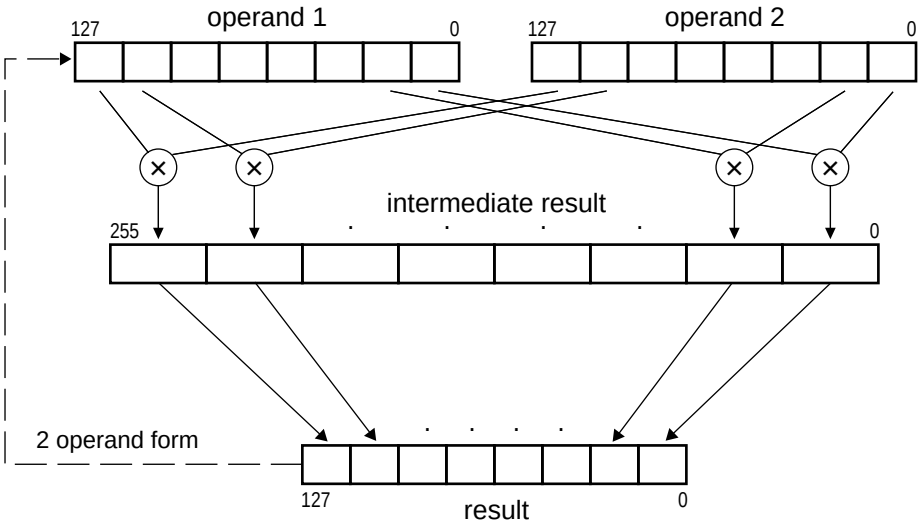

Figure 4-33. (V)PMULHW, (V)PMULLW, and (V)PMULHRSW Instructions

The (V)PMULHUW instruction performs the same multiplication as (V)PMULHW but on unsigned operands. Without this instruction, it is difficult to perform unsigned integer multiplies using SSE instructions. The instruction is useful in 3D rasterization, which operates on unsigned pixel values.

The (V)PMULUDQ instruction preserves the full precision of results by multiplying only half of the source-vector elements. It multiplies together the least significant doubleword (treating each as an unsigned 32-bit integer) of each quadword in the two source operands, writes the full 64-bit result of the low-order multiply to the low-order quadword of the destination, and writes the high-order product to the high-order quadword of the destination. Figure 4-34 below shows a (V)PMULUDQ operation using the example of 128-bit operands.

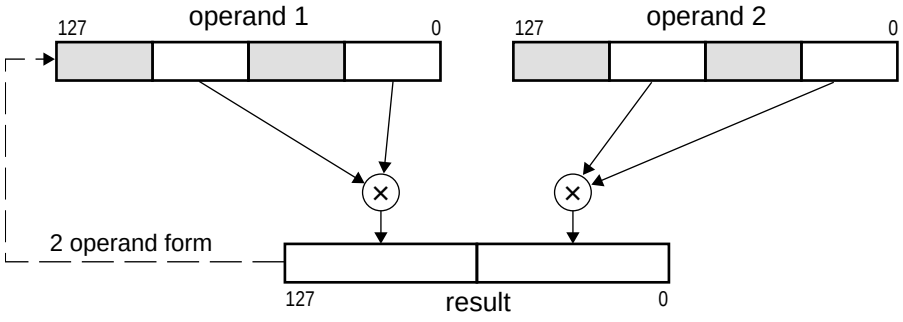

Figure 4-34. (V)PMULUDQ Multiply Operation

The 256-bit form of VPMULUDQ instruction performs the same operation on each half of the source operands to produce a 256-bit packed quadword result.

The (V)PMULLD instruction writes the lower 32 bits of the 64-bit product of a signed 32-bit integer multiplication of the corresponding doublewords of the source operands to each element of the destination.

PMULDQ and the 128-bit form of VPMULDQ writes the 64-bit signed product of the least-significant doubleword of the two source operands to the low quadword of the result and the 64-bit signed product of the low doubleword of the upper quadword of two source operands (bits [95:64]) to the upper quadword of the result. The 256-bit form of VPMULDQ performs similar operations on the upper 128 bits of the source operands to produce the upper 128 bits of the result.

For the legacy form and 128-bit extended form of these instructions, the first source operand is an XMM register and the second source operand is either an XMM register or a 128-bit memory location. For the 256-bit extended form, the first source operand is a YMM register and the second source operand is either a YMM register or a 256-bit memory location. For the legacy form, the first source XMM register is also the destination. For the extended form, a separate destination register is specified in the instruction.

AVX2 adds support for 256-bit operands to the AVX forms of these instructions.

See “Shift and Rotate” on page 175 for shift instructions that can be used to perform multiplication and division by powers of 2.

4.6.4.5 Multiply-Add

This instruction multiplies the elements of two source vectors and adds their intermediate results in a single operation.

- (V)PMADDWD—Packed Multiply Words and Add Doublewords

The (V)PMADDWD instruction multiplies each 16-bit signed value in the first source operand by the corresponding 16-bit signed value in the second source operand. The instruction then adds the adjacent 32-bit intermediate results of each multiplication, and writes the 32-bit result of each addition into the corresponding doubleword of the destination. For vectors of *n* number of source elements (src), *m* number of destination elements (dst), and n = 2m, the operation is:

```
dst[j] = ((src1[i] * src2[i]) + (src1[i+1] * src2[i+1]))
```

where: j = 0 to m – 1
i = 2j

(V)PMADDWD thus performs four or eight signed multiply-adds in parallel. Figure 4-35 below diagrams the operation using the example of 128-bit operands.

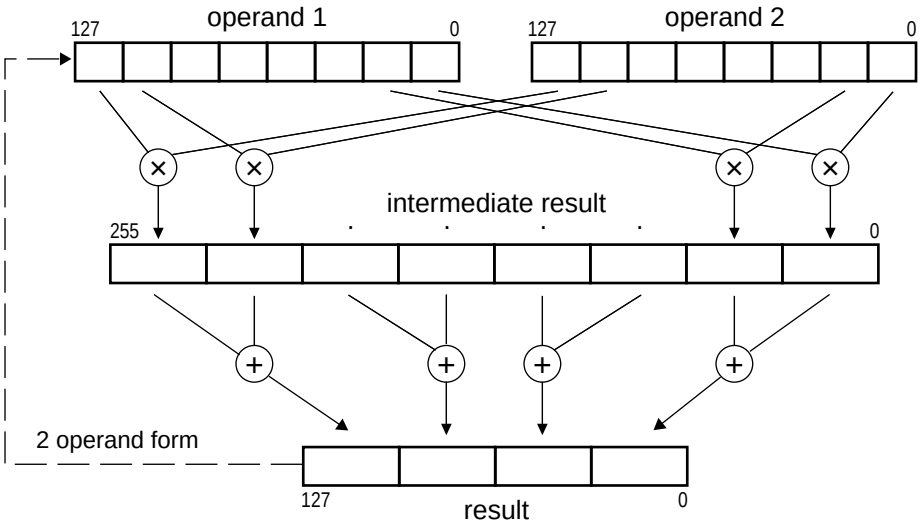

Figure 4-35. (V)PMADDWD Multiply-Add Operation

(V)PMADDWD can be used with one source operand (for example, a coefficient) taken from memory and the other source operand (for example, the data to be multiplied by that coefficient) taken from an XMM/YMM register. The instruction can also be used together with the (V)PADDD instruction (page 165) to compute dot products. Scaling can be done, before or after the multiply, using a vector-shift instruction (page 175).

For PMADDWD, the first source XMM register is also the destination. VPMADDWD specifies a separate destination XMM/YMM register encoded in the instruction. AVX2 adds support for 256-bit operands to the AVX forms of these instructions.

4.6.5 Enhanced Media

4.6.5.1 Multiply-Add and Accumulate

The multiply and accumulate and multiply, add and accumulate instructions operate on and produce packed signed integer values. These instructions allow the accumulation of results from (possibly) many iterations of similar operations without a separate intermediate addition operation to update the accumulator register.

The operation of a typical XOP integer multiply and accumulate instruction is shown in Figure 4-36 on page 171. The multiply and accumulate instructions operate on and produce packed signed integer values. These instructions first multiply the value in the first source operand by the corresponding value in the second source operand. Each signed integer product is then added to the corresponding value in the third source operand, which is the accumulator and is identical to the destination operand. The results may or may not be saturated prior to being written to the destination register, depending on the instruction.

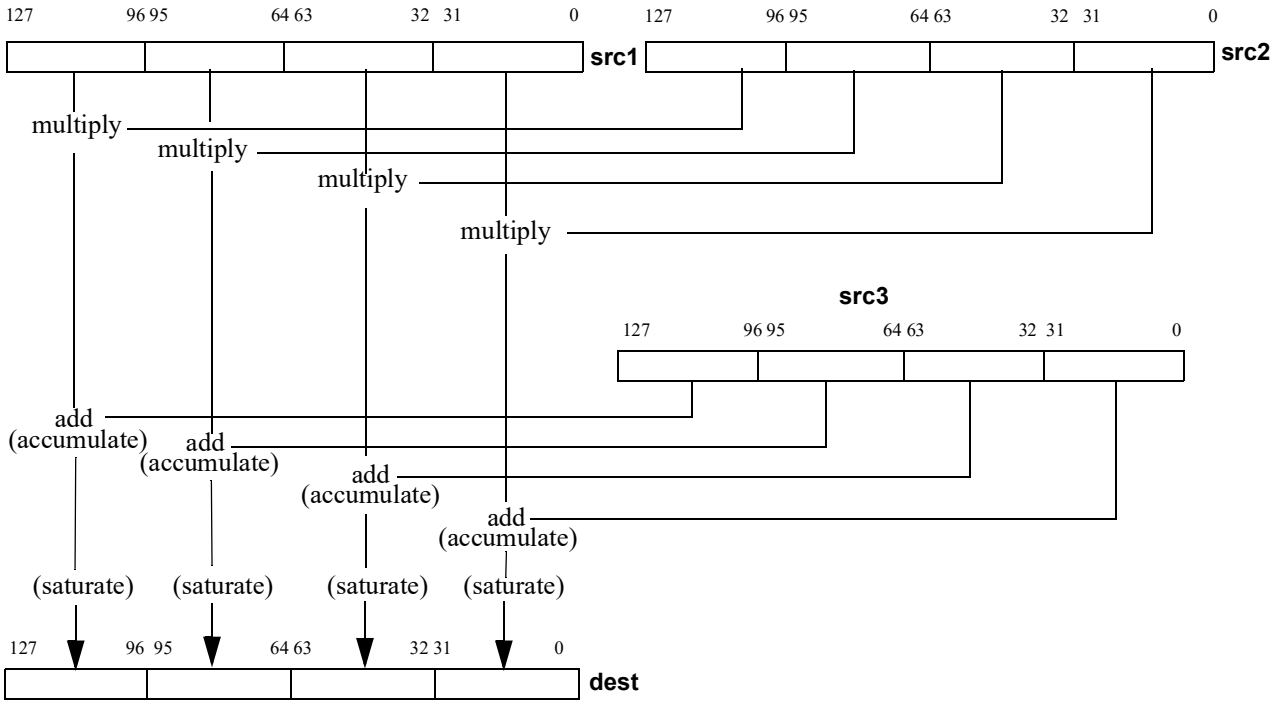

Figure 4-36. Operation of Multiply and Accumulate Instructions

The XOP instruction extensions provide the following integer multiply and accumulate instructions.

- VPMACSSWW—Packed Multiply Accumulate Signed Word to Signed Word with Saturation
- VPMACSWW—Packed Multiply Accumulate Signed Word to Signed Word
- VPMACSSWD—Packed Multiply Accumulate Signed Word to Signed Doubleword with Saturation
- VPMACSWD—Packed Multiply Accumulate Signed Word to Signed Doubleword
- VPMACSSDD—Packed Multiply Accumulate Signed Doubleword to Signed Doubleword with Saturation
- VPMACSDD—Packed Multiply Accumulate Signed Doubleword to Signed Doubleword
- VPMACSSDQL—Packed Multiply Accumulate Signed Low Doubleword to Signed Quadword with Saturation
- VPMACSSDQH—Packed Multiply Accumulate Signed High Doubleword to Signed Quadword with Saturation
- VPMACSDQL—Packed Multiply Accumulate Signed Low Doubleword to Signed Quadword
- VPMACSDQH—Packed Multiply Accumulate Signed High Doubleword to Signed Quadword

The operation of the multiply, add and accumulate instructions is illustrated in Figure 4-37.

The multiply, add and accumulate instructions first multiply each packed signed integer value in the first source operand by the corresponding packed signed integer value in the second source operand. The odd and even adjacent resulting products are then added. Each resulting sum is then added to the corresponding packed signed integer value in the third source operand.

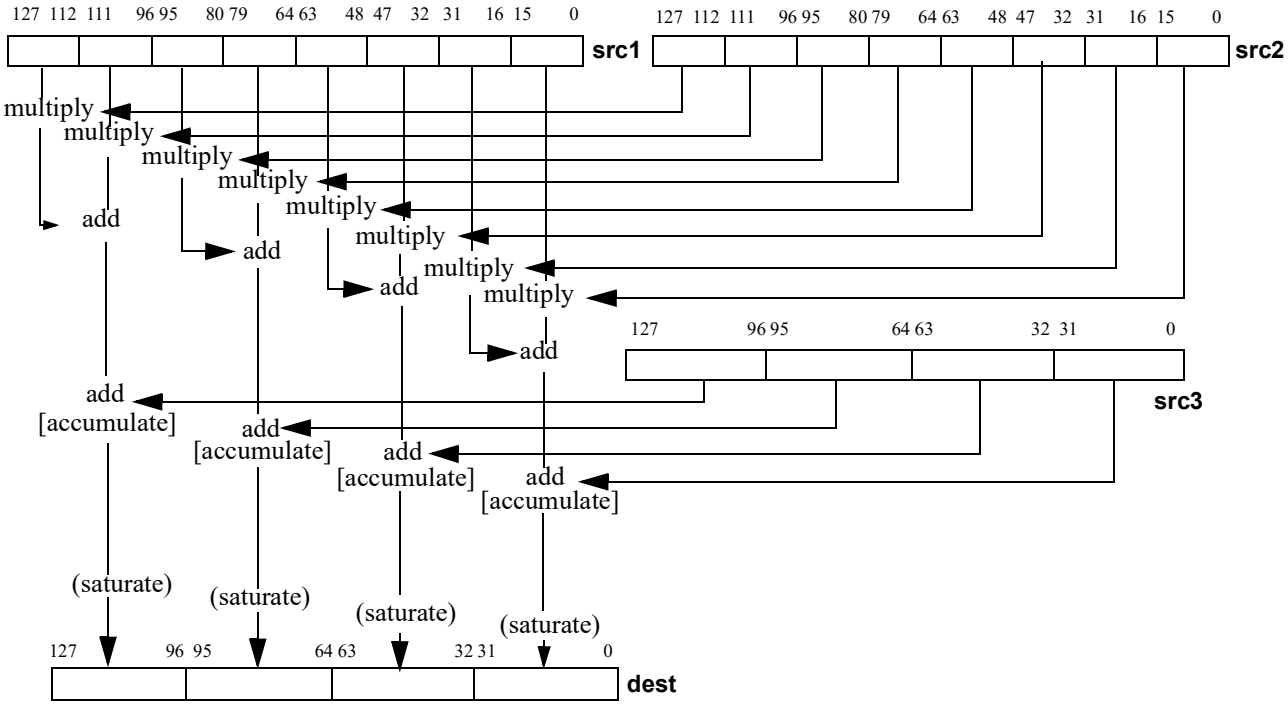

Figure 4-37. Operation of Multiply, Add and Accumulate Instructions

The XOP instruction set provides the following integer multiply, add and accumulate instructions.

- VPMADCSSWD—Packed Multiply Add and Accumulate Signed Word to Signed Doubleword with Saturation
- VPMADCSWD—Packed Multiply Add and Accumulate Signed Word to Signed Doubleword

4.6.5.2 Packed Integer Horizontal Add and Subtract

The packed horizontal add and subtract signed byte instructions successively add adjacent pairs of signed integer values from the source XMM register or 128-bit memory operand and pack the (sign extended) integer result of each addition in the destination.

- VPHADDBW—Packed Horizontal Add Signed Byte to Signed Word
- VPHADDBD—Packed Horizontal Add Signed Byte to Signed Doubleword
- VPHADDBQ—Packed Horizontal Add Signed Byte to Signed Quadword
- VPHADDDQ—Packed Horizontal Add Signed Doubleword to Signed Quadword

- VPHADDUBW—Packed Horizontal Add Unsigned Byte to Word
- VPHADDUBD—Packed Horizontal Add Unsigned Byte to Doubleword
- VPHADDUBQ—Packed Horizontal Add Unsigned Byte to Quadword
- VPHADDUWD—Packed Horizontal Add Unsigned Word to Doubleword
- VPHADDUWQ—Packed Horizontal Add Unsigned Word to Quadword
- VPHADDUDQ—Packed Horizontal Add Unsigned Doubleword to Quadword
- VPHADDWD—Packed Horizontal Add Signed Word to Signed Doubleword
- VPHADDWQ—Packed Horizontal Add Signed Word to Signed Quadword
- VPHSUBBW—Packed Horizontal Subtract Signed Byte to Signed Word
- VPHSUBWD—Packed Horizontal Subtract Signed Word to Signed Doubleword
- VPHSUBDQ—Packed Horizontal Subtract Signed Doubleword to Signed Quadword

4.6.5.3 Average

- (V)PAVGB—Packed Average Unsigned Bytes
- (V)PAVGW—Packed Average Unsigned Words

The (V)PAVG*x* instructions compute the rounded average of each unsigned 8-bit ((V)PAVGB) or 16-bit ((V)PAVGW) integer value in the first operand and the corresponding, same-sized unsigned integer in the second operand and write the result in the corresponding, same-sized element of the destination. The rounded average is computed by adding each pair of operands, adding 1 to the temporary sum, and then right-shifting the temporary sum by one bit-position. For vectors of *n* number of elements, the operation is:

```
operand1[i] = ((operand1[i] + operand2[i]) + 1) ÷ 2
```

where: i = 0 to n – 1

The (V)PAVGB instruction is useful for MPEG decoding, in which motion compensation performs many byte-averaging operations between and within macroblocks. In addition to speeding up these operations, (V)PAVGB can free up registers and make it possible to unroll the averaging loops.

The legacy form of these instructions support 128-bit operands. AVX2 adds support for 256-bit operands to the AVX forms of these instructions.

4.6.5.4 Sum of Absolute Differences

- (V)PSADBW—Packed Sum of Absolute Differences of Bytes into a Word

The (V)PSADBW instruction computes the absolute values of the differences of corresponding 8-bit signed integer values in the two quadword halves of both source operands, sums the differences for each quadword half, and writes the two unsigned 16-bit integer results in the destination. The sum for the high-order half is written in the least-significant word of the destination's high-order quadword, with the remaining bytes cleared to all 0s. The sum for the low-order half is written in the least-significant word of the destination's low-order quadword, with the remaining bytes cleared to all 0s.

Figure 4-38 shows the (V)PSADBW operation. Sums of absolute differences are useful, for example, in computing the L1 norm in motion-estimation algorithms for video compression.

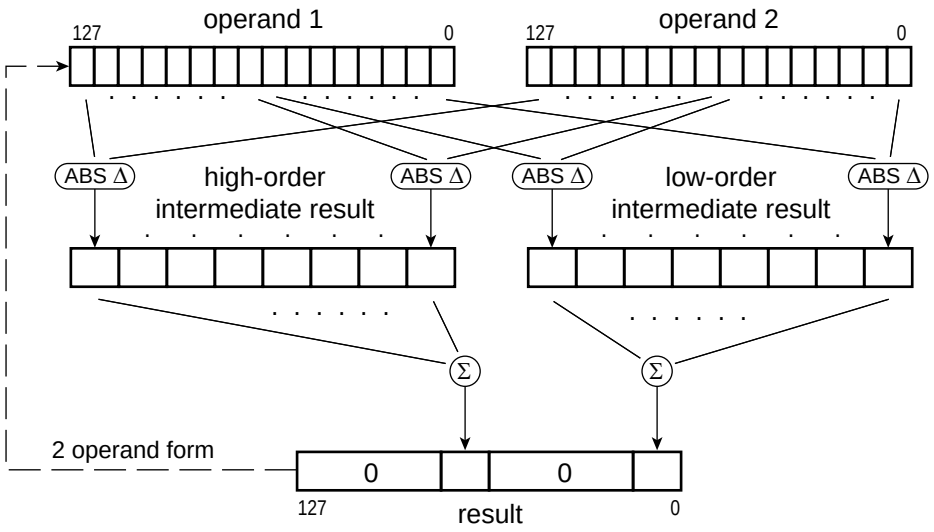

Figure 4-38. (V)PSADBW Sum-of-Absolute-Differences Operation

For PSADBW, the first source XMM register is also the destination. VPSADBW specifies a separate destination YMM/XMM register encoded in the instruction.

AVX2 extends the function of VPSADBW to operate on 256-bit operands and produce 4 sums of absolute differences.

4.6.5.5 Improved Sums of Absolute Differences for 4-Byte Blocks

- (V)MPSADBW—Performs eight 4-byte wide Sum of Absolute Differences (SAD) operations to produce eight word integers.

The (V)MPSADBW instruction performs eight 4-byte wide SAD operations per instruction to produce eight results. Compared to (V)PSADBW, (V)MPSADBW operates on smaller chunks (4-byte instead of 8-byte chunks). This makes the instruction better suited to video coding standards such as VC.1 and H.264.

(V)MPSADBW performs four times the number of absolute difference operations than that of (V)PSADBW (per instruction). This can improve performance for dense motion searches.

(V)MPSADBW uses a 4-byte wide field from a source operand. The offset of the 4-byte field within the 128-bit source operand is specified by two immediate control bits. (V)MPSADBW produces eight 16-bit SAD results. Each 16-bit SAD result is formed from overlapping pairs of 4 bytes in the destination with the 4-byte field from the source operand. (V)MPSADBW uses eleven consecutive bytes in the destination operand. Its offset is specified by a control bit in the immediate byte (i.e. the offset can be from byte 0 or from byte 4).

For MPSADBW, the first source XMM register is also the destination. VMPSADBW specifies a separate destination YMM/XMM register encoded in the instruction.

AVX2 extends the function of VMPSADBW to operate on 256-bit operands and produce 16 sums of absolute differences.

4.6.6 Shift and Rotate

The vector-shift instructions are useful for scaling vector elements to higher or lower precision, packing and unpacking vector elements, and multiplying and dividing vector elements by powers of 2.

4.6.6.1 Left Logical Shift

- (V)PSLLW—Packed Shift Left Logical Words
- (V)PSLLD—Packed Shift Left Logical Doublewords
- (V)PSLLQ—Packed Shift Left Logical Quadwords
- (V)PSLLDQ—Packed Shift Left Logical Double Quadword

The (V)PSLLW, (V)PSLLD, and (V)PSLLQ instructions left-shift each of the 16-bit, 32-bit, or 64-bit values, respectively, in the first source operand by the number of bits specified in the second source operand. The instructions then write each shifted value into the corresponding, same-sized element of the destination. The low-order bits that are emptied by the shift operation are cleared to 0. The shift count (second source operand) is specified by the contents of a register, a value loaded from memory, or an immediate byte.

In integer arithmetic, left logical shifts effectively multiply unsigned operands by positive powers of 2. Thus, for vectors of *n* number of elements, the operation is:

$$operand1[i] = operand1[i] * 2^{operand2}$$

where: i = 0 to n – 1

The (V)PSLLDQ instruction differs from the other three left-shift instructions because it operates on bytes rather than bits. It left-shifts the value in a YMM/XMM register by the number of bytes specified in an immediate byte value.

In the legacy form of these instructions, the first source XMM register is also the destination. The extended form specifies a separate destination YMM/XMM register encoded in the instruction. AVX2 adds support for 256-bit operands to the extended form of these instructions.

4.6.6.2 Right Logical Shift

- (V)PSRLW—Packed Shift Right Logical Words
- (V)PSRLD—Packed Shift Right Logical Doublewords
- (V)PSRLQ—Packed Shift Right Logical Quadwords
- (V)PSRLDQ—Packed Shift Right Logical Double Quadword

The (V)PSRLW, (V)PSRLD, and (V)PSRLQ instructions right-shift each of the 16-bit, 32-bit, or 64-bit values, respectively, in the first source operand by the number of bits specified in the second source operand. The instructions then write each shifted value into the corresponding, same-sized element of the destination. The high-order bits that are emptied by the shift operation are cleared to 0. The shift count (second source operand) is specified by the contents of a register, a value loaded from memory, or an immediate byte.

In integer arithmetic, right logical bit-shifts effectively divide unsigned or positive-signed operands by positive powers of 2. Thus, for vectors of *n* number of elements, the operation is:

$$operand1[i] = operand1[i] \div 2^{operand2}$$

where: i = 0 to n – 1

The (V)PSRLDQ instruction differs from the other three right-shift instructions because it operates on bytes rather than bits. It right-shifts the value in a YMM/XMM register by the number of bytes specified in an immediate byte value. (V)PSRLDQ can be used, for example, to move the high 8 bytes of an XMM register to the low 8 bytes of the register. In some implementations, however, (V)PUNPCKHQDQ may be a better choice for this operation.

In the legacy form of these instructions, the first source XMM register is also the destination. The extended form specifies a separate destination YMM/XMM register encoded in the instruction. AVX2 adds support for 256-bit operands to the extended form of these instructions.

4.6.6.3 Right Arithmetic Shift

- (V)PSRAW—Packed Shift Right Arithmetic Words
- (V)PSRAD—Packed Shift Right Arithmetic Doublewords

The (V)PSRA*x* instructions right-shift each of the 16-bit ((V)PSRAW) or 32-bit ((V)PSRAD) values in the first operand by the number of bits specified in the second operand. The instructions then write each shifted value into the corresponding, same-sized element of the destination. The high-order bits that are emptied by the shift operation are filled with the sign bit of the initial value.

In integer arithmetic, right arithmetic shifts effectively divide signed operands by positive powers of 2. Thus, for vectors of *n* number of elements, the operation is:

$$operand1[i] = operand1[i] \div 2^{operand2}$$

where: i = 0 to n – 1

In the legacy form of these instructions, the first source XMM register is also the destination. The extended form specifies a separate destination YMM/XMM register encoded in the instruction. AVX2 adds support for 256-bit operands to the extended form of these instructions.

4.6.6.4 Packed Integer Shifts

The packed integer shift instructions shift each element of the vector in the first source XMM or 128-bit memory operand by the amount specified by a control byte contained in the least significant byte of the corresponding element of the second source operand. The result of each shift operation is returned

in the destination XMM register. This allows load-and-shift from memory operations, with either the source operand or the shift-count operand being memory-based, as indicated by the XOP.W bit. The XOP instruction set provides the following packed integer shift instructions:

- VPSHLB—Packed Shift Logical Bytes
- VPSHLW—Packed Shift Logical Words
- VPSHLD—Packed Shift Logical Doublewords
- VPSHLQ—Packed Shift Logical Quadwords
- VPSHAB—Packed Shift Arithmetic Bytes
- VPSHAW—Packed Shift Arithmetic Words
- VPSHAD—Packed Shift Arithmetic Doublewords
- VPSHAQ—Packed Shift Arithmetic Quadwords

There is no legacy form for these instructions.

4.6.6.5 Packed Integer Rotate

There are two variants of the packed integer rotate instructions. The first is identical to that described above (see “Packed Integer Shifts”). In the second variant, the control byte is supplied as an 8-bit immediate operand that specifies a single rotate amount for every element in the first source operand.

The XOP instruction set provides the following packed integer rotate instructions:

- VPROTB—Packed Rotate Bytes
- VPROTW—Packed Rotate Words
- VPROTD—Packed Rotate Doublewords
- VPROTQ—Packed Rotate Quadwords

There is no legacy form for these instructions.

4.6.7 Compare

The integer vector-compare instructions compare two operands and either write a mask or the maximum or minimum value.

4.6.7.1 Compare and Write Mask

- (V)PCMPEQB—Packed Compare Equal Bytes
- (V)PCMPEQW—Packed Compare Equal Words
- (V)PCMPEQD—Packed Compare Equal Doublewords
- (V)PCMPEQQ—Packed Compare Equal Quadwords
- (V)PCMPGTB—Packed Compare Greater Than Signed Bytes
- (V)PCMPGTW—Packed Compare Greater Than Signed Words
- (V)PCMPGTD—Packed Compare Greater Than Signed Doublewords

- (V)PCMPGTQ—Packed Compare Greater Than Signed Quadwords

The (V)PCMPEQ*x* and (V)PCMPGT*x* instructions compare corresponding bytes, words, doublewords, or quadwords in the two source operands. The instructions then write a mask of all 1s or 0s for each compare into the corresponding, same-sized element of the destination. Figure 4-39 shows a (V)PCMPEQ*x* compare operation.

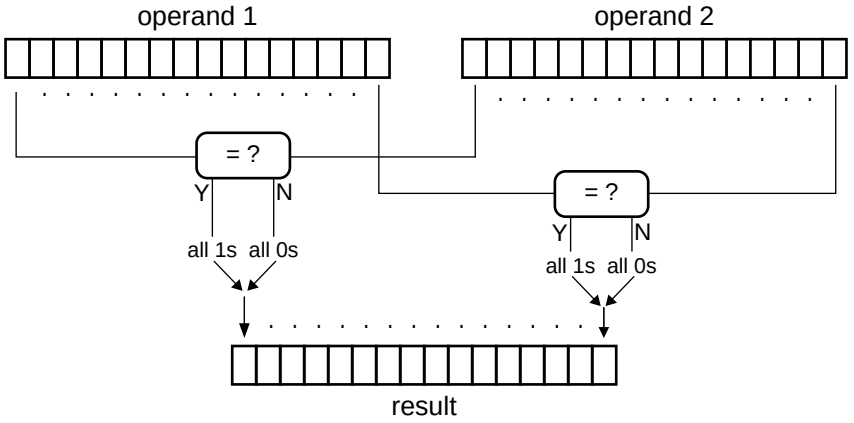

Figure 4-39. (V)PCMPEQ*x* Compare Operation

For the (V)PCMPEQ*x* instructions, if the compared values are equal, the result mask is all 1s. If the values are not equal, the result mask is all 0s. For the (V)PCMPGT*x* instructions, if the signed value in the first operand is greater than the signed value in the second operand, the result mask is all 1s. If the value in the first operand is less than or equal to the value in the second operand, the result mask is all 0s.

For the legacy form and the 128-bit extended form of these instructions, the first source operand is an XMM register and the second source operand is either an XMM register or a 128-bit memory location. For the 256-bit extended form, the first source operand is a YMM register and the second source operand is either a YMM register or a 256-bit memory location. In the legacy form of these instructions, the first source XMM register is also the destination. The extended form specifies a separate destination YMM/XMM register encoded in the instruction.

By specifying the same register for both operands, (V)PCMPEQ*x* can be used to set the bits in a register to all 1s.

Figure 4-21 on page 148 shows an example of a non-branching sequence that implements a two-way multiplexer—one that is equivalent to the following sequence of ternary operators in C or C++:

```
r0 = a0 > b0 ? a0 : b0
r1 = a1 > b1 ? a1 : b1
r2 = a2 > b2 ? a2 : b2
r3 = a3 > b3 ? a3 : b3
r4 = a4 > b4 ? a4 : b4
r5 = a5 > b5 ? a5 : b5
```

```
r6 = a6 > b6 ? a6 : b6
r7 = a7 > b7 ? a7 : b7
```

Assuming xmm0 contains the vector a, and xmm1 contains the vector b, the above C sequence can be implemented with the following assembler sequence:

```
MOVQ        xmm3, xmm0
PCMPGTW     xmm3, xmm1  ; a > b ? 0xffff : 0
PAND        xmm0, xmm3  ; a > b ? a: 0
PANDN       xmm3, xmm1  ; a > b ? 0 : b
POR         xmm0, xmm3  ; r = a > b ? a: b
```

In the above sequence, (V)PCMPGTW, (V)PAND, (V)PANDN, and (V)POR operate, in parallel, on all four elements of the vectors.

4.6.7.2 Compare and Write Minimum or Maximum

- (V)PMAXUB—Packed Maximum Unsigned Bytes
- (V)PMAXUW—Packed Maximum Unsigned Words
- (V)PMAXUD— Packed Maximum Unsigned Doublewords
- (V)PMAXSB—Packed Maximum Signed Bytes
- (V)PMAXSW—Packed Maximum Signed Words
- (V)PMAXSD—Packed Maximum Signed Doublewords
- (V)PMINUB—Packed Minimum Unsigned Bytes
- (V)PMINUW—Packed Minimum Unsigned Words
- (V)PMINUD—Packed Minimum Unsigned Doublewords
- (V)PMINSB—Packed Minimum Signed Bytes
- (V)PMINSW—Packed Minimum Signed Words
- (V)PMINSD—Packed Minimum Signed Doublewords

The (V)PMAXUB, (V)PMAXUW, and (V)PMAXUD and the (V)PMINUB, (V)PMINUW, (V)PMINUD instructions compare each of the 8-bit, 16-bit, or 32-bit unsigned integer values in the first operand with the corresponding 8-bit, 16-bit, or 32-bit unsigned integer values in the second operand. The instructions then write the maximum ((V)PMAXU*x*) or minimum ((V)PMINU*x*) of the two values for each comparison into the corresponding element of the destination.

The (V)PMAXSB, (V)PMAXSW, (V)PMAXSD and the (V)PMINSB, (V)PMINSW, (V)PMINSD instructions perform operations analogous to the (V)PMAXU*x* and (V)PMINU*x* instructions, except on 16-bit signed integer values.

For the legacy form and the 128-bit extended form of these instructions, the first source operand is an XMM register and the second source operand is either an XMM register or a 128-bit memory location. For the 256-bit extended form, the first source operand is a YMM register and the second source operand is either a YMM register or a 256-bit memory location. In the legacy form of these

instructions, the first source XMM register is also the destination. The extended form specifies a separate destination YMM/XMM register encoded in the instruction.

4.6.7.3 Packed Integer Comparison and Predicate Generation

- VPCOMUB—Compare Vector Unsigned Bytes
- VPCOMUW—Compare Vector Unsigned Words
- VPCOMUD—Compare Vector Unsigned Doublewords
- VPCOMUQ—Compare Vector Unsigned Quadwords
- VPCOMB—Compare Vector Signed Bytes
- VPCOMW—Compare Vector Signed Words
- VPCOMD—Compare Vector Signed Doublewords
- VPCOMQ—Compare Vector Signed Quadwords

These XOP comparison instructions compare packed integer values in the first source XMM register with corresponding packed integer values in the second source XMM register or 128-bit memory. The type of comparison is specified by the immediate-byte operand. The resulting predicate is placed in the destination XMM register. If the condition is true, all bits in the corresponding field in the destination register are set to 1s; otherwise all bits in the field are set to 0s.

Table 4-10. Immediate Operand Values for Unsigned Vector Comparison Operations

Immediate Operand Byte		Comparison Operation
Bits 7:3	Bits 2:0	
00000b	000b	Less Than
	001b	Less Than or Equal
	010b	Greater Than
	011b	Greater Than or Equal
	100b	Equal
	101b	Not Equal
	110b	False
	111b	True

The integer comparison and predicate generation instructions compare corresponding packed signed or unsigned bytes in the first and second source operands and write the result of each comparison in the corresponding element of the destination. The result of each comparison is a value of all 1s (TRUE) or all 0s (FALSE). The type of comparison is specified by the three low-order bits of the immediate-byte operand.

4.6.7.4 String and Text Processing Instructions

- (V)PCMPESTRI — Packed compare explicit-length strings, return index in ECX/RCX

- (V)PCMPESTRM — Packed compare explicit-length strings, return mask in XMM0
- (V)PCMPISTRI — Packed compare implicit-length strings, return index in ECX/RCX
- (V)PCMPISTRM — Packed compare implicit-length strings, return mask in XMM0

These four instructions use XMM registers to process string or text elements of up to 128-bits (16 bytes or 8 words). Each instruction uses an immediate byte to support an extensive set of programmable controls. These instructions return the result of processing each pair of string elements using either an index or a mask. Each instruction has an extended SSE (AVX) counterpart with the same functionality.

The capabilities of these instructions include:

- Handling string/text fragments consisting of bytes or words, either signed or unsigned
- Support for partial string or fragments less than 16 bytes in length, using either explicit length or implicit null-termination
- Four types of string compare operations on word/byte elements
- Up to 256 compare operations performed in a single instruction on all string/text element pairs
- Built-in aggregation of intermediate results from comparisons
- Programmable control of processing on intermediate results
- Programmable control of output formats in terms of an index or mask
- Bidirectional support for the index format
- Support for two mask formats: bit or natural element width
- Does not require 16-byte alignment for memory operand

All four instructions require the use of an immediate byte to control operation. The first source operand is an XMM register The second source operand can be either an XMM register or a 128-bit memory location. The immediate byte provides programmable control with the following attributes:

- Input data format
- Compare operation mode
- Intermediate result processing
- Output selection

Depending on the output format associated with the instruction, the text/string processing instructions implicitly uses either a general-purpose register (ECX/RCX) or an XMM register (XMM0) to return the final result. Neither of the source operands are modified.

Two of the four text-string processing instructions specify string length explicitly. They use two general-purpose registers (EDX, EAX) to specify the number of valid data elements (either word or byte) in the source operands. The other two instructions specify valid string elements using null termination. A data element is considered valid only if it has a lower index than the least significant null data element.

These instructions do not perform alignment checking on memory operands.

4.6.8 Logical

The vector-logic instructions perform Boolean logic operations, including AND, OR, and exclusive OR.

4.6.8.1 AND

- (V)PAND—Packed Logical Bitwise AND
- (V)PANDN—Packed Logical Bitwise AND NOT
- (V)PTEST—Packed Bit Test

The (V)PAND instruction performs a logical bitwise AND of the values in the first and second operands and writes the result to the destination.

The (V)PANDN instruction inverts the first operand (creating a ones-complement of the operand), ANDs it with the second operand, and writes the result to the destination. Table 4-11 shows an example.

Table 4-11. Example PANDN Bit Values

Operand1 Bit	Operand1 Bit (Inverted)	Operand2 Bit	PANDN Result Bit
1	0	1	0
1	0	0	0
0	1	1	1
0	1	0	0

For the legacy form and the 128-bit extended form of (V)PAND and (V)PANDN, the first source operand is an XMM register and the second source operand is either an XMM register or a 128-bit memory location. For the 256-bit extended form, the first source operand is a YMM register and the second source operand is either a YMM register or a 256-bit memory location. In the legacy form of these instructions, the first source XMM register is also the destination. The extended form specifies a separate destination YMM/XMM register encoded in the instruction.

AVX2 adds support for 256-bit operands to the VPAND and VPANDN instructions.

The packed bit test instruction (V)PTEST is similar to the general-purpose instruction TEST. Using the first source operand as a bit mask, (V)PTEST may be used to test whether the bits in the second source operand that correspond to the set bits in the mask are all zeros. If this is true rFLAGS[ZF] is set. If all the bits in the second source operand that correspond to the cleared bits in the mask are all zeros, then the rFLAGS[CF] bit is set.

Because neither source operand is modified, (V)PTEST simplifies branching operations, such as branching on signs of packed floating-point numbers, or branching on zero fields.

The AVX instruction VPTEST has both a 128-bit and a 256-bit form.

4.6.8.2 OR and Exclusive OR

- (V)POR—Packed Logical Bitwise OR
- (V)PXOR—Packed Logical Bitwise Exclusive OR

The (V)POR instruction performs a logical bitwise OR of the values in the first and second operands and writes the result to the destination.

The (V)PXOR instruction is analogous to (V)POR except it performs a bit-wise exclusive OR of the two source operands. (V)PXOR can be used to clear all bits in an XMM register by specifying the same register for both operands.

For the legacy form and the 128-bit extended form of these instructions, the first source operand is an XMM register and the second source operand is either an XMM register or a 128-bit memory location. For the 256-bit extended form, the first source operand is a YMM register and the second source operand is either a YMM register or a 256-bit memory location. In the legacy form of these instructions, the first source XMM register is also the destination. The extended form specifies a separate destination YMM/XMM register encoded in the instruction.

AVX2 adds support for 256-bit operands to the extended forms of these instructions.

4.6.9 Save and Restore State

These instructions save and restore the entire processor state for legacy SSE instructions.

4.6.9.1 Save and Restore 128-Bit, 64-Bit, and x87 State

- FXSAVE—Save XMM, MMX, and x87 State
- FXRSTOR—Restore XMM, MMX, and x87 State

The FXSAVE and FXRSTOR instructions save and restore the entire 512-byte processor state for legacy SSE instructions, 64-bit media instructions, and x87 floating-point instructions. The architecture supports two memory formats for FXSAVE and FXRSTOR, a 512-byte 32-bit legacy format and a 512-byte 64-bit format. Selection of the 32-bit or 64-bit format is determined by the effective operand size for the FXSAVE and FXRSTOR instructions. For details, see “FXSAVE and FXRSTOR Instructions” in Volume 2.

4.6.9.2 Save and Restore Extended Processor Context

- XSAVE—Save Extended Processor Context.
- XRSTOR—Restore Extended Processor Context.

The XSAVE and XRSTOR instructions provide a flexible means of saving and restoring not only the x87, 64-bit media, and legacy SSE state, but also the extended SSE context. The first 512 bytes of the save area supports the FXSAVE/FXRSTOR 512-byte 64-bit format. Subsequent bytes support an extensible data structure to be used for extended processor context such as the extended SSE context including the contents of the YMM registers. XSAVEOPT, XSAVEC, XSAVES and XRSTORS are

optional optimized variants of XSAVE and XRSTOR. For details, see the descriptions of these instructions in Volume 4.

4.6.9.3 Save and Restore Control and Status

- (V)STMXCSR—Store MXCSR Control/Status Register
- (V)LDMXCSR—Load MXCSR Control/Status Register

The (V)STMXCSR and (V)LDMXCSR instructions save and restore the 32-bit contents of the MXCSR register. For further information, see Section 4.2.2 “MXCSR Register” on page 115.

4.7 Instruction Summary—Floating-Point Instructions

This section summarizes the SSE instructions that operate on scalar and packed floating-point values. Software running at any privilege level can use any of the instructions discussed below, given that hardware and system software support is provided and the appropriate instruction subset is enabled. Detection and enablement of instruction subsets is normally handled by operating system software. Hardware support for each instruction subset is indicated by processor feature bits. These are accessed via the CPUID instruction. See Volume 3 for details on the CPUID instruction and the feature bits associated with the SSE instruction set.

The SSE instructions discussed below include those that use the YMM/XMM registers as well as instructions that convert data from floating-point to integer formats. For more detail on each instruction, see individual instruction reference pages in the Instruction Reference chapter of Volume 4, “128-Bit and 256-Bit Media Instructions.”

For a summary of the integer SSE instructions including instructions that convert from integer to floating-point formats, see Section 4.6 “Instruction Summary—Integer Instructions” on page 149.

For a summary of the 64-bit media floating-point instructions, see “Instruction Summary—Floating-Point Instructions” on page 270. For a summary of the x87 floating-point instructions, see “Instruction Summary” on page 310.

The following subsections are organized by functional groups. These are:

- Data Transfer
- Data Conversion
- Data Reordering
- Arithmetic
- Fused Multiply-Add Instructions
- Compare
- Logical

Most of the instructions described below have both legacy and AVX versions. For the 128-bit media instructions, the extended version is functionally equivalent to the legacy version except legacy

instructions leave the upper octword of the YMM register that overlays the destination XMM register unchanged, while the 128-bit AVX instruction always clears the upper octword. The descriptions that follow apply equally to the legacy instruction and its extended AVX version. Generally, for those extended instructions that have 256-bit variants, the number of elements operated upon in parallel doubles. Other differences will be noted at the end of the discussion.

4.7.1 Data Transfer

The data-transfer instructions copy 32-bit, 64-bit, 128-bit, or 256-bit data from memory to a YMM/XMM register, from a YMM/XMM register to memory, or from one register to another. The MOV mnemonic, which stands for *move*, is a misnomer. A copy function is actually performed instead of a move. A new copy of the source value is created at the destination address, and the original copy remains unchanged at its source location.

4.7.1.1 Move

- (V)MOVAPS—Move Aligned Packed Single-Precision Floating-Point
- (V)MOVAPD—Move Aligned Packed Double-Precision Floating-Point
- (V)MOVUPS—Move Unaligned Packed Single-Precision Floating-Point
- (V)MOVUPD—Move Unaligned Packed Double-Precision Floating-Point
- (V)MOVHPS—Move High Packed Single-Precision Floating-Point
- (V)MOVHPD—Move High Packed Double-Precision Floating-Point
- (V)MOVLPS—Move Low Packed Single-Precision Floating-Point
- (V)MOVLPD—Move Low Packed Double-Precision Floating-Point
- (V)MOVHLPS—Move Packed Single-Precision Floating-Point High to Low
- (V)MOVLHPS—Move Packed Single-Precision Floating-Point Low to High
- (V)MOVSS—Move Scalar Single-Precision Floating-Point
- (V)MOVSD—Move Scalar Double-Precision Floating-Point
- (V)MOVDDUP—Move Double-Precision and Duplicate
- (V)MOVSLDUP—Move Single-Precision High and Duplicate
- (V)MOVSHDUP—Move Single-Precision Low and Duplicate

Figure 4-40 on page 187 summarizes the capabilities of the floating-point move instructions except (V)MOVDDUP, (V)MOVSLDUP, (V)MOVSHDUP which are described in the following section.

The (V)MOVAPx instructions copy a vector of four (eight, for 256-bit form) single-precision floating-point values ((V)MOVAPS) or a vector of two (four) double-precision floating-point values ((V)MOVAPD) from the second operand to the first operand—i.e., from an YMM/XMM register or 128-bit (256-bit) memory location or to another YMM/XMM register, or vice versa. A general-protection exception occurs if a memory operand is not aligned on a 16-byte (32-byte) boundary, unless alternate alignment checking behavior is enabled by setting MSCSR[MM]. See Section 4.3.2 “Data Alignment” on page 120.

The (V)MOVUP*x* instructions perform operations analogous to the (V)MOVAP*x* instructions, except that unaligned memory operands do not cause a general-protection exception or invoke the alignment checking mechanism.

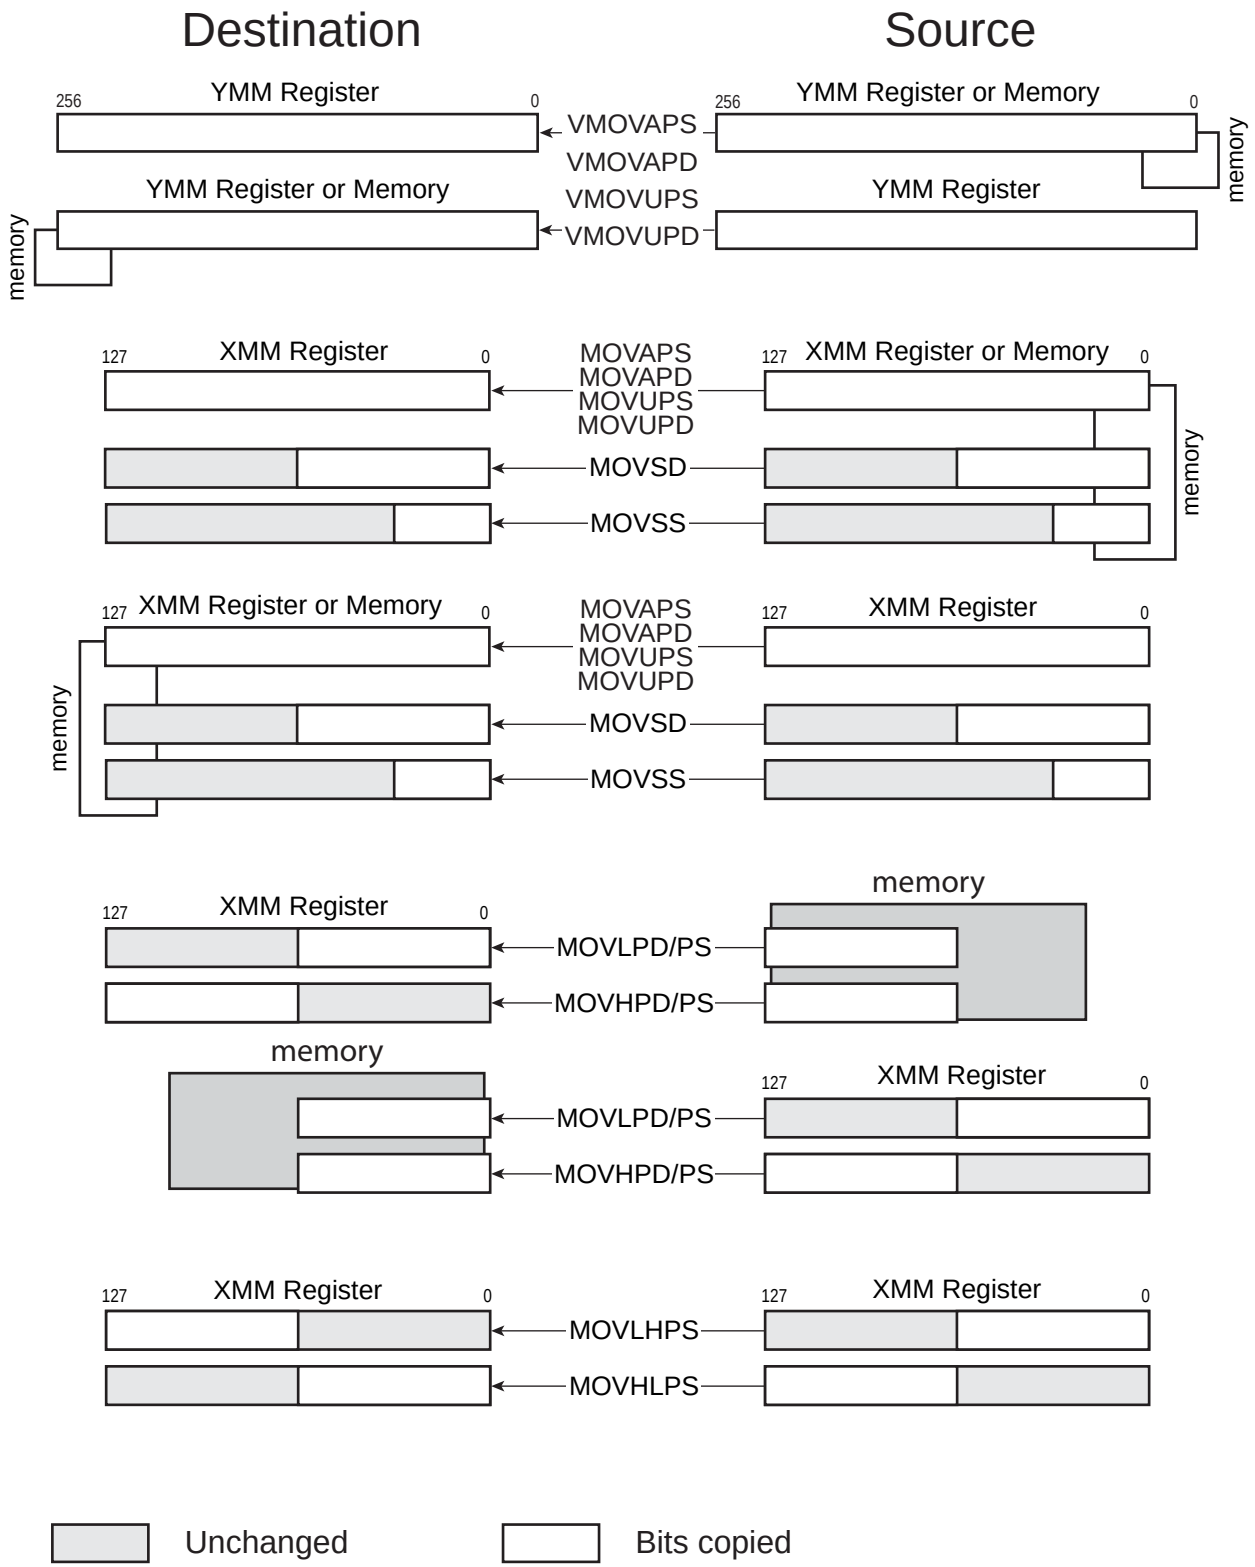

Figure 4-40. Floating-Point Move Operations

The (V)MOVHPS and (V)MOVHPD instructions copy a vector of two single-precision floating-point values ((V)MOVHPS) or one double-precision floating-point value ((V)MOVHPD) from a 64-bit memory location to the high-order 64 bits of an XMM register, or from the high-order 64 bits of an XMM register to a 64-bit memory location. In the memory-to-register case, the low-order 64 bits of the destination XMM register are not modified.

The (V)MOVLPS and (V)MOVLPD instructions copy a vector of two single-precision floating-point values ((V)MOVLPS) or one double-precision floating-point value ((V)MOVLPD) from a 64-bit memory location to the low-order 64 bits of an XMM register, or from the low-order 64 bits of an XMM register to a 64-bit memory location. In the memory-to-register case, the high-order 64 bits of the destination XMM register are not modified.

The (V)MOVHLPS instruction copies a vector of two single-precision floating-point values from the high-order 64 bits of an XMM register to the low-order 64 bits of another XMM register. The high-order 64 bits of the destination XMM register are not modified. The (V)MOVLHPS instruction performs an analogous operation except in the opposite direct (low-order to high-order), and the low-order 64 bits of the destination XMM register are not modified.

The (V)MOVSS instruction copies a scalar single-precision floating-point value from the low-order 32 bits of an XMM register or a 32-bit memory location to the low-order 32 bits of another XMM register, or vice versa. If the source operand is an XMM register, the high-order 96 bits of the destination XMM register are either cleared or left unmodified based on the instruction encoding. If the source operand is a 32-bit memory location, the high-order 96 bits of the destination XMM register are cleared to all 0s.

The (V)MOVSD instruction copies a scalar double-precision floating-point value from the low-order 64 bits of an XMM register or a 64-bit memory location to the low-order 64 bits of another XMM register, or vice versa. If the source operand is an XMM register, the high-order 64 bits of the destination XMM register are not modified. If the source operand is a memory location, the high-order 64 bits of the destination XMM register are cleared to all 0s.

The above MOVSD instruction should not be confused with the same-mnemonic MOVSD (move string doubleword) instruction in the general-purpose instruction set. Assemblers distinguish the two instructions by their operand data types.

The basic function of each corresponding extended (V) form instruction is the same as the legacy form. The instructions VMOVSS, VMOVSD, VMOVHPS, VMOVHPD, VMOVLPS, VMOVHLPS, VMOVLHPS provide additional function, supporting the merging in of bits from a second register source operand.

4.7.1.2 Move with Duplication

These instructions move two copies of the affected data segments from the source XMM register or 128-bit memory operand to the target destination register.

The (V)MOVDDUP moves one copy of the lower quadword of the source operand into each quadword half of the destination operand. The 256-bit version of VMOVDDUP copies and duplicates the two even-indexed quadwords.

The (V)MOVSLDUP instruction moves two copies of the first (least significant) doubleword of the source operand into the first two doubleword segments of the destination operand and moves two copies of the third doubleword of the source operand into the third and fourth doubleword segments of the destination operand. The 256-bit version of VMOVSLDUP writes two copies the even-indexed doubleword elements of the source YMM register to ascending quadwords of the destination YMM register.

The (V)MOVSHDUP instruction moves two copies of the second doubleword of the source operand into the first two doubleword segments of the destination operand and moves two copies of the fourth doubleword of the source operand into the upper two doubleword segments of the destination operand. The 256-bit version of VMOVSHDUP writes two copies the odd-indexed doubleword elements of the source YMM register to ascending quadwords of the destination YMM register.

4.7.1.3 Move Non-Temporal

The move non-temporal instructions are *streaming-store* instructions. They minimize pollution of the cache.

- (V)MOVNTPD—Move Non-temporal Packed Double-Precision Floating-Point
- (V)MOVNTPS—Move Non-temporal Packed Single-Precision Floating-Point
- MOVNTSD—Move Non-temporal Scalar Double-Precision Floating-Point
- MOVNTSS—Move Non-temporal Scalar Single-Precision Floating-Point

These instructions indicate to the processor that their data is *non-temporal*, which assumes that the data they reference will be used only once and is therefore not subject to cache-related overhead (as opposed to *temporal* data, which assumes that the data will be accessed again soon and should be cached). The non-temporal instructions use weakly-ordered, write-combining buffering of write data, and they minimize cache pollution. The exact method by which cache pollution is minimized depends on the hardware implementation of the instruction. For further information, see “Memory Optimization” on page 98.

The (V)MOVNTP*x* instructions copy four packed single-precision floating-point ((V)MOVNTPS) or two packed double-precision floating-point ((V)MOVNTPD) values from an XMM register into a 128-bit memory location. The 256-bit form of the VMOVNTP*x* instructions store the contents of the specified source YMM register to memory.

The MOVNTS*x* instructions store one double precision floating point XMM register value into a 64 bit memory location or one single precision floating point XMM register value into a 32-bit memory location.

4.7.1.4 Move Mask

- (V)MOVMSKPS—Extract Packed Single-Precision Floating-Point Sign Mask

- (V)MOVMSKPD—Extract Packed Double-Precision Floating-Point Sign Mask

The (V)MOVMSKPS instruction copies the sign bits of four (eight, for the 256-bit form) single-precision floating-point values in an XMM (YMM) register to the four (eight) low-order bits of a 32-bit or 64-bit general-purpose register, with zero-extension. The (V)MOVMSKPD instruction copies the sign bits of two (four) double-precision floating-point values in an XMM (YMM) register to the two (four) low-order bits of a general-purpose register, with zero-extension. The result of either instruction is a sign-bit mask that can be used for data-dependent branching. Figure 4-41 shows the MOVMSKPS operation.

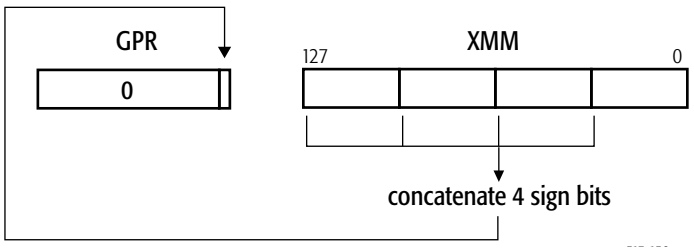

Figure 4-41. (V)MOVMSKPS Move Mask Operation

4.7.2 Data Conversion

The floating-point data-conversion instructions convert floating-point operands to integer operands.

These data-conversion instructions take 128-bit floating-point source operands. For data-conversion instructions that take 128-bit integer source operands, see “Data Conversion” on page 155. For data-conversion instructions that take 64-bit source operands, see “Data Conversion” on page 257 and “Data Conversion” on page 271.

4.7.2.1 Convert Floating-Point to Floating-Point

These instructions convert floating-point data types in XMM registers or memory into different floating-point data types in XMM registers.

- (V)CVTPS2PD—Convert Packed Single-Precision Floating-Point to Packed Double-Precision Floating-Point
- (V)CVTPD2PS—Convert Packed Double-Precision Floating-Point to Packed Single-Precision Floating-Point
- (V)CVTSS2SD—Convert Scalar Single-Precision Floating-Point to Scalar Double-Precision Floating-Point
- (V)CVTSD2SS—Convert Scalar Double-Precision Floating-Point to Scalar Single-Precision Floating-Point

The (V)CVTPS2PD instruction converts two (four, for the 256-bit form) single-precision floating-point values in the low-order 64 bits (entire 128 bits) of the source operand–either a XMM register or a

64-bit (128-bit) memory location–to two (four) double-precision floating-point values in the destination operand–an XMM (YMM) register.

The (V)CVTPD2PS instruction converts two (four, for the 256-bit form) double-precision floating-point values in the source operand –either an XMM (YMM) register or a 64-bit (128-bit) memory location–to two (four) single-precision floating-point values. The 128-bit form zero-extends the 64-bit packed result to 128 bits before writing it to the destination XMM register. The 256-bit form writes the 128-bit packed result to the destination XMM register. If the result of the conversion is an inexact value, the value is rounded.

The (V)CVTSS2SD instruction converts a single-precision floating-point value in the low-order 32 bits of the source operand to a double-precision floating-point value in the low-order 64 bits of the destination. For the legacy form of the instruction, the high-order 64 bits in the destination XMM register are not modified. In the extended form, the high-order 64 bits are copied from another source XMM register.

The (V)CVTSD2SS instruction converts a double-precision floating-point value in the low-order 64 bits of the source operand to a single-precision floating-point value in the low-order 32 bits of the destination. For the legacy form of the instruction, the three high-order doublewords in the destination XMM register are not modified. In the extended form, the three high-order doublewords are copied from another source XMM register. If the result of the conversion is an inexact value, the value is rounded.

4.7.2.2 Convert Floating-Point to XMM Integer

These instructions convert floating-point data types in YMM/XMM registers or memory into integer data types in YMM/XMM registers.

- (V)CVTPS2DQ—Convert Packed Single-Precision Floating-Point to Packed Doubleword Integers
- (V)CVTPD2DQ—Convert Packed Double-Precision Floating-Point to Packed Doubleword Integers
- (V)CVTTPS2DQ—Convert Packed Single-Precision Floating-Point to Packed Doubleword Integers, Truncated
- (V)CVTTPD2DQ—Convert Packed Double-Precision Floating-Point to Packed Doubleword Integers, Truncated

The (V)CVTPS2DQ and (V)CVTTPS2DQ instructions convert four (eight, in the 256-bit version) single-precision floating-point values in the source operand to four (eight) 32-bit signed integer values in the destination. For the 128-bit form, the source operand is either an XMM register or a 128-bit memory location and the destination is an XMM register. For the 256-bit form, the source operand is either a YMM register or a 256-bit memory location and the destination is a YMM register. For the (V)CVTPS2DQ instruction, if the result of the conversion is an inexact value, the value is rounded, but for the (V)CVTTPS2DQ instruction such a result is truncated (rounded toward zero).

The (V)CVTPD2DQ and (V)CVTTPD2DQ instructions convert two (four, in 256-bit version) double-precision floating-point values in the source operand to two (four) 32-bit signed integer values in the destination. For the 128-bit form, the source operand is either an XMM register or a 128-bit memory location and the destination is the low-order 64 bits of an XMM register. The high-order 64 bits in the destination XMM register are cleared to all 0s. For the 256-bit form, the source operand is either a YMM register or a 256-bit memory location and the destination is a XMM register. For the (V)CVTPD2DQ instruction, if the result of the conversion is an inexact value, the value is rounded, but for the (V)CVTTPD2DQ instruction such a result is truncated (rounded toward zero).

For a description of SSE instructions that convert in the opposite direction—integer to floating-point—see “Convert Integer to Floating-Point” on page 155.

4.7.2.3 Convert Floating-Point to MMX™ Integer

These instructions convert floating-point data types in XMM registers or memory into integer data types in MMX registers.

- CVTPS2PI—Convert Packed Single-Precision Floating-Point to Packed Doubleword Integers
- CVTPD2PI—Convert Packed Double-Precision Floating-Point to Packed Doubleword Integers
- CVTTPS2PI—Convert Packed Single-Precision Floating-Point to Packed Doubleword Integers, Truncated
- CVTTPD2PI—Convert Packed Double-Precision Floating-Point to Packed Doubleword Integers, Truncated

The CVTPS2PI and CVTTPS2PI instructions convert two single-precision floating-point values in the low-order 64 bits of an XMM register or a 64-bit memory location to two 32-bit signed integer values in an MMX register. For the CVTPS2PI instruction, if the result of the conversion is an inexact value, the value is rounded, but for the CVTTPS2PI instruction such a result is truncated (rounded toward zero).

The CVTPD2PI and CVTTPD2PI instructions convert two double-precision floating-point values in an XMM register or a 128-bit memory location to two 32-bit signed integer values in an MMX register. For the CVTPD2PI instruction, if the result of the conversion is an inexact value, the value is rounded, but for the CVTTPD2PI instruction such a result is truncated (rounded toward zero).

Before executing a CVTxPS2PI or CVTxPD2PI instruction, software should ensure that the MMX registers are properly initialized so as to prevent conflict with their aliased use by x87 floating-point instructions. This may require clearing the MMX state, as described in “Accessing Operands in MMX™ Registers” on page 232.

For a description of SSE instructions that convert in the opposite direction—integer in MMX registers to floating-point in XMM registers—see “Convert MMX Integer to Floating-Point” on page 155. For a summary of instructions that operate on MMX registers, see Chapter 5, “64-Bit Media Programming.”

4.7.2.4 Convert Floating-Point to GPR Integer

These instructions convert floating-point data types in XMM registers or memory into integer data types in GPR registers.

- (V)CVTSS2SI—Convert Scalar Single-Precision Floating-Point to Signed Doubleword or Quadword Integer
- (V)CVTSD2SI—Convert Scalar Double-Precision Floating-Point to Signed Doubleword or Quadword Integer
- (V)CVTTSS2SI—Convert Scalar Single-Precision Floating-Point to Signed Doubleword or Quadword Integer, Truncated
- (V)CVTTSD2SI—Convert Scalar Double-Precision Floating-Point to Signed Doubleword or Quadword Integer, Truncated

The (V)CVTSS2SI and (V)CVTTSS2SI instructions convert a single-precision floating-point value in the low-order 32 bits of an XMM register or a 32-bit memory location to a 32-bit or 64-bit signed integer value in a general-purpose register. For the (V)CVTSS2SI instruction, if the result of the conversion is an inexact value, the value is rounded, but for the (V)CVTTSS2SI instruction such a result is truncated (rounded toward zero).

The (V)CVTSD2SI and (V)CVTTSD2SI instructions convert a double-precision floating-point value in the low-order 64 bits of an XMM register or a 64-bit memory location to a 32-bit or 64-bit signed integer value in a general-purpose register. For the (V)CVTSD2SI instruction, if the result of the conversion is an inexact value, the value is rounded, but for the (V)CVTTSD2SI instruction such a result is truncated (rounded toward zero).

For a description of SSE instructions that convert in the opposite direction—integer in GPR registers to floating-point in XMM registers—see “Convert GPR Integer to Floating-Point” on page 156. For a summary of instructions that operate on GPR registers, see Chapter 3, “General-Purpose Programming.”

4.7.2.5 Half-Precision Floating-Point Conversion

The F16C instruction subset supports the 16-bit floating-point data type with two instructions (VCVTPH2PS and VCVTPS2PH) to convert 16-bit floating-point values to and from single-precision format. The half-precision floating point data type is discussed in “Half-Precision Floating-Point Data Type” on page 130.

- VCVTPH2PS—Convert Half-Precision Floating-Point to Single-Precision Floating Point
- VCVTPS2PH—Convert Single-Precision Floating-Point to Half-Precision Floating Point

These two instructions are provided for the purpose of moving data to or from memory, while converting a single-precision floating point operand to a half-precision floating-point operand or vice versa in one instruction. These instructions allow the storage of floating point data in half-precision format, thereby conserving memory space. These instructions have both 128-bit and 256-bit forms utilizing the three-byte VEX prefix (C4h).

4.7.3 Data Reordering

The floating-point data-reordering instructions insert, extract, pack, unpack and interleave, or shuffle the elements of vector operands.

4.7.3.1 Insertion and Extraction from XMM Registers

These instructions simplify data insertion and extraction between general-purpose registers (GPR) and XMM registers. When accessing memory, no alignment is required for these instructions (unless alignment checking is enabled).

- (V)EXTRACTPS—Extracts a single-precision floating-point value from any doubleword offset in an XMM register and stores the result to memory or a general-purpose register.
- (V)INSERTPS—Inserts a single floating-point value from either a 32-bit memory location or from a specified element in an XMM register to a selected element in the destination XMM register based on a mask specified in an immediate byte. In addition, the ZMASK field in the mask allows the insertion of +0.0 into any element in the destination. In the legacy form, any doublewords in destination that do not receive either a selected doubleword from the source or +0.0 based on the ZMASK field are not modified. In the extended form, these doublewords are copied from another XMM register.

4.7.3.2 Packed Blending

These instructions conditionally copy a data element in a source operand to the same element in the destination.

- (V)BLENDPS—Packed Single-Precision Floating-Point
- (V)BLENDPD—Packed Double-Precision Floating-Point
- (V)BLENDVPS—Packed Variable Blend Single-Precision Floating-Point
- (V)BLENDVPD—Packed Variable Blend Double-Precision Floating-Point

(V)BLENDPS, (V)BLENDPD, (V)BLENDVPS, and (V)BLENDVPD copy single- or double-precision floating point elements from either of two source operands to the specified destination register based on selector bits in a mask. The mask for (V)BLENDPS, (V)BLENDPD is contained in an immediate byte. For (V)BLENDVPS and (V)BLENDVPD the mask is composed of the sign bits of the floating-point elements of an operand register. The variable blend instructions BLENDVPS and PBLENDVPD use the implicit operand XMM0 to provide the selector mask.

In the legacy form of these instructions, the first source XMM register is also the destination. The extended form specifies a separate destination XMM register encoded in the instruction.

The VBLENDPS, VBLENDVPS, VBLENDPD, and VBLENDVPD instructions have 256-bit forms which copy eight or four selected floating-point elements from one of two 256-bit source operands to the destination YMM register.

4.7.3.3 Unpack and Interleave

These instructions interleave vector elements from the high or low halves of two floating-point source operands.

- (V)UNPCKHPS—Unpack High Single-Precision Floating-Point
- (V)UNPCKHPD—Unpack High Double-Precision Floating-Point
- (V)UNPCKLPS—Unpack Low Single-Precision Floating-Point
- (V)UNPCKLPD—Unpack Low Double-Precision Floating-Point

The (V)UNPCKHPx instructions copy the high-order two (four, in the 256-bit form) single-precision floating-point values ((V)UNPCKHPS) or one (two) double-precision floating-point value(s) ((V)UNPCKHPD) in the first and second source operands and interleave them in the destination register. The low-order 64 bits of the source operands are ignored. The first source is an XMM (YMM) register and the second is either an XMM (YMM) or a 128-bit (256-bit) memory location.

The (V)UNPCKLPx instructions are analogous to their high-element counterparts except that they take elements from the low quadword of each source vector and ignore elements in the high quadword.

In the legacy form of these instructions, the first source XMM register is also the destination. In the extended form, a separate destination XMM (YMM) register is specified via the instruction encoding.

Figure 4-42 below shows an example of one of these instructions, (V)UNPCKLPS. The elements written to the destination register are taken from the low half of the source operands. Note that elements from operand 2 are placed to the left of elements from operand 1.

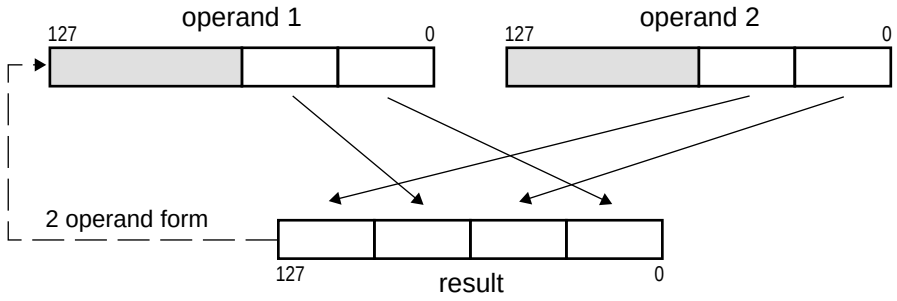

Figure 4-42. (V)UNPCKLPS Unpack and Interleave Operation

4.7.3.4 Shuffle

These instructions reorder the elements of a vector.

- (V)SHUFPS—Shuffle Packed Single-Precision Floating-Point
- (V)SHUFPD—Shuffle Packed Double-Precision Floating-Point

The (V)SHUFPS instruction moves any two of the four single-precision floating-point values in the first source operand to the low-order quadword of the destination and moves any two of the four

single-precision floating-point values in the second source operand to the high-order quadword of the destination. The source element selected for each doubleword of the destination is determined by a 2-bit field in an immediate byte.

Figure 4-43 below shows the (V)SHUFPS shuffle operation. (V)SHUFPS is useful, for example, in color imaging when computing alpha saturation of RGB values. In this case, (V)SHUFPS can replicate an alpha value in a register so that parallel comparisons with three RGB values can be performed.

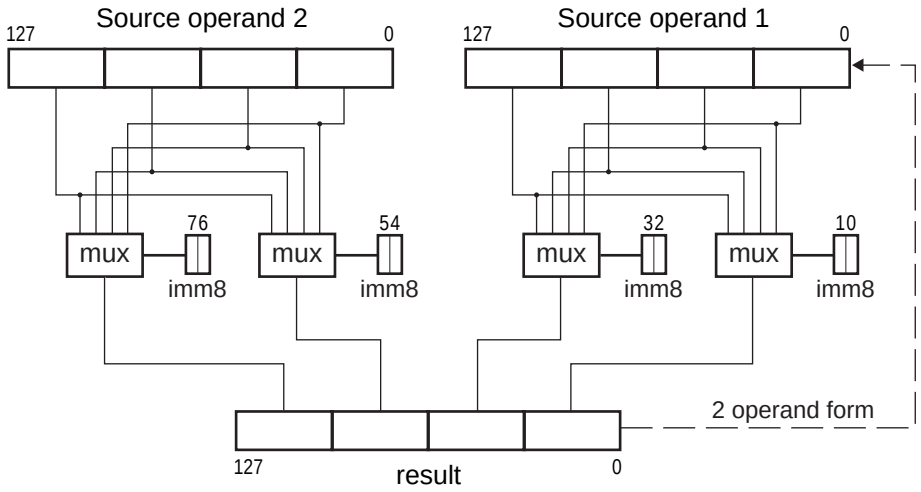

Figure 4-43. (V)SHUFPS Shuffle Operation

The (V)SHUFPD instruction moves either of the two double-precision floating-point values in the first source operand to the low-order quadword of the destination and moves either of the two double-precision floating-point values in the second source operand to the high-order quadword of the destination. The source element selected for each doubleword of the destination is determined by a bit field in an immediate byte.

For both instructions the first source operand is an XMM register and the second is either an XMM register or a 128-bit memory location. In the legacy form of these instructions, the first source XMM register is also the destination. In the extended form, a separate destination XMM register is specified via the instruction encoding.

The 256-bit forms of VSHFPS and VSHUFPD replicate the operation of each instruction's 128-bit form on the high-order octword of the 256-bit operands. The destination is a YMM register.

4.7.3.5 Fraction Extract

The fraction extract instructions isolate the fractional portions of vector or scalar floating point operands. The XOP instruction set provides the following fraction extract instructions:

- VFRCZPD—Extract Fraction Packed Double-Precision Floating-Point
- VFRCZPS—Extract Fraction Packed Single-Precision Floating-Point

- VFRCZSD— Extract Fraction Scalar Double-Precision Floating-Point
- VFRCZSS— Extract Fraction Scalar Single-Precision Floating Point

The result of the VFRCZPD and VFRCZPS instructions is a vector of integer numbers. The result of the VFRCZSD and VFRCZSS instructions is a scalar integer number.

The VFRCZPD and VFRCZPS instructions extract the fractional portions of a vector of double-precision or single-precision floating-point values in an XMM or YMM register or a 128-bit or 256-bit memory location and write the results in the corresponding field in the destination register.

The VFRCZSS and VFRCZSD instructions extract the fractional portion of the single-precision or double-precision scalar floating-point value in an XMM register or 32-bit or 64-bit memory location and writes the result in the lower element of the destination register. The upper elements of the destination XMM register are unaffected by the operation, while the upper 128 bits of the corresponding YMM register are cleared to zeros.

4.7.4 Arithmetic

The floating-point arithmetic instructions operate on two vector or scalar floating-point operands and produce a floating-point result of the same data type. For two operand forms, the result overwrites the first source operand. Vector arithmetic instructions apply the same arithmetic operation on pairs of elements from two floating-point vector operands and produce a vector result. Figure 4-44 below provides a schematic for the vector floating-point arithmetic instructions. The figure depicts 4 elements in each operand, but the actual number can be 2, 4, or 8 depending on the element size (either single precision or double precision) and vector size (128 bits or 256 bits). Each arithmetic instruction performs a unique arithmetic operation.

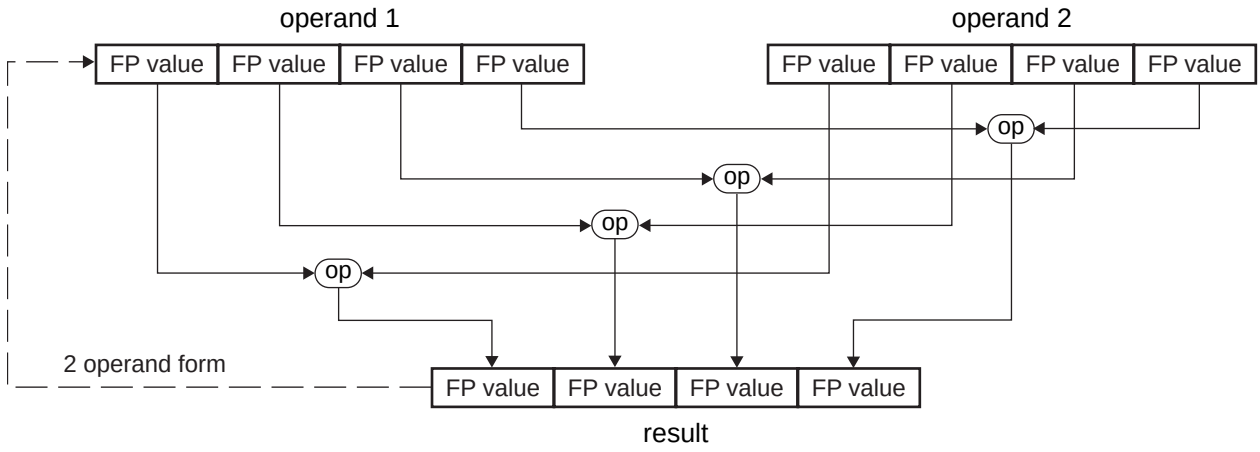

Figure 4-44. Vector Arithmetic Operation

The extended SSE versions of the arithmetic instructions that operate on packed data types support 256-bit data types. For the vector instructions this means that both the operands and the results have

twice the number of elements as the 128-bit forms. Legacy SSE instructions and extended scalar instructions support only 128-bit operands.

4.7.4.1 Addition

- (V)ADDPS—Add Packed Single-Precision Floating-Point
- (V)ADDPD—Add Packed Double-Precision Floating-Point
- (V)ADDSS—Add Scalar Single-Precision Floating-Point
- (V)ADDSD—Add Scalar Double-Precision Floating-Point

The (V)ADDPS instruction adds each of four (eight, for 256-bit form) single-precision floating-point values in the first source operand (an XMM or YMM register) to the corresponding single-precision floating-point values in the second source operand (either a YMM/XMM register or a 128-bit or 256-bit memory location) and writes the result in the corresponding doubleword of the destination.

Figure 4-45 below provides a schematic representation of the (V)ADDPS instruction. The instruction performs four addition operations in parallel. The 256-bit form of VADDPS doubles the number of operations and result elements to eight.

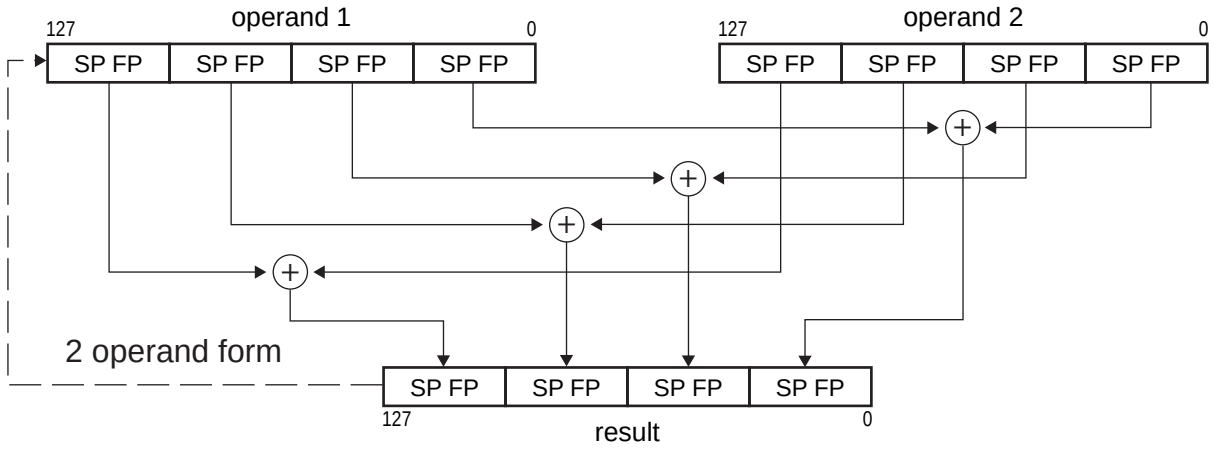

Figure 4-45. (V)ADDPS Arithmetic Operation

The (V)ADDPD instruction performs an analogous operation for double-precision floating-point values.

(V)ADDSS and (V)ADDSD operate respectively on single-precision and double-precision floating-point (scalar) values in the low-order bits of their operands. Each adds two floating-point values together and produces a single floating-point result. These extended instructions VADDSS and VADDSD have no 256-bit form.

The (V)ADDSS instruction adds the single-precision floating-point value in the first source operand (an XMM register) to the single-precision floating-point value in the second source operand (an XMM register or a doubleword memory location) and writes the result in the low-order doubleword of the

destination XMM register. For the legacy form, the three high-order doublewords of the destination are not modified. VADDSS copies the three high-order doublewords of the source operand to the destination.

The (V)ADDSD instruction adds the double-precision floating-point value in the first source operand (an XMM register) to the double-precision floating-point value in the low-order quadword of the second source operand (an XMM register or quadword memory location) and writes the result in the low-order quadword of the destination XMM register. For the legacy form, the high-order quadword of the destination is not modified. VADDSD copies the high-order quadword of the source operand to the destination.

For the legacy instructions, the first source register is also the destination. In the extended form, a separate destination XMM or YMM register is specified via the instruction encoding.

4.7.4.2 Horizontal Addition

- (V)HADDPS—Horizontal Add Packed Single-Precision Floating-Point
- (V)HADDPD—Horizontal Subtract Packed Double-Precision Floating-Point

The (V)HADDPS instruction adds the single-precision floating point values in the first and second doublewords of the first source operand (an XMM register) and stores the sum in the first doubleword of the destination XMM register. It adds the single-precision floating point values in the third and fourth doublewords of the first source operand and stores the sum in the second doubleword of the destination XMM register. It adds the single-precision floating point values in the first and second doublewords of the second source operand (either an XMM register or a 128-bit memory location) and stores the sum in the third doubleword of the destination XMM register. It adds single-precision floating point values in the third and fourth doublewords of the second source operand and stores the sum in the fourth doubleword of the destination XMM register.

The (V)HADDPD instruction adds the two double-precision floating point values in the upper and lower quadwords of the first source operand (an XMM register) and stores the sum in the first quadword of the destination XMM register. It adds the two values in the upper and lower quadwords of the second source operand (either an XMM register or a 128-bit memory location) and stores the sum in the second quadword of the destination XMM register.

The 256-bit forms of VHADDPS and VHADDPD perform the same operation as described on both the upper and lower octword of the 256-bit source operands and store the result to the destination YMM register.

For the legacy instructions, the first source register is also the destination. For the extended instructions, a separate destination register is specified by the instruction encoding.

4.7.4.3 Subtraction

- (V)SUBPS—Subtract Packed Single-Precision Floating-Point
- (V)SUBPD—Subtract Packed Double-Precision Floating-Point
- (V)SUBSS—Subtract Scalar Single-Precision Floating-Point

- (V)SUBSD—Subtract Scalar Double-Precision Floating-Point

The (V)SUBPS instruction subtracts each of four (eight, for 256-bit form) single-precision floating-point values in the second source operand (either a YMM/XMM register or a 128-bit or 256-bit memory location) from the corresponding single-precision floating-point value in the first source operand (an XMM or YMM register) and writes the result in the corresponding quadword of the destination XMM or YMM register. For vectors of *n* number of elements, the operations are:

```
operand1[i] = operand1[i] - operand2[i]
```

where: i = 0 to n – 1

The (V)SUBPD instruction performs an analogous operation for two (four, for 256-bit form) double-precision floating-point values.

(V)SUBSS and (V)SUBSD operate respectively on single-precision and double-precision floating-point (scalar) values in the low-order bits of their operands. Each subtracts the floating-point value in the second source operand from the first and produces a single floating-point result. The extended instructions VADDSS and VADDSD have no 256-bit form.

The (V)SUBSS instruction subtracts the single-precision floating-point value in the second source operand (an XMM register or a doubleword memory location) from the single-precision floating-point value in the first source operand (an XMM register) and writes the result in the low-order doubleword of the destination (an XMM register). In the legacy form, the three high-order doublewords of the destination are not modified. VADDSS copies the upper three doublewords of the source to the destination.

The (V)SUBSD instruction subtracts the double-precision floating-point value in the second source operand (an XMM register or a quadword memory location) from the double-precision floating-point value in the first source operand (an XMM register) and writes the result in the low-order quadword of the destination. In the legacy form, the high-order quadword of the destination is not modified. VADDSD copies the upper quadword of the source to the destination.

For the legacy instructions, the first source register is also the destination. In the extended form, a separate destination register is specified via the instruction encoding.

4.7.4.4 Horizontal Subtraction

- (V)HSUBPS—Horizontal Subtract Packed Single-Precision Floating-Point
- (V)HSUBPD—Horizontal Subtract Packed Double-Precision Floating-Point

The (V)HSUBPS instruction subtracts the single-precision floating-point value in the second doubleword of the first source operand (an XMM register) from that in the first doubleword of the first source operand and stores the result in the first doubleword of the destination XMM register. It subtracts the fourth doubleword of the first source operand from the third doubleword of the first source operand and stores the result in the second doubleword of the destination. It subtracts the single-precision floating-point value in the second doubleword of the second source operand (an XMM register or 128-bit memory location) from that in the first doubleword of the second source

operand and stores the result in the third doubleword of the destination register. It subtracts the fourth doubleword of the second source operand from the third doubleword of the second source operand and stores the result in the fourth doubleword of the destination.

The (V)HSUBPD instruction subtracts the double-precision floating-point value in the upper quadword of the first source operand (an XMM register) from that in the lower quadword of the first source operand and stores the difference in the low-order quadword of the destination XMM register. The difference from the subtraction of the double-precision floating-point value in the upper quadword of the second source operand (an XMM register or 128-bit memory location) from that in the lower quadword of the second source operand is stored in the second quadword of the destination operand.

VHSUBPS and VHSUBPD each have a 256-bit form. For these instructions the first source operand is a YMM register and the second is either a YMM or a 256-bit memory location. These instructions perform the same operation as their 128-bit counterparts on both the lower and upper quadword of their operands.

For the legacy instructions, the first source register is also the destination. For the extended instructions, a separate destination register is specified by the instruction encoding.

4.7.4.5 Horizontal Search

- (V)PHMINPOSUW—Packed Horizontal Minimum and Position Unsigned Word

(V)PHMINPOSUW finds the value and location of the minimum unsigned word from one of 8 horizontally packed unsigned words in its source operand (an XMM register or a 128-bit memory location). The resulting value and location (offset within the source) are packed into the low doubleword of the destination XMM register. Video encoding can be improved by using (V)MPSADBW and (V)PHMINPOSUW together.

4.7.4.6 Simultaneous Addition and Subtraction

- (V)ADDSUBPS—Add/Subtract Packed Single-Precision Floating-Point
- (V)ADDSUBPD—Add/Subtract Packed Double-Precision Floating-Point

The (V)ADDSUBPS instruction adds two (four, for the 256-bit form) pairs of odd-indexed single-precision floating-point elements from the source operands and writes the sums to the corresponding elements of the destination; subtracts the even-indexed elements of the second operand from the corresponding elements of the first operand and writes the differences to the corresponding elements of the destination. The first source operand is an XMM (YMM) register and the second operand is either an XMM (YMM) register or a 128-bit (256-bit) memory location. For the legacy instruction, the first source operand is also the destination. For the extended forms, the result is written to the specified separate destination YMM/XMM register.

The (V)ADDSUBPS instruction adds one (two, for the 256-bit form) pair(s) of odd-indexed double-precision floating-point elements from the source operands and writes the sums to the corresponding elements of the destination; subtracts the even-indexed elements of the second operand from the corresponding elements of the first operand and writes the differences to the corresponding elements of the destination.The first source operand is an XMM (YMM) register and the second operand is

either an XMM (YMM) register or a 128-bit (256-bit) memory location. For the legacy instruction, the first source operand is also the destination. For the extended forms, the result is written to the specified separate destination YMM/XMM register.

4.7.4.7 Multiplication

- (V)MULPS—Multiply Packed Single-Precision Floating-Point
- (V)MULPD—Multiply Packed Double-Precision Floating-Point
- (V)MULSS—Multiply Scalar Single-Precision Floating-Point
- (V)MULSD—Multiply Scalar Double-Precision Floating-Point

The (V)MULPS instruction multiplies each of four (eight for the 256-bit form) single-precision floating-point values in the first source operand (XMM or YMM register) operand by the corresponding single-precision floating-point value in the second source operand (either a register or a memory location) and writes the result to the corresponding doubleword of the destination XMM (YMM) register. The (V)MULPD instruction performs an analogous operation for two (four) double-precision floating-point values.

VMULSS and VMULLSD have no 256-bit form.

The (V)MULSS instruction multiplies the single-precision floating-point value in the low-order doubleword of the first source operand (an XMM register) by the single-precision floating-point value in the low-order doubleword of the second source operand (an XMM register or a 32-bit memory location) and writes the result in the low-order doubleword of the destination XMM register. MULSS leaves the three high-order doublewords of the destination unmodified. VMULSS copies the three high-order doublewords of the first source operand to the destination.

The (V)MULSD instruction multiplies the double-precision floating-point value in the low-order quadword of the first source operand (an XMM register) by the double-precision floating-point value in the low-order quadword of the second source operand (an XMM register or a 64-bit memory location) and writes the result in the low-order quadword of the destination XMM register. MULSD leaves the high-order quadword of the destination unmodified. VMULSD copies the upper quadword of the first source operand to the destination.

For the legacy instructions, the first source register is also the destination. For the extended instructions, a separate destination register is specified by the instruction encoding.

4.7.4.8 Division

- (V)DIVPS—Divide Packed Single-Precision Floating-Point
- (V)DIVPD—Divide Packed Double-Precision Floating-Point
- (V)DIVSS—Divide Scalar Single-Precision Floating-Point
- (V)DIVSD—Divide Scalar Double-Precision Floating-Point

The (V)DIVPS instruction divides each of the four (eight for the 256-bit form) single-precision floating-point values in the first source operand (an XMM or a YMM register) by the corresponding

single-precision floating-point value in the second source operand (either a register or a memory location) and writes the result in the corresponding doubleword of the destination XMM (YMM) register. For vectors of *n* number of elements, the operations are:

```
operand1[i] = operand1[i] ÷ operand2[i]
```

where: i = 0 to n – 1

The (V)DIVPD instruction performs an analogous operation for two (four) double-precision floating-point values.

VDIVSS and VDIVSD have no 256-bit form.

The (V)DIVSS instruction divides the single-precision floating-point value in the low-order doubleword of the first source operand (an XMM register) by the single-precision floating-point value in the low-order doubleword of the second source operand (an XMM register or a 32-bit memory location) and writes the result in the low-order doubleword of the destination XMM register. DIVSS leaves the three high-order doublewords of the destination unmodified. VDIVSS copies the three high-order doublewords of the first source operand to the destination.

The (V)DIVSD instruction divides the double-precision floating-point value in the low-order quadword of the first source operand (an XMM register) by the double-precision floating-point value in the low-order quadword of the second source operand (an XMM register or a 64-bit memory location) and writes the result in the low-order quadword of the destination XMM register. DIVSS leaves the high-order quadword of the destination unmodified. VDIVSD copies the upper quadword of the first source operand to the destination.

For the legacy instructions, the first source XMM register is also the destination. For the extended instructions, a separate destination register is specified by the instruction encoding.

If accuracy requirements allow, convert floating-point division by a constant to a multiply by the reciprocal. Divisors that are powers of two and their reciprocals are exactly representable, and therefore do not cause an accuracy issue, except for the rare cases in which the reciprocal overflows or underflows.

4.7.4.9 Square Root

- (V)SQRTPS—Square Root Packed Single-Precision Floating-Point
- (V)SQRTPD—Square Root Packed Double-Precision Floating-Point
- (V)SQRTSS—Square Root Scalar Single-Precision Floating-Point
- (V)SQRTSD—Square Root Scalar Double-Precision Floating-Point

The (V)SQRTPS instruction computes the square root of each of four (eight for the 256-bit form) single-precision floating-point values in the source operand (an XMM register or 128-bit memory location) and writes the result in the corresponding doubleword of the destination XMM (YMM) register. The (V)SQRTPD instruction performs an analogous operation for two double-precision floating-point values.

VSQRTSS and VSQRTSD have no 256-bit form.

The (V)SQRTSS instruction computes the square root of the low-order single-precision floating-point value in the source operand (an XMM register or 32-bit memory location) and writes the result in the low-order doubleword of the destination XMM register. SQRTSS leaves the three high-order doublewords of the destination XMM register unmodified. VSQRTSS copies the three high-order doublewords of the first source operand to the destination.

The (V)SQRTSD instruction computes the square root of the low-order double-precision floating-point value in the source operand (an XMM register or 64-bit memory location) and writes the result in the low-order quadword of the destination XMM register. SQRTSD leaves the high-order quadword of the destination XMM register unmodified. VSQRTSD copies the upper quadword of the first source operand to the destination.

For the legacy instructions, the first source XMM register is also the destination. For the extended instructions, a separate destination register is specified by the instruction encoding.

4.7.4.10 Reciprocal Square Root

- (V)RSQRTPS—Reciprocal Square Root Packed Single-Precision Floating-Point
- (V)RSQRTSS—Reciprocal Square Root Scalar Single-Precision Floating-Point

The (V)RSQRTPS instruction computes the approximate reciprocal of the square root of each of four (eight for the 256-bit form) single-precision floating-point values in the source operand (an XMM register or 128-bit memory location) and writes the result in the corresponding doubleword of the destination XMM (YMM) register.

The (V)RSQRTSS instruction computes the approximate reciprocal of the square root of the low-order single-precision floating-point value in the source operand (an XMM register or 32-bit memory location) and writes the result in the low-order doubleword of the destination XMM register. RSQRTSS leaves the three high-order doublewords in the destination XMM register unmodified. VRSQRTSS copies the three high-order doublewords from the source operand to the destination.

For the legacy instructions, the first source register is also the destination. For the extended instructions, a separate destination register is specified by the instruction encoding.

For both (V)RSQRTPS and (V)RSQRTSS, the maximum relative error is less than or equal to $1.5 * 2^{-12}$.

4.7.4.11 Reciprocal Estimation

- (V)RCPPS—Reciprocal Packed Single-Precision Floating-Point
- (V)RCPSS—Reciprocal Scalar Single-Precision Floating-Point

The (V)RCPPS instruction computes the approximate reciprocal of each of the four (eight, for the 256-bit form) single-precision floating-point values in the source operand (an XMM register or 128-bit memory location) and writes the result in the corresponding doubleword of the destination XMM (YMM) register.

The (V)RCPSS instruction computes the approximate reciprocal of the low-order single-precision floating-point value in the source operand (an XMM register or 32-bit memory location) and writes the result in the low-order doubleword of the destination XMM register. RCPSS leaves the three high-order doublewords in the destination unmodified. VRCPSS copies the three high-order doublewords from the source to the destination

For the legacy instructions, the first source register is also the destination. For the extended instructions, a separate destination register is specified by the instruction encoding.

For both (V)RCPPS and (V)RCPSS, the maximum relative error is less than or equal to $1.5 * 2^{-12}$.

4.7.4.12 Dot Product

- (V)DPPS—Dot Product Single-Precision Floating-Point
- (V)DPPD—Dot Product Double-Precision Floating-Point

The (V)DPPS instruction computes one (two, for the 256-bit form) single-precision dot product(s), selectively summing one, two, three, or four products of the corresponding source elements of the source operands and then copies this dot product to any combination of four elements in (the upper and lower octword of) the destination. An immediate byte selects which products are computed and to which elements of the destination the dot product is copied. The 256-bit form utilizes the single immediate byte to control the computation of both the upper and the lower octword of the result.

The first source operand is an XMM (YMM) register. The second source operand is either an XMM register or a 128-bit memory location (YMM register or a 256-bit memory location). For the legacy instructions, the first source register is also the destination. For the extended instructions, a separate destination register is specified by the instruction encoding.

The (V)DPPD instruction performs the analogous operation on packed double-precision floating-point operands.

As an example, a single DPPS instruction can be used to compute a two, three, or four element dot product. A single 256-bit VDPPS instruction can be used to compute two dot products of up to four elements each.

4.7.4.13 Floating-Point Round Instructions with Selectable Rounding Mode

- (V)ROUNDPS—Round Packed Single-Precision Floating-Point
- (V)ROUNDPD—Round Packed Double-Precision Floating-Point
- (V)ROUNDSS—Round Scalar Single-Precision
- (V)ROUNDSD—Round Scalar Double-Precision

High level languages and libraries often expose rounding operations that have a variety of numeric rounding and exception behaviors. These four rounding instructions cover scalar and packed single and double-precision floating-point operands. The rounding mode can be selected using one of the IEEE-754 modes (Nearest, -Inf, +Inf, and Truncate) without changing the current rounding mode. Alternately, the instruction can be forced to use the current rounding mode.

The (V)ROUNDPS and (V)ROUNDPD instructions round each of the four (eight, for the 256-bit form) single-precision values or two (four) double-precision values in the source operand (either an XMM register or a 128-bit memory location or, for the 256-bit form, a YMM register or 256-bit memory location) based on controls in an immediate byte and write the results to the respective elements of the destination XMM (YMM) register.

The (V)ROUNDSS and (V)ROUNDSD instructions round the single-precision or double-precision floating-point value from the source operand based on the rounding control specified in an immediate byte and write the results to the low-order doubleword or quadword of an XMM register. The source operand is either the low-order doubleword or quadword of an XMM register or a 32-bit or 64-bit memory location. For the legacy forms of these instructions, the upper three doublewords or high-order quadword of the destination are not modified. VROUNDSS copies the upper three doublewords of a second XMM register to the destination. VROUNDSD copies the high-order quadword of a second XMM register to the destination.

4.7.5 Fused Multiply-Add Instructions

The fused multiply-add (FMA) instructions comprise AMD's four operand FMA4 instruction set and the three operand FMA instruction set.

The FMA instructions provide a set of fused multiply-add mathematical operations. The basic FMA instruction performs a multiply of two floating-point scalar or vector operands followed by a second operation in which the product of the first operation is added to a third scalar or vector floating-point operand. The result is rounded to the precision of the source operands and stored in either a distinct destination register or in the register that sourced the first operand. Variants of the basic FMA operation allow for the negation (sign inversion) of the products and the negation of the third scalar operand or elements within the third vector operand.

Figure 4-46 below provides a schematic representation of the scalar FMA instructions. Note that the (× 1/-1) operator in the diagram denotes a negation (sign inversion) operation performed in some of the instructions.

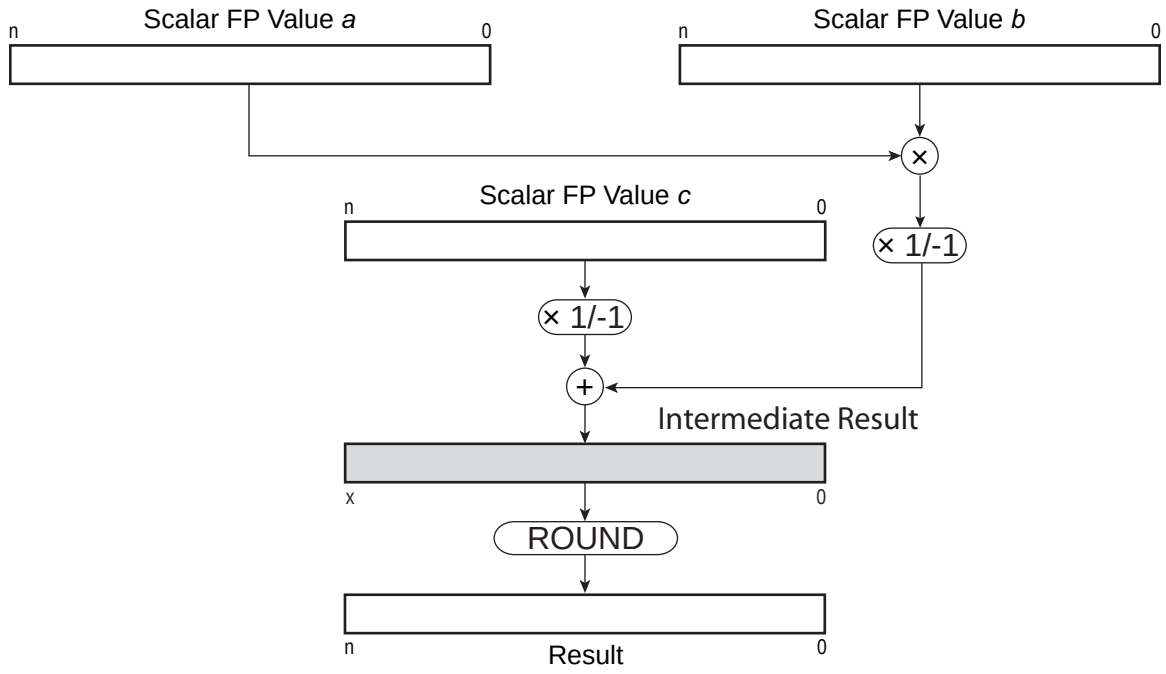

Figure 4-46. Scalar FMA Instructions

Figure 4-47 below provides a schematic representation of the vector FMA instructions. Note that the (× 1/-1) operator in the diagram denotes a negation (sign inversion) operation performed in some of the instructions. For illustrative purposes, four-element vectors are shown in the figure. The 128- and 256-bit data types support from 2 to 8 elements per vector.

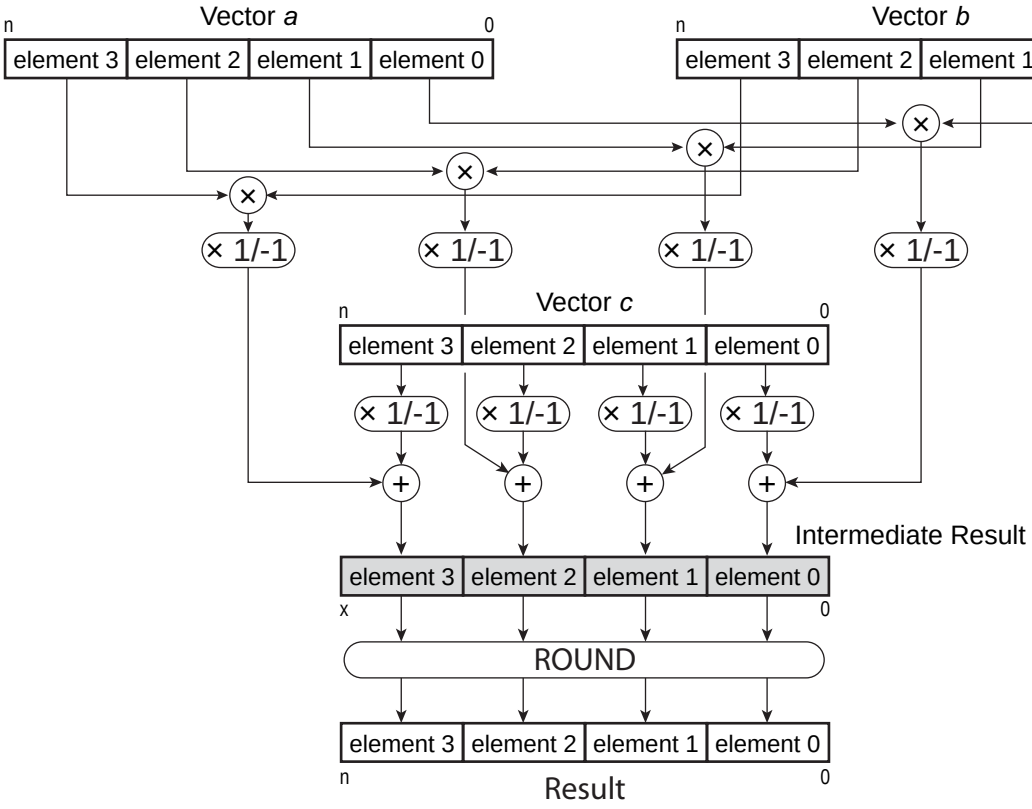

Figure 4-47. Vector FMA Instructions

Fused multiply-add instructions can improve the performance and accuracy of many computations that involve the accumulation of multiple products, such as the dot product operation and matrix multiplication. Intermediate results may utilize a non-standard (higher) precision (using more significant bits) than the standard single-precision or double-precision floating-point formats allow. A fused multiply-add can be faster and more precise than the equivalent operations performed serially because the step of rounding intermediate results can be skipped.

The FMA4 instructions support the specification of three operand sources (YMM/XMM registers or memory) and a distinct destination register. This enables non-destructive computations where the result does not overwrite one of the source operand registers. For the three operand FMA instructions the result always overwrites the first source register. Variants within the set allow for the negation (sign inversion) of operands or vector operand elements and/or intermediate values.

Six basic instruction variants are defined. These are:

- Fused multiply-add of scalar and vector (packed) single- and double-precision floating-point values:
- Fused multiply-alternating add/subtract of vector (packed) single- and double-precision floating-point values
- Fused multiply-alternating subtract/add of vector (packed) single- and double-precision floating-point values
- Fused multiply-subtract of scalar and vector (packed) single- and double-precision floating-point values
- Fused negative multiply-add of scalar and vector (packed) single- and double-precision floating-point values
- Fused negative multiply-subtract of scalar and vector (packed) single- and double-precision floating-point values

Note that a scalar operation is not defined for the fused multiply-alternating add/subtract and the fused multiply-alternating subtract/add instructions. Each variant will be discussed below.

4.7.5.1 Operand Source Specification

Each instruction operates on three operands to produce a result. Individual instruction forms within a variant allow either the second or third operand to be sourced from memory. In the following descriptions, the first operand will be referred to as operand *a*, the second will be referred to as operand *b* and the third operand *c*.

The instruction syntax for specifying this alternate sourcing of the second and third operands differs between the FMA4 and the three operand FMA instructions.

The FMA4 instructions use the same instruction mnemonic allowing the memory operand source to appear in either the second or third operand position:

```
VF(N)Moptxx dest_reg, src_reg1, src_reg2/mem, src_reg3
VF(N)Moptxx dest_reg, src_reg1, src_reg2, src_reg3/mem
```

The three-operand instructions utilize three different instruction mnemonics having the following syntax:

```
VF(N)Mopt132xx src_reg1, src_reg2, src_reg3/mem
VF(N)Mopt213xx src_reg1, src_reg2, src_reg3/mem
VF(N)Mopt231xx src_reg1, src_reg2, src_reg3/mem
```

Where *opt* represents the instruction operation and *xx* represents the operand data type.

Operand sourcing for each instruction form is described in the following table:

Figure 4-48. Operand Source / Destination Specification

Instruction	Operand a	Operand b	Operand c	Result
VF(N)M*opt**xx***	*src_reg1*	*src_reg2 / mem*	*src_reg3*	*dest_reg*
VF(N)M*opt**xx***	*src_reg1*	*src_reg2*	*src_reg3 / mem*	*dest_reg*
VF(N)M*opt*132*xx*	*src_reg1*	*src_reg3 / mem*	*src_reg2*	*src_reg1*
VF(N)M*opt*213*xx*	*src_reg2*	*src_reg1*	*src_reg3 / mem*	*src_reg1*
VF(N)M*opt*231*xx*	*src_reg2*	*src_reg3 / mem*	*src_reg1*	*src_reg1*

The specific operations performed by the six variants are described in the next sections.

4.7.5.2 Multiply and Add Instructions

VFMADDPD / VFMADD132PD / VFMADD213PD / VFMADD231PD

Multiplies together the double-precision floating-point vectors *a* and *b*, adds the product to the double-precision floating-point vector *c*, and performs rounding to produce the double-precision floating-point vector result.

VFMADDPS / VFMADD132PS / VFMADD213PS / VFMADD231PS

Multiplies together the single-precision floating-point vectors *a* and *b*, adds the product to the single-precision floating-point vector *c*, and performs rounding to produce the single-precision floating-point vector result.

VFMADDSD / VFMADD132SD / VFMADD213SD / VFMADD231SD

Multiplies together the double-precision floating-point scalars *a* and *b*, adds the product to the double-precision floating-point scalar *c*, and performs rounding to produce the double-precision floating-point scalar result.

VFMADDSS / VFMADD132SS / VFMADD213SS / VFMADD231SS

Multiplies together the single-precision floating-point scalars *a* and *b*, adds the product to the single-precision floating-point scalar *c*, and performs rounding to produce the single-precision floating-point scalar result.

4.7.5.3 Multiply with Alternating Add/Subtract Instructions

VFMADDSUBPD / VFMADDSUB132PD / VFMADDSUB213PD / VFMADDSUB231PD

Multiplies together the double-precision floating-point vectors *a* and *b*, adds each odd-numbered element of the double-precision floating-point vector *c* to the corresponding element of the product, subtracts each even-numbered element of double-precision floating-point vector *c* from the corresponding element of the product, and performs rounding to produce the double-precision floating-point vector result.

VFMADDSUBPS / VFMADDSUB132PS / VFMADDSUB213PS / VFMADDSUB231PS

Multiplies together the single-precision floating-point vectors *a* and *b*, adds each odd-numbered element of the single-precision floating-point vector *c* to the corresponding element of the product, subtracts each even-numbered element of single-precision floating-point vector *c* from the corresponding element of the product, and performs rounding to produce the single-precision floating-point vector result.

4.7.5.4 Multiply with Alternating Subtract/Add Instructions

VFMSUBADDPD / VFMSUBADD132PD / VFMSUBADD213PD / VFMSUBADD231PD

Multiplies together the double-precision floating-point vectors *a* and *b*, adds each even-numbered element of the double-precision floating-point vector *c* to the corresponding element of the product, subtracts each odd-numbered element of double-precision floating-point vector *c* from the corresponding element of the product, and performs rounding to produce the double-precision floating-point vector result.

VFMSUBADDPS / VFMSUBADD132PS / VFMSUBADD213PS / VFMSUBADD231PS

Multiplies together the single-precision floating-point vectors *a* and *b*, adds each even-numbered element of the single-precision floating-point vector *c* to the corresponding element of the product, subtracts each odd-numbered element of single-precision floating-point vector *c* from the corresponding element of the product, and performs rounding to produce the single-precision floating-point vector result.

4.7.5.5 Multiply and Subtract Instructions

VFMSUBPD / VFMSUB132PD / VFMSUB213PD / VFMSUB231PD

Multiplies together the double-precision floating-point vectors *a* and *b*, subtracts the double-precision floating-point vector *c* from the product, and performs rounding to produce the double-precision floating-point vector result.

VFMSUBPS / VFMSUB132PS / VFMSUB213PS / VFMSUB231PS

Multiplies together the single-precision floating-point vectors *a* and *b*, subtracts the single-precision floating-point vector *c* from the product, and performs rounding to produce the single-precision floating-point vector result.

VFMSUBSD / VFMSUB132SD / VFMSUB213SD / VFMSUB231SD

Multiplies together the double-precision floating-point scalars *a* and *b*, subtracts the double-precision floating-point scalar *c* from the product, and performs rounding to produce the double-precision floating-point result.

VFMSUBSS / VFMSUB132SS / VFMSUB213SS / VFMSUB231SS

Multiplies together the single-precision floating-point scalars *a* and *b*, subtracts the single-precision floating-point scalar *c* from the product, and performs rounding to produce the single-precision floating-point result.

4.7.5.6 Negative Multiply and Add Instructions

VFNMADDPD / VFNMADD132PD / VFNMADD213PD / VFNMADD231PD

Multiplies together the double-precision floating-point vectors *a* and *b*, negates (inverts the sign) the product, adds this intermediate result to the double-precision floating-point vector *c*, and performs rounding to produce the double-precision floating-point vector result.

VFNMADDPS / VFNMADD132PS / VFNMADD213PS / VFNMADD231PS

Multiplies together the single-precision floating-point vectors *a* and *b*, negates (inverts the sign) the product, adds this intermediate result to the single-precision floating-point vector *c*, and performs rounding to produce the single-precision floating-point vector result.

VFNMADDSD / VFNMADD132SD / VFNMADD213SD / VFNMADD231SD

Multiplies together the double-precision floating-point scalars *a* and *b*, negates (inverts the sign) the product, adds this intermediate result to the double-precision floating-point scalar *c*, and performs rounding to produce the double-precision floating-point result.

VFNMADDSS / VFNMADD132SS / VFNMADD213SS / VFNMADD231SS

Multiplies together the single-precision floating-point scalars *a* and *b*, negates (inverts the sign) the product, adds this intermediate result to the single-precision floating-point scalar *c*, and performs rounding to produce the single-precision floating-point result.

4.7.5.7 Negative Multiply and Subtract Instructions

VFNMSUBPD / VFNMSUB132PD / VFNMSUB213PD / VFNMSUB231PD

Multiplies together the double-precision floating-point vectors *a* and *b*, negates the product (inverts the sign), adds this intermediate result to the negated double-precision floating-point vector *c*, and performs rounding to produce the double-precision floating-point vector result.

VFNMSUBPS / VFNMSUB132PS / VFNMSUB213PS / VFNMSUB231PS

Multiplies together the single-precision floating-point vectors *a* and *b*, negates the product (inverts the sign), adds this intermediate result to the negated single-precision floating-point vector *c*, and performs rounding to produce the single-precision floating-point vector result.

VFNMSUBSD / VFNMSUB132SD / VFNMSUB213SD / VFNMSUB231SD

Multiplies together the double-precision floating-point scalars *a* and *b*, negates the product (inverts the sign), adds this intermediate result to the negated double-precision floating-point scalar *c*, and performs rounding to produce the double-precision floating-point result.

VFNMSUBSS / VFNMSUB132SS / VFNMSUB213SS / VFNMSUB231SS

Multiplies together the single-precision floating-point scalars *a* and *b*, negates the product (inverts the sign), adds this intermediate result to the negated single-precision floating-point scalar *c*, and performs rounding to produce the single-precision floating-point result.

4.7.6 Compare

The floating-point vector-compare instructions compare two operands, and they either write a mask, or they write the maximum or minimum value, or they set flags. Compare instructions can be used to avoid branches. Figure 4-21 on page 148 shows an example of using compare instructions.

4.7.6.1 Compare and Write Mask

- (V)CMPPS—Compare Packed Single-Precision Floating-Point
- (V)CMPPD—Compare Packed Double-Precision Floating-Point
- (V)CMPSS—Compare Scalar Single-Precision Floating-Point
- (V)CMPSD—Compare Scalar Double-Precision Floating-Point

The (V)CMPPS instruction compares each of four (eight, for 256-bit form) single-precision floating-point values in the first source operand with the corresponding single-precision floating-point value in the second source operand and writes the result in the corresponding 32 bits of the destination. The type of comparison is specified by the three (five, for the AVX forms) low-order bits of the immediate-byte operand. The result of each compare is a 32-bit value of all 1s (TRUE) or all 0s (FALSE). Some compare operations that are not directly supported by the immediate-byte encodings can be implemented by swapping the contents of the source and destination operands before executing the compare.

The (V)CMPPD instruction performs an analogous operation for two (four, for the 256-bit form) double-precision floating-point values.

The first source operand is an XMM (YMM) register. The second source operand is either an XMM register or a 128-bit memory location (YMM register or a 256-bit memory location). For the legacy form of the instructions, the first source register is also the destination. The extended form of the instructions encodes a separate destination XMM (YMM) register.

The (V)CMPSS instruction performs an analogous operation for single-precision floating-point values. The first source operand is the low-order doubleword of an XMM register. The second source operand is either the low-order doubleword of an XMM register or a 32-bit memory location. CMPSS leaves the three high-order doublewords of the destination unmodified. VCMPSS copies the three

high-order doublewords of the first source operand to the destination. For CMPSS the first source operand is also the destination.

The (V)CMPSD instruction performs an analogous operation on double-precision floating-point values. CMPSD leaves the high-order quadword of the destination XMM register unmodified. VCMPSD copies the high-order quadword of the first source operand to the destination.

Figure 4-49 shows a (V)CMPPD compare operation.

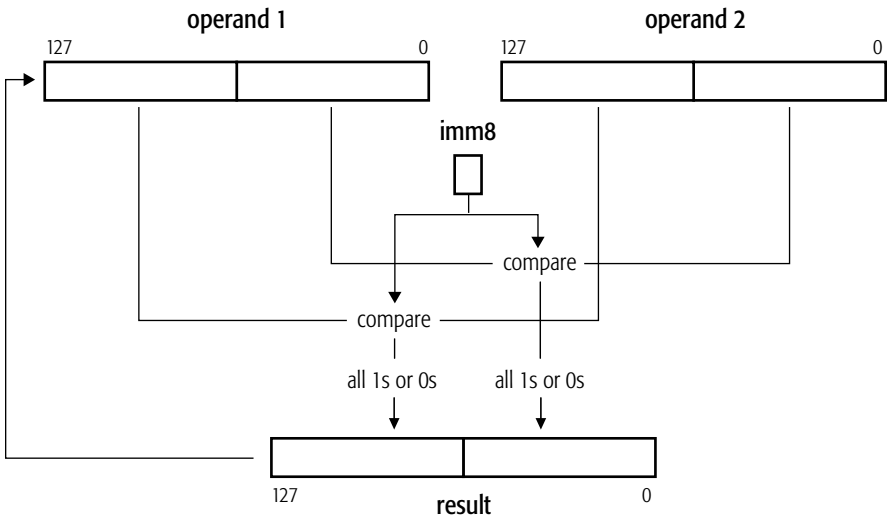

Figure 4-49. (V)CMPPD Compare Operation

4.7.6.2 Compare and Write Minimum or Maximum

- (V)MAXPS—Maximum Packed Single-Precision Floating-Point
- (V)MAXPD—Maximum Packed Double-Precision Floating-Point
- (V)MAXSS—Maximum Scalar Single-Precision Floating-Point
- (V)MAXSD—Maximum Scalar Double-Precision Floating-Point
- (V)MINPS—Minimum Packed Single-Precision Floating-Point
- (V)MINPD—Minimum Packed Double-Precision Floating-Point
- (V)MINSS—Minimum Scalar Single-Precision Floating-Point
- (V)MINSD—Minimum Scalar Double-Precision Floating-Point

The (V)MAXPS and (V)MINPS instructions compare each of four (eight, for the 256-bit form) single-precision floating-point values in the first source operand with the corresponding single-precision floating-point value in the second source operand and write the maximum or minimum, respectively, of the two (four) values to the corresponding doubleword of the destination. The (V)MAXPD and (V)MINPD instructions perform analogous operations on pairs of double-precision floating-point

values. The first source operand is an XMM (YMM) register and the second is either an XMM register or a 128-bit memory location (or for the 256-bit form, a YMM register or a 256-bit memory location). The destination for the legacy forms is the source operand register. The extended instructions specify a separate destination register in their encoding.

The (V)MAXSS and (V)MINSS instructions compare the single-precision floating-point value of the first source operand with the single-precision floating-point value in the second source operand and write the maximum or minimum, respectively, of the two values to the low-order 32 bits of the destination XMM register. The first source operand is the low-order doubleword of an XMM register and the second is either the low-order doubleword of an XMM register or a 32-bit memory location. The legacy forms do not modify the three high-order doublewords of the destination. The extended forms merge in the corresponding bits from an additional XMM source operand.

The (V)MAXSD and (V)MINSD instructions compare the double-precision floating-point value of the first source operand with the double-precision floating-point value in the second source operand and write the maximum or minimum, respectively, of the two values to the low-order quadword of the destination XMM register. The first source operand is the low-order doubleword of an XMM register and the second is either the low-order doubleword of an XMM register or a 32-bit memory location. The legacy forms do not modify the high-order quadword of the destination XMM register. The extended forms merge in the corresponding bits from an additional XMM source operand.

The destination for the legacy forms is the source operand register. The extended instructions specify a separate destination register in their encoding.

The (V)MIN*x* and (V)MAX*x* instructions are useful for clamping (saturating) values, such as color values in 3D geometry and rasterization.

4.7.6.3 Compare and Write rFLAGS

- (V)COMISS—Compare Ordered Scalar Single-Precision Floating-Point
- (V)COMISD—Compare Ordered Scalar Double-Precision Floating-Point
- (V)UCOMISS—Unordered Compare Scalar Single-Precision Floating-Point
- (V)UCOMISD—Unordered Compare Scalar Double-Precision Floating-Point

The (V)COMISS instruction performs an ordered compare of the single-precision floating-point value in the low-order 32 bits of the first operand with the single-precision floating-point value in the second operand (either the low-order 32 bits of an XMM register or a 32-bit memory location) and sets the zero flag (ZF), parity flag (PF), and carry flag (CF) bits in the rFLAGS register to reflect the result of the compare. The OF, AF, and SF bits in rFLAGS are set to zero.

The (V)COMISD instruction performs an analogous operation on the double-precision floating-point source operands. The (V)UCOMISS and (V)UCOMISD instructions perform an analogous, but unordered, compare operations. Figure 4-50 on page 216 shows a (V)COMISD compare operation.

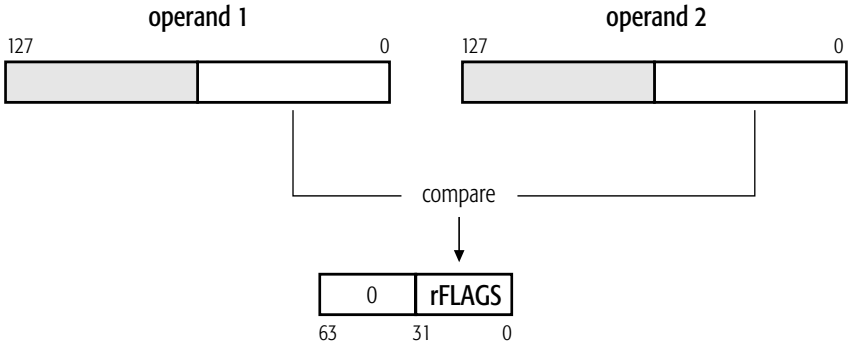

Figure 4-50. (V)COMISD Compare Operation

The difference between an ordered and unordered comparison has to do with the conditions under which a floating-point invalid-operation exception (IE) occurs. In an ordered comparison ((V)COMISS or (V)COMISD), an IE exception occurs if either of the source operands is either type of NaN (QNaN or SNaN). In an unordered comparison, the exception occurs only if a source operand is an SNaN. For a description of NaNs, see Section "Floating-Point Number Types" on page 124. For a description of exceptions, see "Exceptions" on page 218.

4.7.7 Logical

The vector-logic instructions perform Boolean logic operations, including AND, OR, and exclusive OR. The extended forms of the instructions support both 128-bit and 256-bit operands.

4.7.7.1 And

- (V)ANDPS—Logical Bitwise AND Packed Single-Precision Floating-Point
- (V)ANDPD—Logical Bitwise AND Packed Double-Precision Floating-Point
- (V)ANDNPS—Logical Bitwise AND NOT Packed Single-Precision Floating-Point
- (V)ANDNPD—Logical Bitwise AND NOT Packed Double-Precision Floating-Point

The (V)ANDPS instruction performs a logical bitwise AND of the four (eight, for the 256-bit form) packed single-precision floating-point values in the first source operand and the corresponding four (eight) single-precision floating-point values in the second source operand and writes the result to the destination. The (V)ANDPD instruction performs an analogous operation on the two (four) packed double-precision floating-point values. The (V)ANDNPS and (V)ANDNPD instructions invert the elements of the first source vector (creating a one's complement of each element), AND them with the elements of the second source vector, and write the result to the destination. The first source operand is an XMM (YMM) register. The second source operand is either another XMM (YMM) register or a 128-bit (256-bit) memory location. For the legacy instructions, the destination is also the first source operand. For the extended forms, the destination is a separately specified XMM (YMM) register.

4.7.7.2 Or

- (V)ORPS—Logical Bitwise OR Packed Single-Precision Floating-Point
- (V)ORPD—Logical Bitwise OR Packed Double-Precision Floating-Point

The (V)ORPS instruction performs a logical bitwise OR of four (eight, for the 256-bit form) single-precision floating-point values in the first source operand and the corresponding four (eight) single-precision floating-point values in the second operand and writes the result to the destination. The (V)ORPD instruction performs an analogous operation on pairs of two double-precision floating-point values. The first source operand is an XMM (YMM) register. The second source operand is either another XMM (YMM) register or a 128-bit (256-bit) memory location. For the legacy instructions, the destination is also the first source operand. For the extended forms, the destination is a separately specified XMM (YMM) register.

4.7.7.3 Exclusive Or

- (V)XORPS—Logical Bitwise Exclusive OR Packed Single-Precision Floating-Point
- (V)XORPD—Logical Bitwise Exclusive OR Packed Double-Precision Floating-Point

The (V)XORPS instruction performs a logical bitwise exclusive OR of four (eight, for the 256-bit form) single-precision floating-point values in the first operand and the corresponding four (eight) single-precision floating-point values in the second operand and writes the result to the destination. The (V)XORPD instruction performs an analogous operation on pairs of two double-precision floating-point values. The first source operand is an XMM (YMM) register. The second source operand is either another XMM (YMM) register or a 128-bit (256-bit) memory location. For the legacy instructions, the destination is also the first source operand. For the extended forms, the destination is a separately specified XMM (YMM) register.

4.8 Instruction Prefixes

Instruction prefixes, in general, are described in “Instruction Prefixes” on page 76. The following restrictions apply to the use of instruction prefixes with SSE instructions.

4.8.1 Supported Prefixes

The following prefixes can be used with SSE instructions:

- *Address-Size Override*—The 67h prefix affects only operands in memory. The prefix is ignored by all other SSE instructions.
- *Operand-Size Override*—The 66h prefix is used to form the opcodes of certain SSE instructions. The prefix is ignored by all other SSE instructions.
- *Segment Overrides*—The 2Eh (CS), 36h (SS), 3Eh (DS), 26h (ES), 64h (FS), and 65h (GS) prefixes affect only operands in memory. In 64-bit mode, the contents of the CS, DS, ES, SS segment registers are ignored.

- *REP*—The F2 and F3h prefixes do not function as repeat prefixes for the SSE instructions. Instead, they are used to form the opcodes of certain SSE instructions. The prefixes are ignored by all other SSE instructions.
- *REX*—The REX prefixes affect operands that reference a GPR or XMM register when running in 64-bit mode. It allows access to the full 64-bit width of any of the 16 extended GPRs and to any of the 16 extended XMM registers. The REX prefix also affects the FXSAVE and FXRSTOR instructions, in which it selects between two types of 512-byte memory-image format, as described in "Media and x87 Processor State" in Volume 2. The prefix is ignored by all other SSE instructions.

4.8.1.1 Special-Use and Reserved Prefixes

The following prefixes are used as opcode bytes in some SSE instructions and are reserved in all other SSE instructions:

- *Operand-Size Override*—The 66h prefix.
- *REP*—The F2 and F3h prefixes.

4.8.1.2 Prefixes That Cause Exceptions

The following prefixes cause an exception:

- *LOCK*—The F0h prefix causes an invalid-opcode exception when used with SSE instructions.

4.9 Feature Detection

As discussed in Section 4.1.2 "Origins" on page 112, the SSE instruction set is composed of a large number of subsets. To avoid a #UD fault when attempting to execute any of these instructions, hardware must support the instruction subset, system software must indicate its support of SSE context management, and the subset must be enabled. Hardware support for each subset is indicated by a processor feature bit. These are accessed via the CPUID instruction. See Volume 3 for details on the CPUID instruction and the feature bits associated with the SSE Instruction set.

4.10 Exceptions

Types of Exceptions

SSE instructions can generate two types of exceptions:

- *General-Purpose Exceptions*, described below in "General-Purpose Exceptions"
- *SIMD Floating-Point Exception*, described below in "SIMD Floating-Point Exception Causes" on page 220

Relation to x87 Exceptions

Although the SSE instructions and the x87 floating-point instructions each have certain exceptions with the same names, the exception-reporting and exception-handling methods used by the two instruction subsets are distinct and independent of each other. If procedures using both types of instructions are run in the same operating environment, separate services routines should be provided for the exceptions of each type of instruction subset.

4.10.1 General-Purpose Exceptions

The sections below list general-purpose exceptions generated and not generated by SSE instructions. For a summary of the general-purpose exception mechanism, see “Interrupts and Exceptions” on page 91. For details about each exception and its potential causes, see “Exceptions and Interrupts” in Volume 2.

4.10.1.1 Exceptions Generated

The SSE instructions can generate the following general-purpose exceptions:

- #DB—Debug Exception (Vector 1)
- #UD—Invalid-Opcode Exception (Vector 6)
- #NM—Device-Not-Available Exception (Vector 7)
- #DF—Double-Fault Exception (Vector 8)
- #SS—Stack Exception (Vector 12)
- #GP—General-Protection Exception (Vector 13)
- #PF—Page-Fault Exception (Vector 14)
- #MF—x87 Floating-Point Exception-Pending (Vector 16)
- #AC—Alignment-Check Exception (Vector 17)
- #MC—Machine-Check Exception (Vector 18)
- #XF—SIMD Floating-Point Exception (Vector 19)

A device not available exception (#NM) can occur if:

- an attempt is made to execute a SSE instruction when the task switch bit (TS) of the control register (CR0) is set to 1 (CR0.TS = 1), or
- an attempt is made to execute an FXSAVE or FXRSTOR instruction when the floating-point software-emulation (EM) bit in control register 0 is set to 1 (CR0.EM = 1).

An invalid-opcode exception (#UD) can occur if:

- a CPUID feature flag indicates that a feature is not supported (see “Feature Detection” on page 218), or
- a SIMD floating-point exception occurs when the operating-system XMM exception support bit (OSXMMEXCPT) in control register 4 is cleared to 0 (CR4.OSXMMEXCPT = 0).
- an instruction subset is supported but not enabled.

Only the following SSE instructions, all of which can access an MMX register, can cause an #MF exception:

- Data Conversion: CVTPD2PI, CVTPS2PI, CPTPI2PD, CVTPI2PS, CVTTPD2PI, CVTTPS2PI.
- Data Transfer: MOVDQ2Q, MOVQ2DQ.

For details on the system control-register bits, see "System-Control Registers" in Volume 2. For details on the machine-check mechanism, see "Machine Check Mechanism" in Volume 2.

For details on #XF exceptions, see "SIMD Floating-Point Exception Causes" on page 220.

4.10.1.2 Exceptions Not Generated

The SSE instructions do not generate the following general-purpose exceptions:

- #DE—Divide-by-zero-error exception (Vector 0)
- Non-Maskable-Interrupt Exception (Vector 2)
- #BP—Breakpoint Exception (Vector 3)
- #OF—Overflow exception (Vector 4)
- #BR—Bound-range exception (Vector 5)
- Coprocessor-segment-overrun exception (Vector 9)
- #TS—Invalid-TSS exception (Vector 10)
- #NP—Segment-not-present exception (Vector 11)
- #MC—Machine-check exception (Vector 18)

For details on all general-purpose exceptions, see "Exceptions and Interrupts" in Volume 2.

4.10.2 SIMD Floating-Point Exception Causes

The SIMD floating-point exception is the logical OR of the six floating-point exceptions (IE, DE, ZE, OE, UE, PE) that are reported (signalled) in the MXCSR register's exception flags (See Section 4.2.2 "MXCSR Register" on page 115). Each of these six exceptions can be either masked or unmasked by software, using the mask bits in the MXCSR register.

4.10.2.1 Exception Vectors

The SIMD floating-point exception is listed above as #XF (Vector 19) but it actually causes either an #XF exception or a #UD (Vector 6) exception, if an unmasked IE, DE, ZE, OE, UE, or PE exception is reported. The choice of exception vector is determined by the operating-system XMM exception support bit (OSXMMEXCPT) in control register 4 (CR4):

- When CR4.OSXMMEXCPT = 1, a #XF exception occurs.
- When CR4.OSXMMEXCPT = 0, a #UD exception occurs.

SIMD floating-point exceptions are precise. If an exception occurs when it is masked, the processor responds in a default way that does not invoke the SIMD floating-point exception service routine. If an

exception occurs when it is unmasked, the processor suspends processing of the faulting instruction precisely and invokes the exception service routine.

4.10.2.2 Exception Types and Flags

SIMD floating-point exceptions are differentiated into six types, five of which are mandated by the IEEE 754 standard. These six types and their bit-flags in the MXCSR register are shown in Table 4-12. The causes and handling of such exceptions are described below.

Table 4-12. SIMD Floating-Point Exception Flags

Exception and Mnemonic	MXCSR Bit[1]	Comparable IEEE 754 Exception
Invalid-operation exception (IE)	0	Invalid Operation
Denormalized operation exception (DE)	1	*none*
Zero-divide exception (ZE)	2	Division by Zero
Overflow exception (OE)	3	Overflow
Underflow exception (UE)	4	Underflow
Precision exception (PE)	5	Inexact

Note:
1. *See "MXCSR Register" on page 115 for a summary of each exception.*

The sections below describe the causes for the SIMD floating-point exceptions. The pseudocode equations in these descriptions assume logical TRUE = 1 and the following definitions:

Max_{normal}

The largest normalized number that can be represented in the destination format. This is equal to the format's largest representable finite, positive or negative value. (Normal numbers are described in "Normalized Numbers" on page 125.)

Min_{normal}

The smallest normalized number that can be represented in the destination format. This is equal to the format's smallest precisely representable positive or negative value with an unbiased exponent of 1.

$Result_{infinite}$

A result of infinite precision, which is representable when the width of the exponent and the width of the significand are both infinite.

$Result_{round}$

A result, after rounding, whose unbiased exponent is infinitely wide and whose significand is the width specified for the destination format. (Rounding is described in "Floating-Point Rounding" on page 129.)

$Result_{round,\ denormal}$

A result, after rounding and denormalization. (Denormalization is described in "Denormalized (Tiny) Numbers" on page 125.)

Masked and unmasked responses to the exceptions are described in "SIMD Floating-Point Exception Masking" on page 226. The priority of the exceptions is described in "SIMD Floating-Point Exception Priority" on page 224.

4.10.2.3 Invalid-Operation Exception (IE)

The IE exception occurs due to one of the attempted invalid operations shown in Table 4-13.

Table 4-13. Invalid-Operation Exception (IE) Causes

Operation	Condition
Any Arithmetic Operation, and (V)CVTPS2PD, (V)CVTPD2PS, (V)CVTSS2SD, (V)CVTSD2SS	A source operand is an SNaN
(V)MAXPS, (V)MAXPD, (V)MAXSS, (V)MAXSD (V)MINPS, (V)MINPD, (V)MINSS, (V)MINSD (V)CMPPS, (V)CMPPD, (V)CMPSS, (V)CMPSD (V)COMISS, (V)COMISD	A source operand is a NaN (QNaN or SNaN)
(V)ADDPS, (V)ADDPD, (V)ADDSS, (V)ADDSD, (V)ADDSUBPS. (V)ADDSUBPD, (V)HADDPS, (V)HADDPD	Source operands are infinities with opposite signs
(V)SUBPS, (V)SUBPD, (V)SUBSS, (V)SUBSD, (V)ADDSUBPS, (V)ADDSUBPD, (V)HSUBPS, (V)HSUBPD	Source operands are infinities with same sign
(V)MULPS, (V)MULPD, (V)MULSS, (V)MULSD	Source operands are zero and infinity
(V)DIVPS, (V)DIVPD, (V)DIVSS, (V)DIVSD	Source operands are both infinity or both zero
(V)SQRTPS, (V)SQRTPD, (V)SQRTSS, (V)SQRTSD	Source operand is less than zero (except ±0, which returns ±0)
Data conversion from floating-point to integer: CVTPS2PI, CVTPD2PI, (V)CVTSS2SI, (V)CVTSD2SI, (V)CVTPS2DQ, (V)CVTPD2DQ, CVTTPS2PI, CVTTPD2PI, (V)CVTTPD2DQ, (V)CVTTPS2DQ, (V)CVTTSS2SI, (V)CVTTSD2SI)	Source operand is a NaN, infinite, or not representable in destination data type

4.10.2.4 Denormalized-Operand Exception (DE)

The DE exception occurs when one of the source operands of an instruction is in denormalized form, as described in "Denormalized (Tiny) Numbers" on page 125.

4.10.2.5 Zero-Divide Exception (ZE)

The ZE exception occurs when an instruction attempts to divide zero into a non-zero finite dividend.

4.10.2.6 Overflow Exception (OE)

The OE exception occurs when the value of a rounded floating-point result is larger than the largest representable normalized positive or negative floating-point number in the destination format. Specifically:

$$OE = Result_{round} > Max_{normal}$$

An overflow can occur through computation or through conversion of higher-precision numbers to lower-precision numbers.

4.10.2.7 Underflow Exception (UE)

The UE exception occurs when the value of a rounded, non-zero floating-point result is too small to be represented as a normalized positive or negative floating-point number in the destination format. Such a result is called a *tiny* number, associated with the Precision Exception (PE) described immediately below.

If UE exceptions are masked by the underflow mask (UM) bit, a UE exception occurs only if the denormalized form of the rounded result is imprecise. Specifically:

$$UE = ((UM=0 \text{ and } (Result_{round} < Min_{normal}) \text{ or } ((UM=1 \text{ and } (Result_{round,\ denormal}) != Result_{infinite})$$

Underflows can occur, for example, by taking the reciprocal of the largest representable number, or by converting small numbers in double-precision format to a single-precision format, or simply through repeated division. The flush-to-zero (FZ) bit in the MXCSR offers additional control of underflows that are masked. See Section 4.2.2 “MXCSR Register” on page 115 for details.

4.10.2.8 Precision Exception (PE)

The PE exception, also called the *inexact-result* exception, occurs when a rounded floating-point result differs from the infinitely precise result and thus cannot be represented precisely in the destination format. This exception is caused by—among other things—rounding of underflow or overflow results according to the rounding control (RC) field in the MXCSR, as described in “Floating-Point Rounding” on page 129.

If an overflow or underflow occurs and the OE or UE exceptions are masked by the overflow mask (OM) or underflow mask (UM) bit, a PE exception occurs only if the rounded result (for OE) or the denormalized form of the rounded result (for UE) is imprecise. Specifically:

$$PE = ((Result_{round,\ denormal} \text{ or } Result_{round}) != Result_{infinite}) \text{ or } (OM=1 \text{ and } (Result_{round} > Max_{normal})) \text{ or } (UM=1 \text{ and } (Result_{round,\ denormal} < Min_{normal}))$$

Software that does not require exact results normally masks this exception.

4.10.3 SIMD Floating-Point Exception Priority

Figure 4-14 on page 224 shows the priority with which the processor recognizes multiple, simultaneous SIMD floating-point exceptions and operations involving QNaN operands. Each exception type is characterized by its timing, as follows:

- *Pre-Computation*—an exception that is recognized before an instruction begins its operation.
- *Post-Computation*—an exception that is recognized after an instruction completes its operation.

For masked (but not unmasked) post-computation exceptions, a result may be written to the destination, depending on the type of exception. Operations involving QNaNs do not necessarily cause exceptions, but the processor handles them with the priority shown in Table 4-14 relative to the handling of exceptions.

Table 4-14. Priority of SIMD Floating-Point Exceptions

Priority	Exception or Operation	Timing
1	Invalid-operation exception (IE) when accessing SNaN operand	Pre-Computation
2	Operation involving a QNaN operand[1]	—
3	Any other type of invalid-operation exception (IE)	Pre-Computation
	Zero-divide exception (ZE)	Pre-Computation
4	Denormalized operation exception (DE)	Pre-Computation
5	Overflow exception (OE)	Post-Computation
	Underflow exception (UE)	Post-Computation
6	Precision (inexact) exception (PE)	Post-Computation

Note:
1. *Operations involving QNaN operands do not, in themselves, cause exceptions but they are handled with this priority relative to the handling of exceptions.*

Figure 4-51 on page 225 shows the prioritized procedure used by the processor to detect and report SIMD floating-point exceptions. Each of the two types of exceptions—pre-computation and post-computation—is handled independently and completely in the sequence shown. If there are no unmasked exceptions, the processor responds to masked exceptions. Because of this two-step process, up to two exceptions—one pre-computation and one post-computation—can be caused by each operation performed by a single SIMD instruction.

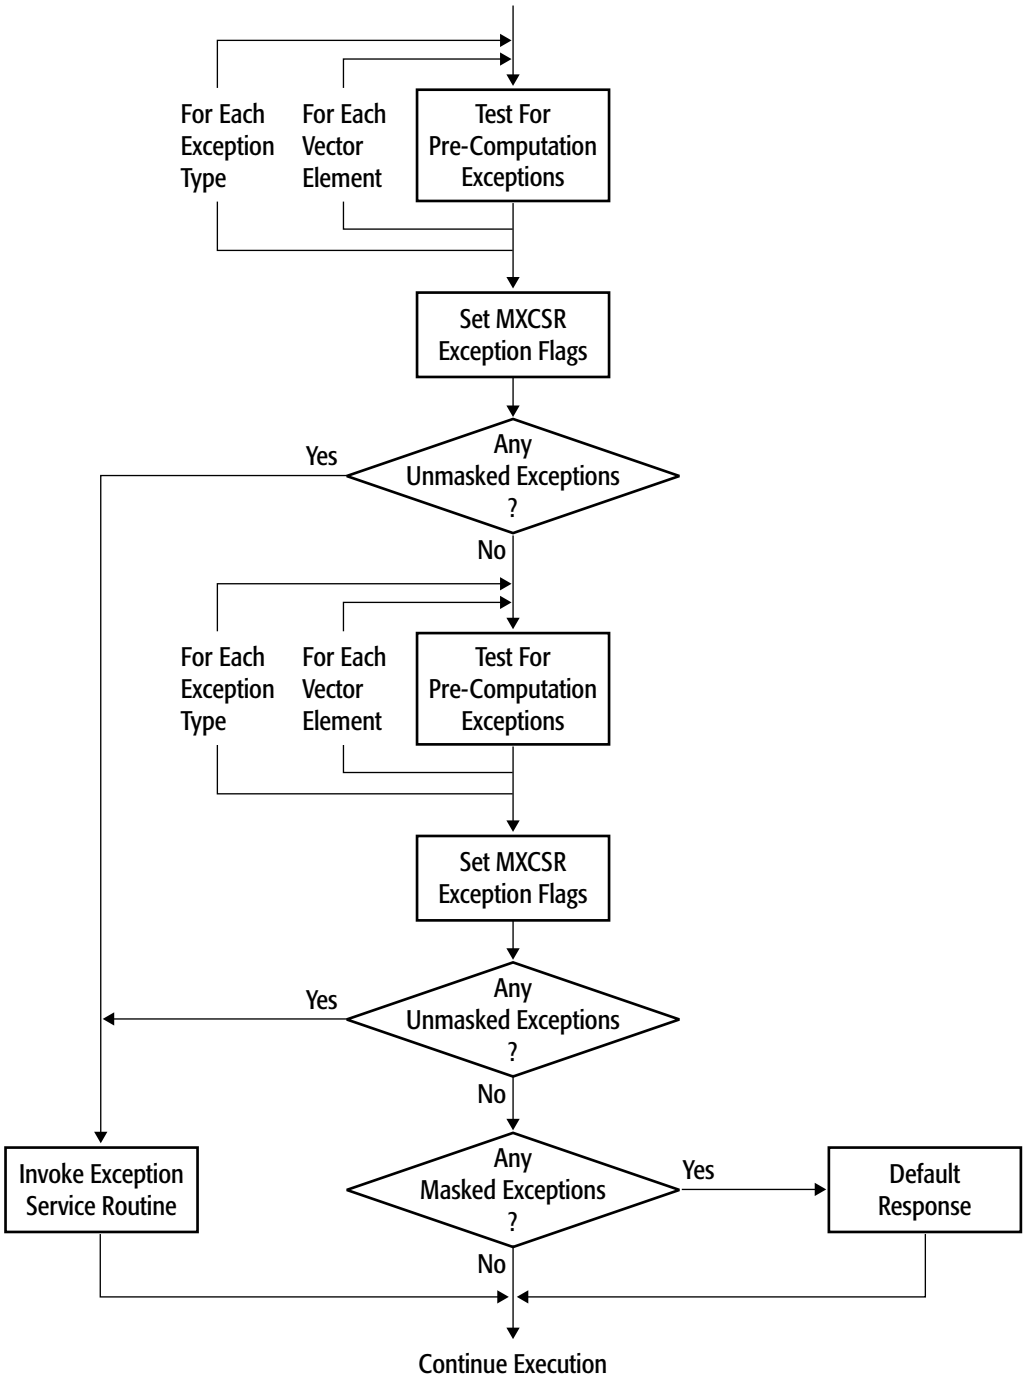

Figure 4-51. SIMD Floating-Point Detection Process

4.10.4 SIMD Floating-Point Exception Masking

The six floating-point exception flags have corresponding exception-flag masks in the MXCSR register, as shown in Table 4-15.

Table 4-15. SIMD Floating-Point Exception Masks

Exception Mask and Mnemonic	MXCSR Bit	Comparable IEEE 754 Exception
Invalid-operation exception mask (IM)	7	Invalid Operation
Denormalized-operand exception mask (DM)	8	*none*
Zero-divide exception mask (ZM)	9	Division by Zero
Overflow exception mask (OM)	10	Overflow
Underflow exception mask (UM)	11	Underflow
Precision exception mask (PM)	12	Inexact

Each mask bit, when set to 1, inhibits invocation of the exception handler for that exception and instead causes a default response. Thus, an unmasked exception is one that invokes its exception handler when it occurs, whereas a masked exception continues normal execution using the default response for the exception type. During power-on initialization, all exception-mask bits in the MXCSR register are set to 1 (masked).

4.10.4.1 Masked Responses

The occurrence of a masked exception does not invoke its exception handler when the exception condition occurs. Instead, the processor handles masked exceptions in a default way, as shown in Table 4-16 on page 227.

Table 4-16. Masked Responses to SIMD Floating-Point Exceptions

Exception	Operation[1]		Processor Response[2]
Invalid-operation exception (IE)	Any of the following, in which one or both operands is an SNaN: • Addition: (V)ADDPS, (V)ADDPD, (V)ADDSS, (V)ADDSD, (V)ADDSUBPD, (V)ADDSUBPS, (V)HADDPS, (V)HADDPD • Subtraction: (V)SUBPS, (V)SUBPD, (V)SUBSS, (V)SUBSD, (V)ADDSUBPD, (V)ADDSUBPS, (V)HSUBPD, (V)HSUBPS • Multiplication: (V)MULPS, (V)MULPD, (V)MULSS, (V)MULSD • Division: (V)DIVPS, (V)DIVPD, (V)DIVSS, (V)DIVSD • Square-root: (V)SQRTPS, (V)SQRTPD, (V)SQRTSS, (V)SQRTSD • Data conversion of floating-point to floating-point: (V)CVTPS2PD, (V)CVTPD2PS, (V)CVTSS2SD, (V)CVTSD2SS		Return a QNaN, based on the rules in Table 4-5 on page 127.
	• Addition of infinities with opposite sign: (V)ADDPS, (V)ADDPD, (V)ADDSS, (V)ADDSD, (V)ADDSUBPS, (V)ADDSUBPD, (V)HADDPD, (V)HADDPS • Subtraction of infinities with same sign: (V)SUBPS, (V)SUBPD, (V)SUBSS, (V)SUBSD, (V)ADDSUBPS, (V)ADDSUBPD, (V)HSUBPS, (V)HSUBPD • Multiplication of zero by infinity: (V)MULPS, (V)MULPD, (V)MULSS, (V)MULSD • Division of zero by zero or infinity by infinity: (V)DIVPS, (V)DIVPD, (V)DIVSS, (V)DIVSD • Square-root in which the operand is non-zero negative: (V)SQRTPS, (V)SQRTPD, (V)SQRTSS, (V)SQRTSD		Return the floating-point indefinite value.
	Any of the following, in which one or both operands is a NaN: • Maximum or Minimum: (V)MAXPS, (V)MAXPD, (V)MAXSS, (V)MAXSD, (V)MINPS, (V)MINPD, (V)MINSS, (V)MINSD		Return second source operand.
	Compare, in which one or both operands is a NaN: (V)CMPPS, (V)CMPPD, (V)CMPSS, (V)CMPSD	Compare is unordered or not-equal	Return mask of all 1s.
		All other compares	Return mask of all 0s.

Note:

1. *For complete details about operations, see “SIMD Floating-Point Exception Causes” on page 220.*
2. *In all cases, the processor sets the associated exception flag in MXCSR. For details about number representation, see “Floating-Point Number Types” on page 124 and “Floating-Point Number Encodings” on page 127.*
3. *This response does not comply with the IEEE 754 standard, but it offers higher performance.*

Table 4-16. Masked Responses to SIMD Floating-Point Exceptions (continued)

Exception	Operation[1]		Processor Response[2]
Invalid-operation exception (IE)	Ordered or unordered scalar compare, in which one or both operands is a NaN ((V)COMISS, (V)COMISD, (V)UCOMISS, (V)UCOMISD).		Sets the result in rFLAGS to "unordered." Clear the overflow (OF), sign (SF), and auxiliary carry (AF) flags in rFLAGS.
	Data conversion from floating-point to integer, in which source operand is a NaN, infinity, or is larger than the representable value of the destination (CVTPS2PI, CVTPD2PI, (V)CVTSS2SI, (V)CVTSD2SI, (V)CVTPS2DQ, (V)CVTPD2DQ, CVTTPS2PI, CVTTPD2PI, (V)CVTTPD2DQ, (V)CVTTPS2DQ, (V)CVTTSS2SI, (V)CVTTSD2SI).		Return the integer indefinite value.
Denormalized-operand exception (DE)	One or both operands is denormal		Return the result using the denormal operand(s).
Zero-divide exception (ZE)	Divide (DIV*x*) zero with non-zero finite dividend		Return signed infinity, with sign bit = XOR of the operand sign bits.
Overflow exception (OE)	Overflow when rounding mode = round to nearest	Sign of result is positive	Return +∞.
		Sign of result is negative	Return –∞.
	Overflow when rounding mode = round toward +∞	Sign of result is positive	Return +∞.
		Sign of result is negative	Return finite negative number with largest magnitude.
	Overflow when rounding mode = round toward -∞	Sign of result is positive	Return finite positive number with largest magnitude.
		Sign of result is negative	Return –∞.
	Overflow when rounding mode = round toward 0	Sign of result is positive	Return finite positive number with largest magnitude.
		Sign of result is negative	Return finite negative number with largest magnitude.

Note:

1. *For complete details about operations, see "SIMD Floating-Point Exception Causes" on page 220.*
2. *In all cases, the processor sets the associated exception flag in MXCSR. For details about number representation, see "Floating-Point Number Types" on page 124 and "Floating-Point Number Encodings" on page 127.*
3. *This response does not comply with the IEEE 754 standard, but it offers higher performance.*

Table 4-16. Masked Responses to SIMD Floating-Point Exceptions (continued)

Exception	Operation[1]		Processor Response[2]
Underflow exception (UE)	Inexact denormalized result	MXCSR flush-to-zero (FZ) bit = 0	Set PE flag and return denormalized result.
		MXCSR flush-to-zero (FZ) bit = 1	Set PE flag and return zero, with sign of true result.[3]
Precision exception (PE)	Inexact normalized or denormalized result	Without OE or UE exception	Return rounded result.
		With masked OE or UE exception	Respond as for OE or UE exception.
		With unmasked OE or UE exception	Respond as for OE or UE exception, and invoke SIMD exception handler.

Note:

1. *For complete details about operations, see "SIMD Floating-Point Exception Causes" on page 220.*
2. *In all cases, the processor sets the associated exception flag in MXCSR. For details about number representation, see "Floating-Point Number Types" on page 124 and "Floating-Point Number Encodings" on page 127.*
3. *This response does not comply with the IEEE 754 standard, but it offers higher performance.*

4.10.4.2 Unmasked Responses

If the processor detects an unmasked exception, it sets the associated exception flag in the MXCSR register and invokes the SIMD floating-point exception handler. The processor does not write a result or change any of the source operands for any type of unmasked exception. The exception handler must determine which exception occurred (by examining the exception flags in the MXCSR register) and take appropriate action.

In all cases of unmasked exceptions, before calling the exception handler, the processor examines the CR4.OSXMMEXCPT bit to see if it is set to 1. If it is set, the processor calls the #XF exception (vector 19). If it is cleared, the processor calls the #UD exception (vector 6). See "System-Control Registers" in Volume 2 for details.

For details about the operations that can cause unmasked exceptions, see "SIMD Floating-Point Exception Causes" on page 220 and Table 4-16 on page 227.

4.10.4.3 Using NaNs in IE Diagnostic Exceptions

Both SNaNs and QNaNs can be encoded with many different values to carry diagnostic information. By means of appropriate masking and unmasking of the invalid-operation exception (IE), software can use signaling NaNs to invoke an exception handler. Within the constraints imposed by the encoding of SNaNs and QNaNs, software may freely assign the bits in the significand of a NaN. See Section "Floating-Point Number Encodings" on page 127 for format details.

For example, software can pre-load each element of an array with a signaling NaN that encodes the array index. When an application accesses an uninitialized array element, the invalid-operation exception is invoked and the service routine can identify that element. A service routine can store

debug information in memory as the exceptions occur. The routine can create a QNaN that references its associated debug area in memory. As the program runs, the service routine can create a different QNaN for each error condition, so that a single test-run can identify a collection of errors.

4.11 Saving, Clearing, and Passing State

4.11.1 Saving and Restoring State

In general, system software should save and restore SSE state between task switches or other interventions in the execution of SSE procedures. Virtually all modern operating systems running on x86 processors implement preemptive multitasking that handle saving and restoring of state across task switches, independent of hardware task-switch support. However, application procedures are also free to save and restore SSE state at any time they deem useful.

Software running at any privilege level may save and restore legacy SSE state by executing the FXSAVE instruction, which saves not only legacy SSE state but also x87 floating-point state. To save and restore the entire SSE context, including the contents of the YMM registers, software must use the XSAVE/XRSTOR instructions (or their optimized variants). These instructions are discussed in Volume 4. Alternatively, software may use multiple move instructions for saving only the contents of selected SSE data registers, or the STMXCSR instruction for saving the MXCSR register state. For details, see “Save and Restore State” on page 183.

4.11.2 Parameter Passing

SSE procedures can use (V)MOV*x* instructions to pass data to other such procedures. This can be done directly, via the YMM/XMM registers, or indirectly by storing data on the procedure stack. When storing to the stack, software should use the rSP register for the memory address and, after the save, explicitly decrement rSP by 16 for each 128-bit XMM register parameter stored on the stack or by 32 for each 256-bit YMM register parameter stored on the stack. Likewise, to load a 128-bit XMM register from the stack, software should increment rSP by 16 after the load or by 32 for each 256-bit YMM register. There is a choice of (V)MOV*x* instructions designed for aligned and unaligned moves, as described in “Data Transfer” on page 150 and “Data Transfer” on page 185.

The processor does not check the data type of instruction operands prior to executing instructions. It only checks them at the point of execution. For example, if the processor executes an arithmetic instruction that takes double-precision operands but is provided with single-precision operands by MOV*x* instructions, the processor will first convert the operands from single precision to double precision prior to executing the arithmetic operation, and the result will be correct. However, the required conversion may cause degradation of performance.

Because of this possibility of data-type mismatching between (V)MOV*x* instructions used to pass parameters and the instructions in the called procedure that subsequently operate on the moved data, the calling procedure should save its own state prior to the call. The called procedure cannot determine the caller’s data types, and thus it cannot optimize its choice of instructions for storing a caller’s state.

For further information, see the software optimization documentation for particular hardware implementations.

4.11.3 Accessing Operands in MMX™ Registers

Software may freely mix SSE instructions (integer or floating-point) with 64-bit media instructions (integer or floating-point) and general-purpose instructions in a single procedure. There are no restrictions on transitioning from SSE procedures to x87 procedures, except when a SSE procedure accesses an MMX register by means of a data-transfer or data-conversion instruction.

In such cases, software should separate such procedures or dynamic link libraries (DLLs) from x87 floating-point procedures or DLLs by clearing the MMX state with the EMMS instruction, as described in Section 5.6.2 “Exit Media State” on page 255. For further details, see Section 5.13 “Mixing Media Code with x87 Code” on page 280.

4.12 Performance Considerations

In addition to typical code optimization techniques, such as those affecting loops and the inlining of function calls, the following considerations may help improve the performance of application programs written with SSE instructions.

These are implementation-independent performance considerations. Other considerations depend on the hardware implementation. For information about such implementation-dependent considerations and for more information about application performance in general, see the data sheets and the software-optimization guides relating to particular hardware implementations.

4.12.1 Use Small Operand Sizes

The performance advantages available with SSE operations is to some extent a function of the data sizes operated upon. The smaller the data size, the more data elements that can be packed into a single vector. The parallelism of computation increases as the number of elements per vector increases.

4.12.2 Reorganize Data for Parallel Operations

Much of the performance benefit from the SSE instructions comes from the parallelism inherent in vector operations. It can be advantageous to reorganize data before performing arithmetic operations so that its layout after reorganization maximizes the parallelism of the arithmetic operations.

The speed of memory access is particularly important for certain types of computation, such as graphics rendering, that depend on the regularity and locality of data-memory accesses. For example, in matrix operations, performance is high when operating on the rows of the matrix, because row bytes are contiguous in memory, but lower when operating on the columns of the matrix, because column bytes are not contiguous in memory and accessing them can result in cache misses. To improve performance for operations on such columns, the matrix should first be transposed. Such transpositions can, for example, be done using a sequence of unpacking or shuffle instructions.

4.12.3 Remove Branches

Branch can be replaced with SSE instructions that simulate predicated execution or conditional moves, as described in “Branch Removal” on page 147. The branch can be replaced with SSE instructions that

simulate predicated execution or conditional moves. Figure 4-21 on page 148 shows an example of a non-branching sequence that implements a two-way multiplexer.

Where possible, break long dependency chains into several shorter dependency chains that can be executed in parallel. This is especially important for floating-point instructions because of their longer latencies.

4.12.4 Use Streaming Loads and Stores

The (V)MOVNTDQ, (V)MOVNTDQA and (V)MASKMOVDQU instructions load or store streaming (non-temporal) data from or to memory. These instructions indicate to the processor that the data they reference will be used only once and is therefore not subject to cache-related overhead (such as write-allocation). A typical case benefitting from streaming stores occurs when data written by the processor is never read by the processor, such as data written to a graphics frame buffer.

CPU read accesses of WC memory type regions normally have significantly lower throughput than accesses to cacheable memory. However, the (V)MOVNTDQA instruction provides a non-temporal hint that can cause adjacent 16-byte items within an aligned 64-byte region of WC memory type (a streaming line) to be fetched and held in a small set of temporary buffers (streaming load buffers). Subsequent streaming loads to other aligned 16-byte items in the same streaming line may be supplied from the streaming load buffer and can improve throughput.

The following programming practices can improve efficiency of (V)MOVNTDQA streaming loads from WC memory:

- Streaming loads must be 16-byte aligned.
- Group streaming loads of the same streaming cache line for effective use of the small number of streaming load buffers. If loads to the same streaming line are excessively spaced apart, it may cause the streaming line to be re-fetched from memory.
- Group streaming loads from at most a few streaming lines together. The number of streaming load buffers is small; grouping a modest number of streams will avoid running out of streaming load buffers and the resultant re-fetching of streaming lines from memory.
- Avoid writing to a streaming line until all 16-byte-aligned reads from the streaming line have occurred. Reading a 16-byte item from a streaming line that has been written, may cause the streaming line to be re-fetched.
- Avoid reading a given 16-byte item within a streaming line more than once; repeated loads of a particular 16-byte item are likely to cause the streaming line to be re-fetched.
- Streaming load buffers, reflecting the WC memory type characteristics, are not required to be snooped by operations from other agents. Software should not rely upon such coherency actions to provide any data coherency with respect to other logical processors or bus agents. Rather, software must insure the consistency of WC memory accesses between producers and consumers.
- Streaming loads may be weakly ordered and may appear to software to execute out of order with respect to other memory operations. Software must explicitly use fences (e.g. MFENCE) if it

needs to preserve order among streaming loads or between streaming loads and other memory operations.

- Streaming loads must not be used to reference memory addresses that are mapped to I/O devices having side effects or when reads to these devices are destructive. This is because MOVNTDQA is speculative in nature.

The following two code examples demonstrate the basic assembly sequences that depict the principles of using MOVNTDQA with a producer-consumer pair accessing a WC memory region.

Example 1: Using MOVNTDQA with a Consumer and PCI Producer

```
// P0: producer is a PCI device writing into the WC space
# the PCI device updates status through a UC flag, "u_dev_status"
# the protocol for "u_dev_status" : 0: produce; 1: consume; 2: all done
  mov eax, $0
  mov [u_dev_status], eax
producerStart:
  mov eax, [u_dev_status] # poll status flag to see if consumer is requesting data
  cmp eax, $0
  jne done # no longer need to produce commence PCI writes to WC region
  mov eax, $1 # producer ready to notify the consumer via status flag
  mov [u_dev_status], eax
# now wait for consumer to signal its status
spinloop:
  cmp [u_dev_status], $1 # was signal received from consumer
  jne producerStart # yes
  jmp spinloop # check again
done:
// producer is finished at this point

// P1: consumer check PCI status flag to consume WC data
  mov eax, $0 # request to the producer
  mov [u_dev_status], eax
consumerStart:
  mov; eax, [u_dev_status] # reads the value of the PCI status
  cmp eax, $1            # has producer written
  jne consumerStart      # tight loop; make it more efficient with pause, etc.
  mfence # producer finished device writes to WC, ensure WC region is coherent
ntread:
  movntdqa xmm0, [addr]
  movntdqa xmm1, [addr + 16]
  movntdqa xmm2, [addr + 32]
  movntdqa xmm3, [addr + 48]
  …          # do more NT reads as needed
  mfence     # ensure PCI device reads the correct value of [u_dev_status]
# now decide whether done or need the producer to produce more data
# if done write a 2 into the variable, otherwise write a 0 into the variable
  mov eax, $0/$2 # end or continue producing
  mov [u_dev_status], eax
# to consume again jump back to consumerStart after storing a 0 into eax
# otherwise, done
```

Example 2: Using MOVNTDQA with Producer-Consumer Threads

```
// P0: producer writes into the WC space
# xchg is an implicitly locked operation
producerStart:
# use a locked operation to prevent races between producer and consumer
# updating this variable. Assume initial value is 0
  mov eax, $0
  xchg eax, [signalVariable] # signalVariable is used for communicating
  cmp eax, $0 # am I supposed to be writing for the consumer
  jne done # I no longer need to produce
  movntdq [addr1], xmm0 # producer writes the data
  movntdq [addr2], xmm1 # ...
# Again use a locked instruction. Serves 2 purposes. Updated value signals
# to consumer and serialization of the lock flushes all WC stores to memory
  mov eax, $1
  xchg [signalVariable], eax # signal to the consumer
# a more efficient spin loop can be done using PAUSE
spinloop:
  cmp [signalVariable], $1 # did I get signal from consumer
  jne producerStart      # yes
  jmp spinloop           # check again
done:
// producer is finished at this point

// P1: consumer reads from write combining space
  mov eax, $0
consumerStart:
  lock; xadd [signalVariable], eax # reads the value of the signal variable in
  cmp eax, $1      # has producer written to signal its state
  jne consumerStart # simple loop; replace with PAUSE to make it more efficient
# read data from WC memory space with MOVNTDQA to achieve higher throughput
ntread: # keep reads from same cache line as close together as possible
  movntdqa xmm0, [addr]
  movntdqa xmm1, [addr + 16]
  movntdqa xmm2, [addr + 32]
  movntdqa xmm3, [addr + 48]
# since a lock prevents younger MOVNTDQA from passing it, the
# above non temporal loads will happen only after producer has signaled

… # do more NT reads as needed

# now decide whether done or need producer to produce more data
# if done, write a 2 into the variable, otherwise write a 0 into the variable
  mov eax, $0/$2 # end or continue producing
  xchg [signalVariable], eax
# to consume again, jump back to consumerStart after storing a 0 into eax
# otherwise, done
```

4.12.5 Align Data

Data alignment is particularly important for performance when data written by one instruction is read by a subsequent instruction soon after the write, or when accessing streaming (non-temporal) data. These cases may occur frequently in 256-bit and 128-bit media procedures.

Accesses to data stored at unaligned locations may benefit from on-the-fly software alignment or from repetition of data at different alignment boundaries, as required by different loops that process the data.

4.12.6 Organize Data for Cacheability

Pack small data structures into cache-line-size blocks. Organize frequently accessed constants and coefficients into cache-line-size blocks and prefetch them. Procedures that access data arranged in memory-bus-sized blocks, or memory-burst-sized blocks, can make optimum use of the available memory bandwidth.

For data that will be used only once in a procedure, consider using non-cacheable memory. Accesses to such memory are not burdened by the overhead of cache protocols.

4.12.7 Prefetch Data

Media applications typically operate on large data sets. Because of this, they make intensive use of the memory bus. Memory latency can be substantially reduced—especially for data that will be used only once—by prefetching such data into various levels of the cache hierarchy. Software can use the PREFETCH*x* instructions very effectively in such cases, as described in “Cache and Memory Management” on page 71.

Some of the best places to use prefetch instructions are inside loops that process large amounts of data. If the loop goes through less than one cache line of data per iteration, partially unroll the loop. Try to use virtually all of the prefetched data. This usually requires unit-stride memory accesses—those in which all accesses are to contiguous memory locations. Exactly one PREFETCH*x* instruction per cache line must be used. For further details, see the *Optimization Guide for AMD Athlon™ 64 and AMD Opteron™ Processors*, order# 25112.

4.12.8 Use SSE Code for Moving Data

Movements of data between memory, GPR, XMM, and MMX registers can take advantage of the parallel vector operations supported by the SSE MOV*x* instructions. Figure 4-13 on page 142 illustrates the range of move operations available.

4.12.9 Retain Intermediate Results in SSE Registers

Keep intermediate results in the SSE (YMM/XMM) registers as much as possible, especially if the intermediate results are used shortly after they have been produced. Avoid spilling intermediate results to memory and reusing them shortly thereafter. Take advantage of the increased number of addressable SSE registers available in 64-bit mode.

4.12.10 Replace GPR Code with SSE Code.

In 64-bit mode, the AMD64 architecture provides twice the number of general-purpose registers (GPRs) as the legacy x86 architecture, thereby reducing potential pressure on GPRs. Nevertheless, general-purpose instructions do not operate in parallel on vectors of elements, as do SSE instructions. Thus, SSE code supports parallel operations and can perform better with algorithms and data that are organized for parallel operations.

4.12.11 Replace x87 Code with SSE Code

One of the most useful advantages of SSE instructions is the ability to intermix integer and floating-point instructions in the same procedure, using a register set that is separate from the GPR, MMX, and x87 register sets. Code written with SSE floating-point instructions can operate in parallel on eight times as many single-precision floating-point operands as can x87 floating-point code. This achieves potentially eight times the computational work of x87 instructions that take single-precision operands. Also, the higher density of SSE floating-point operands may make it possible to remove local temporary variables that would otherwise be needed in x87 floating-point code. SSE code is also easier to write than x87 floating-point code, because the SSE register file is flat, rather than stack-oriented, and in 64-bit mode there are twice the number of SSE registers as x87 registers. Moreover, when integer and floating-point instructions must be used together, SSE floating-point instructions avoid the potential need to save and restore state between integer operations and floating-point procedures.

5 64-Bit Media Programming

This chapter describes the 64-bit media programming model. This model includes all instructions that access the MMX™ registers, including the MMX and 3DNow!™ instructions. Subsequent extensions, part of the Streaming SIMD Extensions (SSE), added new instructions that also utilize MMX registers.

The 64-bit media instructions perform integer and floating-point operations primarily on vector operands (a few of the instructions take scalar operands). The MMX integer operations produce signed, unsigned, and/or saturating results. The 3DNow! floating-point operations take single-precision operands and produce saturating results without generating floating-point exceptions. The instructions that take vector operands can speed up certain types of procedures by significant factors, depending on data-element size and the regularity and locality of data accesses to memory.

The term *64-bit* is used in two different contexts within the AMD64 architecture: the 64-bit media instructions, described in this chapter, and the 64-bit operating mode, described in “64-Bit Mode” on page 6.

5.1 Origins

The 64-bit media instructions were introduced in the following extensions to the legacy x86 architecture:

- *MMX*. The original MMX programming model defined eight 64-bit MMX registers and a number of vector instructions that operate on packed integers held in the MMX registers or sourced from memory. This subset was subsequently extended.
- *3DNow!*. Added vector floating-point instructions, most of which take vector operands in MMX registers or memory locations. This instruction set was subsequently extended.
- *SSE.* The original Steaming SIMD Extensions (SSE1) and the subsequent SSE2 added instructions that perform conversions between operands in the 64-bit MMX registers and other registers.

For details on the extension-set origin of each instruction, see “Instruction Subsets vs. CPUID Feature Sets” in Volume 3.

5.2 Compatibility

64-bit media instructions can be executed in any of the architecture’s operating modes. Existing MMX and 3DNow! binary programs run in legacy and compatibility modes without modification. The support provided by the AMD64 architecture for such binaries is identical to that provided by legacy x86 architectures.

To run in 64-bit mode, 64-bit media programs must be recompiled. The recompilation has no side effects on such programs, other than to make available the extended general-purpose registers and 64-bit virtual address space.

The MMX and 3DNow! instructions introduce no additional registers, status bits, or other processor state to the legacy x86 architecture. Instead, they use the x87 floating-point registers that have long been a part of most x86 architectures. Because of this, 64-bit media procedures require no special operating-system support or exception handlers. When state-saves are required between procedures, the same instructions that system software uses to save and restore x87 floating-point state also save and restore the 64-bit media-programming state.

AMD no longer recommends the use of 3DNow! instructions, which have been superceded by their more efficient 128-bit media counterparts. Relevant recommendations are provided below and in the *AMD64 Programmer's Manual Volume 4: 64-Bit Media and x87 Floating-Point Instructions*.

5.3 Capabilities

The 64-bit media instructions are designed to support multimedia and communication applications that operate on vectors of small-sized data elements. For example, 8-bit and 16-bit integer data elements are commonly used for pixel information in graphics applications, and 16-bit integer data elements are used for audio sampling. The 64-bit media instructions allow multiple data elements like these to be packed into single 64-bit vector operands located in an MMX register or in memory. The instructions operate in parallel on each of the elements in these vectors. For example, 8-bit integer data can be packed in vectors of eight elements in a single 64-bit register, so that a single instruction can operated on all eight byte elements simultaneously.

Typical applications of the 64-bit media integer instructions include music synthesis, speech synthesis, speech recognition, audio and video compression (encoding) and decompression (decoding), 2D and 3D graphics (including 3D texture mapping), and streaming video. Typical applications of the 64-bit media floating-point instructions include digital signal processing (DSP) kernels and front-end 3D graphics algorithms, such as geometry, clipping, and lighting.

These types of applications are referred to as *media* applications. Such applications commonly use small data elements in repetitive loops, in which the typical operations are inherently parallel. In 256-color video applications, for example, 8-bit operands in 64-bit MMX registers can be used to compute transformations on eight pixels per instruction.

5.3.1 Parallel Operations

Most of the 64-bit media instructions perform parallel operations on vectors of operands. *Vector* operations are also called *packed* or *SIMD* (single-instruction, multiple-data) operations. They take operands consisting of multiple elements and operate on all elements in parallel. Figure 5-1 on page 241 shows an example of an integer operation on two vectors, each containing 16-bit (word) elements. There are also 64-bit media instructions that operate on vectors of byte or doubleword elements.

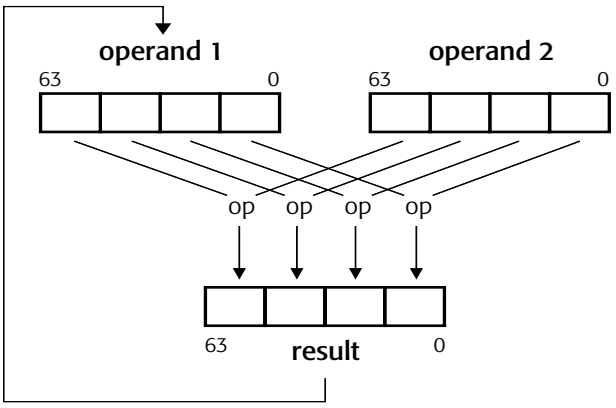

Figure 5-1. Parallel Integer Operations on Elements of Vectors

5.3.2 Data Conversion and Reordering

The 64-bit media instructions support conversions of various integer data types to floating-point data types, and vice versa.

There are also instructions that reorder vector-element ordering or the bit-width of vector elements. For example, the unpack instructions take two vector operands and interleave their low or high elements. Figure 5-2 on page 242 shows an unpack operation (PUNPCKLWD) that interleaves low-order elements of each source operand. If each element of operand 2 has the value zero, the operation zero-extends each element of operand 1 to twice its original width. This may be useful, for example, prior to an arithmetic operation in which the data-conversion result must be paired with another source operand containing vector elements that are twice the width of the pre-conversion (half-size) elements. There are also pack instructions that convert each element of 2x size in a pair of vectors to elements of 1x size, with saturation at maximum and minimum values.

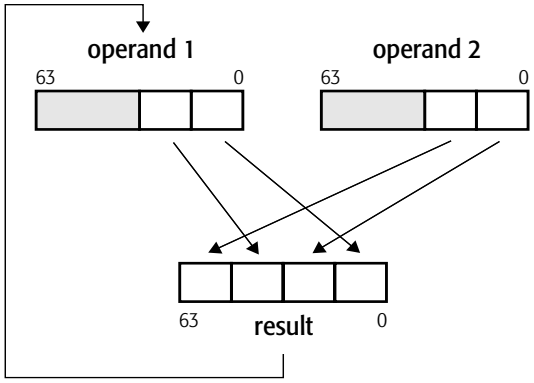

Figure 5-2. Unpack and Interleave Operation

Figure 5-3 shows a shuffle operation (PSHUFW), in which one of the operands provides vector data, and an immediate byte provides shuffle control for up to 256 permutations of the data.

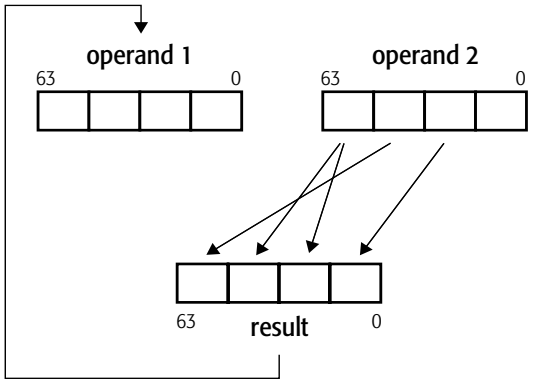

Figure 5-3. Shuffle Operation (1 of 256)

5.3.3 Matrix Operations

Media applications often multiply and accumulate vector and matrix data. In 3D graphics applications, for example, objects are typically represented by triangles, each of whose vertices are located in 3D space by a matrix of coordinate values, and matrix transforms are performed to simulate object movement.

The 64-bit media integer and floating-point instructions can perform several types of matrix-vector or matrix-matrix operations, such as addition, subtraction, multiplication, and accumulation. The integer

instructions can also perform multiply-accumulate operations. Efficient matrix multiplication is further supported with instructions that can first transpose the elements of matrix rows and columns. These transpositions can make subsequent accesses to memory or cache more efficient when performing arithmetic matrix operations.

Figure 5-4 shows a vector multiply-add instruction (PMADDWD) that multiplies vectors of 16-bit integer elements to yield intermediate results of 32-bit elements, which are then summed pair-wise to yield two 32-bit elements.

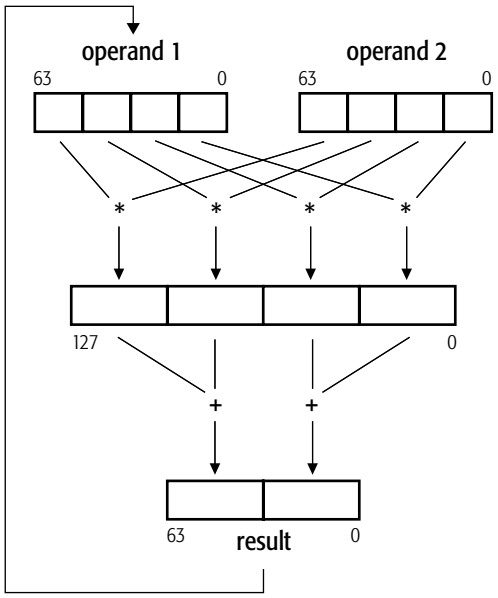

Figure 5-4. Multiply-Add Operation

The operation shown in Figure 5-4 can be used together with transpose and vector-add operations (see "Addition" on page 262) to accumulate *dot product* results (also called *inner* or *scalar products*), which are used in many media algorithms.

5.3.4 Saturation

Several of the 64-bit media integer instructions and most of the 64-bit media floating-point instructions produce vector results in which each element *saturates* independently of the other elements in the result vector. Such results are clamped (limited) to the maximum or minimum value representable by the destination data type when the true result exceeds that maximum or minimum representable value.

Saturation avoids the need for code that tests for potential overflow or underflow. Saturating data is useful for representing physical-world data, such as sound and color. It is used, for example, when combining values for pixel coloring.

5.3.5 Branch Removal

Branching is a time-consuming operation that, unlike most 64-bit media vector operations, does not exhibit parallel behavior (there is only one branch target, not multiple targets, per branch instruction). In many media applications, a branch involves selecting between only a few (often only two) cases. Such branches can be replaced with 64-bit media vector compare and vector logical instructions that simulate predicated execution or conditional moves.

Figure 5-5 shows an example of a non-branching sequence that implements a two-way multiplexer—one that is equivalent to the ternary operator "?:" in C and C++. The comparable code sequence is explained in "Compare and Write Mask" on page 267.

The sequence in Figure 5-5 begins with a vector compare instruction that compares the elements of two source operands in parallel and produces a mask vector containing elements of all 1s or 0s. This mask vector is ANDed with one source operand and ANDed-Not with the other source operand to isolate the desired elements of both operands. These results are then ORed to select the relevant elements from each operand. A similar branch-removal operation can be done using floating-point source operands.

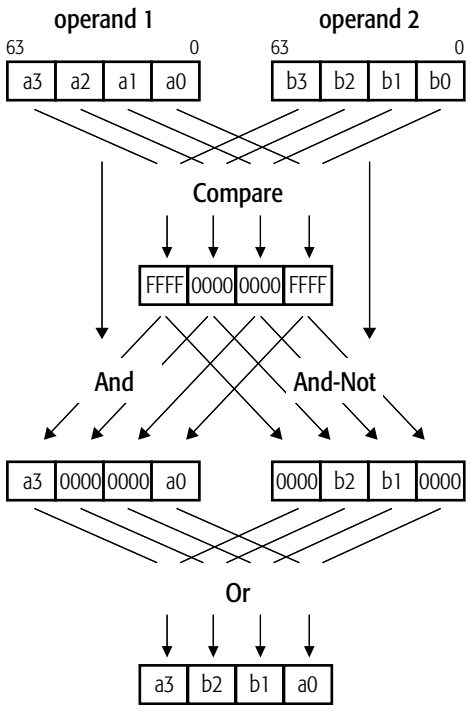

Figure 5-5. Branch-Removal Sequence

5.3.6 Floating-Point (3DNow!™) Vector Operations

Floating-point vector instructions using the MMX registers were introduced by AMD with the 3DNow! technology. These instructions take 64-bit vector operands consisting of two 32-bit single-precision floating-point numbers, shown as *FP single* in Figure 5-6.

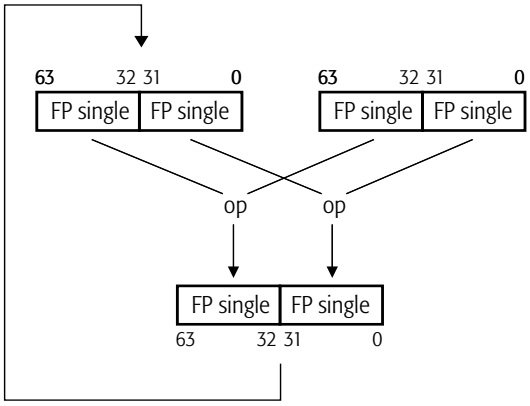

Figure 5-6. Floating-Point (3DNow!™ Instruction) Operations

The AMD64 architecture's 3DNow! floating-point instructions provide a unique advantage over legacy x87 floating-point instructions: They allow integer *and* floating-point instructions to be intermixed in the same procedure, using only the MMX registers. This avoids the need to switch between integer MMX procedures and x87 floating-point procedures—a switch that may involve time-consuming state saves and restores—while at the same time leaving the YMM/XMM register resources free for other applications.

The 3DNow! instructions allow applications such as 3D graphics to accelerate front-end geometry, clipping, and lighting calculations. Picture and pixel data are typically integer data types, although both integer and floating-point instructions are often required to operate completely on the data. For example, software can change the viewing perspective of a 3D scene through transformation matrices by using floating-point instructions in the same procedure that contains integer operations on other aspects of the graphics data.

3DNow! programs typically perform better than x87 floating-point code, because the MMX register file is flat rather than stack-oriented and because 3DNow! instructions can operate on twice as many operands as x87 floating-point instructions. This ability to operate in parallel on twice as many floating-point values in the same register space often makes it possible to remove local temporary variables in 3DNow! code that would otherwise be needed in x87 floating-point code.

5.4 Registers

5.4.1 MMX™ Registers

Eight 64-bit MMX registers, *mmx0–mmx7,* support the 64-bit media instructions. Figure 5-7 shows these registers. They can hold operands for both vector and scalar operations on integer (MMX) and floating-point (3DNow!) data types.

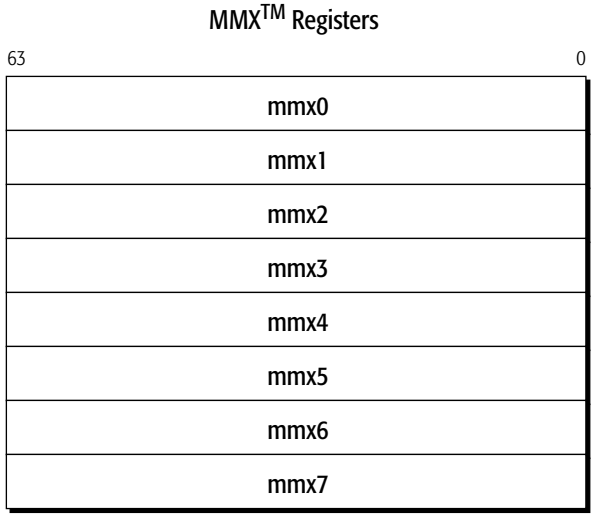

Figure 5-7. 64-Bit Media Registers

The MMX registers are mapped onto the low 64 bits of the 80-bit x87 floating-point physical data registers, FPR0–FPR7, described in Section 6.2. “Registers” on page 286. However, the x87 stack register structure, ST(0)–ST(7), is not used by MMX instructions. The x87 tag bits, top-of-stack pointer (TOP), and high bits of the 80-bit FPR registers are changed when 64-bit media instructions are executed. For details about the x87-related actions performed by hardware during execution of 64-bit media instructions, see “Actions Taken on Executing 64-Bit Media Instructions” on page 278.

5.4.2 Other Registers

Some 64-bit media instructions that perform data transfer, data conversion or data reordering operations (“Data Transfer” on page 256, “Data Conversion” on page 257, and “Data Conversion” on page 271) can access operands in the general-purpose registers (GPRs) or XMM registers. When addressing GPRs or YMM/XMM registers in 64-bit mode, the REX instruction prefix can be used to access the extended GPRs or YMM/XMM registers, as described in “REX Prefixes” on page 79. For a description of the GPR registers, see “Registers” on page 23. For a description of the YMM/XMM registers, see Section 4.2.1. “SSE Registers” on page 113.

5.5 Operands

Operands for a 64-bit media instruction are either referenced by the instruction's opcode or included as an immediate value in the instruction encoding. Depending on the instruction, referenced operands can be located in registers or memory. The data types of these operands include vector and scalar integer, and vector floating-point.

5.5.1 Data Types

Figure 5-8 on page 248 shows the register images of the 64-bit media data types. These data types can be interpreted by instruction syntax and/or the software context as one of the following types of values:

- Vector (packed) single-precision (32-bit) floating-point numbers.
- Vector (packed) signed (two's-complement) integers.
- Vector (packed) unsigned integers.
- Scalar signed (two's-complement) integers.
- Scalar unsigned integers.

Hardware does not check or enforce the data types for instructions. Software is responsible for ensuring that each operand for an instruction is of the correct data type. Software can interpret the data types in ways other than those shown in Figure 5-8 on page 248—such as bit fields or fractional numbers—but the 64-bit media instructions do not directly support such interpretations and software must handle them entirely on its own.

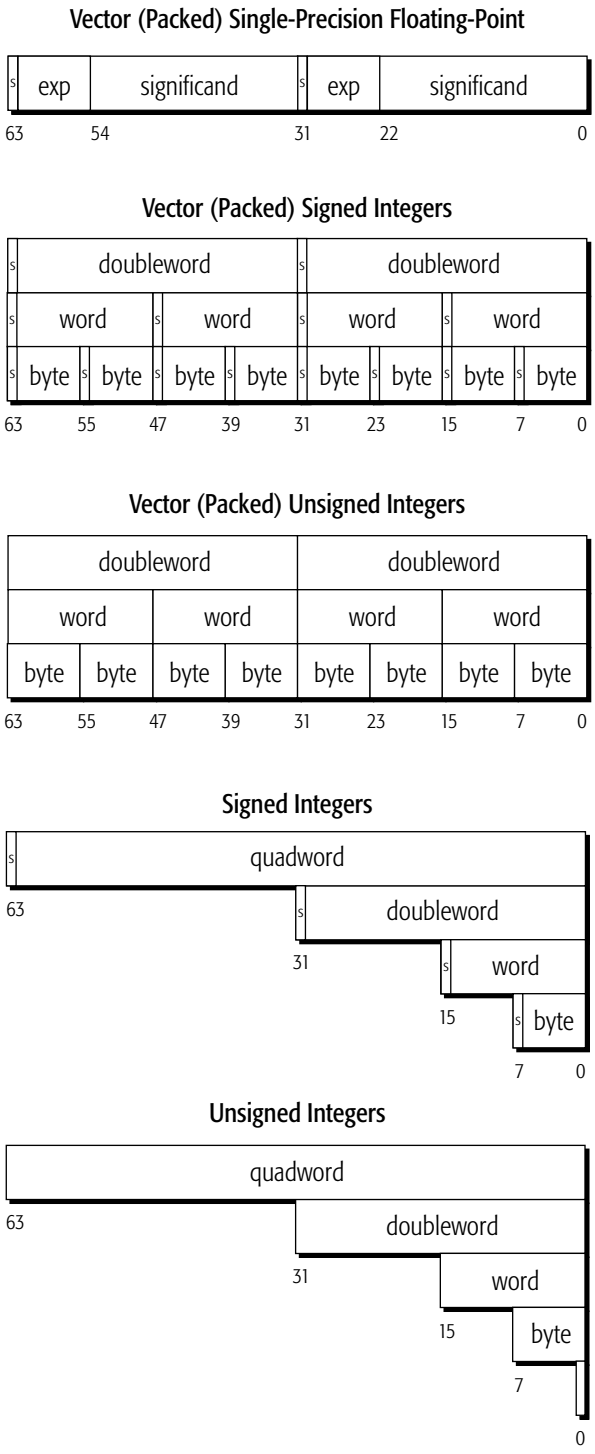

Figure 5-8. 64-Bit Media Data Types

5.5.2 Operand Sizes and Overrides

Operand sizes for 64-bit media instructions are determined by instruction opcodes. Some of these opcodes include an operand-size override prefix, but this prefix acts in a special way to modify the opcode and is considered an integral part of the opcode. The general use of the 66h operand-size override prefix described in “Instruction Prefixes” on page 76 does not apply to 64-bit media instructions.

For details on the use of operand-size override prefixes in 64-bit media instructions, see the opcodes in “64-Bit Media Instruction Reference” in Volume 5.

5.5.3 Operand Addressing

Depending on the 64-bit media instruction, referenced operands may be in registers or memory.

5.5.3.1 Register Operands

Most 64-bit media instructions can access source and destination operands located in MMX registers. A few of these instructions access the XMM or GPR registers. When addressing GPR or XMM registers in 64-bit mode, the REX instruction prefix can be used to access the extended GPR or XMM registers, as described in “Instruction Prefixes” on page 275.

The 64-bit media instructions do not access the rFLAGS register, and none of the bits in that register are affected by execution of the 64-bit media instructions.

5.5.3.2 Memory Operands

Most 64-bit media instructions can read memory for source operands, and a few of the instructions can write results to memory. “Memory Addressing” on page 14, describes the general methods and conditions for addressing memory operands.

5.5.3.3 Immediate Operands

Immediate operands are used in certain data-conversion and vector-shift instructions. Such instructions take 8-bit immediates, which provide control for the operation.

5.5.3.4 I/O Ports

I/O ports in the I/O address space cannot be directly addressed by 64-bit media instructions, and although memory-mapped I/O ports can be addressed by such instructions, doing so may produce unpredictable results, depending on the hardware implementation of the architecture. See the data sheet or software-optimization documentation for particular hardware implementations.

5.5.4 Data Alignment

Those 64-bit media instructions that access a 128-bit operand in memory incur a general-protection exception (#GP) if the operand is not aligned to a 16-byte boundary. These instructions include:

- CVTPD2PI—Convert Packed Double-Precision Floating-Point to Packed Doubleword Integers.

- CVTTPD2PI—Convert Packed Double-Precision Floating-Point to Packed Doubleword Integers, Truncated.
- FXRSTOR—Restore XMM, MMX, and x87 State.
- FXSAVE—Save XMM, MMX, and x87 State.

For other 64-bit media instructions, the architecture does not impose data-alignment requirements for accessing 64-bit media data in memory. Specifically, operands in physical memory do not need to be stored at addresses that are even multiples of the operand size in bytes. However, the consequence of storing operands at unaligned locations is that accesses to those operands may require more processor and bus cycles than for aligned accesses. See "Data Alignment" on page 43 for details.

5.5.5 Integer Data Types

Most of the MMX instructions support operations on the integer data types shown in Figure 5-8 on page 248. These instructions are summarized in "Instruction Summary—Integer Instructions" on page 253. The characteristics of these data types are described below.

5.5.5.1 Sign

Many of the 64-bit media instructions have variants for operating on signed or unsigned integers. For signed integers, the sign bit is the most-significant bit—bit 7 for a byte, bit 15 for a word, bit 31 for a doubleword, or bit 63 for a quadword. Arithmetic instructions that are not specifically named as unsigned perform signed two's-complement arithmetic.

5.5.5.2 Maximum and Minimum Representable Values

Table 5-1 shows the range of representable values for the integer data types.

Table 5-1. Range of Values in 64-Bit Media Integer Data Types

Data-Type Interpretation		Byte	Word	Doubleword	Quadword
Unsigned integers	Base-2 (exact)	0 to $+2^8-1$	0 to $+2^{16}-1$	0 to $+2^{32}-1$	0 to $+2^{64}-1$
	Base-10 (approx.)	0 to 255	0 to 65,535	0 to $4.29 * 10^9$	0 to $1.84 * 10^{19}$
Signed integers[1]	Base-2 (exact)	-2^7 to $+(2^7-1)$	-2^{15} to $+(2^{15}-1)$	-2^{31} to $+(2^{31}-1)$	-2^{63} to $+(2^{63}-1)$
	Base-10 (approx.)	–128 to +127	–32,768 to +32,767	$-2.14 * 10^9$ to $+2.14 * 10^9$	$-9.22 * 10^{18}$ to $+9.22 * 10^{18}$

5.5.5.3 Saturation

Saturating (also called limiting or clamping) instructions limit the value of a result to the maximum or minimum value representable by the destination data type. Saturating versions of integer vector-arithmetic instructions operate on byte-sized and word-sized elements. These instructions—for example, PADDSx, PADDUSx, PSUBSx, and PSUBUSx—saturate signed or unsigned data independently for each element in a vector when the element reaches its maximum or minimum representable value. Saturation avoids overflow or underflow errors.

The examples in Table 5-2 on page 251 illustrate saturating and non-saturating results with word operands. Saturation for other data-type sizes follows similar rules. Once saturated, the saturated value is treated like any other value of its type. For example, if 0001h is subtracted from the saturated value, 7FFFh, the result is 7FFEh.

Table 5-2. Saturation Examples

Operation	Non-Saturated Infinitely Precise Result	Saturated Signed Result	Saturated Unsigned Result
7000h + 2000h	9000h	7FFFh	9000h
7000h + 7000h	E000h	7FFFh	E000h
F000h + F000h	1E000h	E000h	FFFFh
9000h + 9000h	12000h	8000h	FFFFh
7FFFh + 0100h	80FFh	7FFFh	80FFh
7FFFh + FF00h	17EFFh	7EFFh	FFFFh

Arithmetic instructions not specifically designated as saturating perform non-saturating, two's-complement arithmetic.

5.5.5.4 Rounding

There is a rounding version of the integer vector-multiply instruction, PMULHRW, that multiplies pairs of signed-integer word elements and then adds 8000h to the lower word of the doubleword result, thus rounding the high-order word which is returned as the result.

5.5.5.5 Other Fixed-Point Operands

The architecture provides specific support only for integer fixed-point operands—those in which an implied binary point is located to the right of bit 0. Nevertheless, software may use fixed-point operands in which the implied binary point is located in any position. In such cases, software is responsible for managing the interpretation of such implied binary points, as well as any redundant sign bits that may occur during multiplication.

5.5.6 Floating-Point Data Types

All 64-bit media 3DNow! instructions, except PFRCP and PFRSQRT, take 64-bit vector operands. They operate in parallel on two single-precision (32-bit) floating-point values contained in those vectors.

Figure 5-9 shows the format of the vector operands. The characteristics of the single-precision floating-point data types are described below. The 64-bit floating-point media instructions are summarized in "Instruction Summary—Floating-Point Instructions" on page 270.

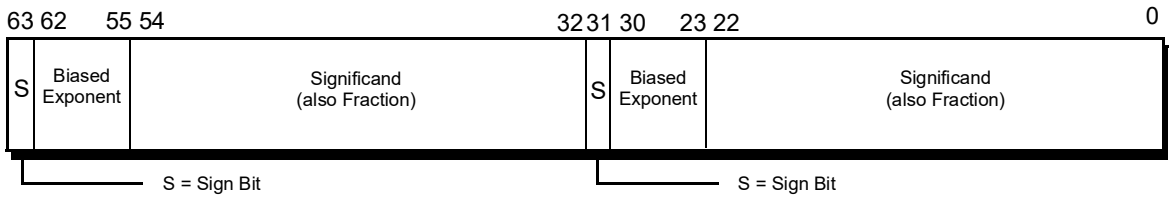

Figure 5-9. 64-Bit Floating-Point (3DNow!™) Vector Operand

5.5.6.1 Single-Precision Format

The single-precision floating-point format supported by 64-bit media instructions is the same format as the normalized IEEE 754 single-precision format. This format includes a sign bit, an 8-bit biased exponent, and a 23-bit significand with one hidden integer bit for a total of 24 bits in the significand. The hidden integer bit is assumed to have a value of 1, and the significand field is also the fraction. The bias of the exponent is 127. However, the 3DNow! format does not support other aspects of the IEEE 754 standard, such as multiple rounding modes, representation of numbers other than normalized numbers, and floating-point exceptions.

5.5.6.2 Range of Representable Values and Saturation

Table 5-3 shows the range of representable values for 64-bit media floating-point data. Table 5-4 shows the exponent ranges. The largest representable positive normal number has an exponent of FEh and a significand of 7FFFFFh, with a numerical value of $2^{127} * (2 - 2^{-23})$. The smallest representable negative normal number has an exponent of 01h and a significand of 000000h, with a numerical value of 2^{-126}.

Table 5-3. Range of Values in 64-Bit Media Floating-Point Data Types

Data-Type Interpretation		Doubleword	Quadword
Floating-point	Base-2 (exact)	2^{-126} to $2^{127} * (2 - 2^{-23})$	Two single-precision floating-point doublewords
	Base-10 (approx.)	$1.17 * 10^{-38}$ to $+3.40 * 10^{38}$	

Table 5-4. 64-Bit Floating-Point Exponent Ranges

Biased Exponent	Description
FFh	Unsupported[1]
00h	Zero

Note:
1. *Unsupported numbers can be used as source operands but produce undefined results.*

Table 5-4. 64-Bit Floating-Point Exponent Ranges (continued)

Biased Exponent	Description
00h<x<FFh	Normal
01h	$2^{(1-127)}$ lowest possible exponent
FEh	$2^{(254-127)}$ largest possible exponent

Note:
1. *Unsupported numbers can be used as source operands but produce undefined results.*

Results that, after rounding, overflow above the maximum-representable positive or negative number are saturated (limited or clamped) at the maximum positive or negative number. Results that underflow below the minimum-representable positive or negative number are treated as zero.

5.5.6.3 Floating-Point Rounding

In contrast to the IEEE standard, which requires four rounding modes, the 64-bit media floating-point instructions support only one rounding mode, depending on the instruction. All such instructions use round-to-nearest, except certain floating-point-to-integer conversion instructions (“Data Conversion” on page 271) which use round-to-zero.

5.5.6.4 No Support for Infinities, NaNs, and Denormals

64-bit media floating-point instructions support only normalized numbers. They do not support infinity, NaN, and denormalized number representations. Operations on such numbers produce undefined results, and no exceptions are generated. If all source operands are normalized numbers, these instructions never produce infinities, NaNs, or denormalized numbers as results.

This aspect of 64-bit media floating-point operations does not comply with the IEEE 754 standard. Software must use only normalized operands and ensure that computations remain within valid normalized-number ranges.

5.5.6.5 No Support for Floating-Point Exceptions

The 64-bit media floating-point instructions do not generate floating-point exceptions. Software must ensure that in-range operands are provided to these instructions.

5.6 Instruction Summary—Integer Instructions

This section summarizes the functions of the integer (MMX and a few SSE and SSE2) instructions in the 64-bit media instruction subset. These include integer instructions that use an MMX register for source or destination and data-conversion instructions that convert from integers to floating-point formats. For a summary of the floating-point instructions in the 64-bit media instruction subset, including data-conversion instructions that convert from floating-point to integer formats, see “Instruction Summary—Floating-Point Instructions” on page 270.

The instructions are organized here by functional group—such as data-transfer, vector arithmetic, and so on. Software running at any privilege level can use any of these instructions, if the CPUID instruction reports support for the instructions (see “Feature Detection” on page 276). More detail on individual instructions is given in the alphabetically organized “64-Bit Media Instruction Reference” in Volume 5.

5.6.1 Syntax

Each instruction has a *mnemonic syntax* used by assemblers to specify the operation and the operands to be used for source and destination (result) data. The majority of 64-bit media integer instructions have the following syntax:

```
MNEMONIC mmx1, mmx2/mem64
```

Figure 5-10 on page 254 shows an example of the mnemonic syntax for a packed add bytes (PADDB) instruction.

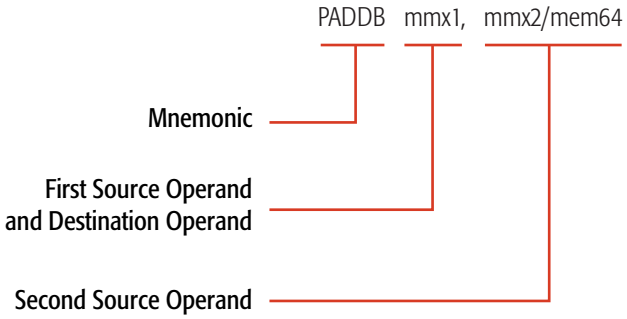

Figure 5-10. Mnemonic Syntax for Typical Instruction

This example shows the PADDB mnemonic followed by two operands, a 64-bit MMX register operand and another 64-bit MMX register or 64-bit memory operand. In most instructions that take two operands, the first (left-most) operand is both a source operand and the destination operand. The second (right-most) operand serves only as a source. Some instructions can have one or more prefixes that modify default properties, as described in “Instruction Prefixes” on page 275.

5.6.1.1 Mnemonics

The following characters are used as prefixes in the mnemonics of integer instructions:

- **CVT**—Convert
- **CVTT**—Convert with truncation
- **P**—Packed (vector)
- **PACK**—Pack elements of 2x data size to 1x data size
- **PUNPCK**—Unpack and interleave elements

In addition to the above prefix characters, the following characters are used elsewhere in the mnemonics of integer instructions:

- **B**—Byte
- **D**—Doubleword
- **DQ**—Double quadword
- **ID**—Integer doubleword
- **IW**—Integer word
- **PD**—Packed double-precision floating-point
- **PI**—Packed integer
- **PS**—Packed single-precision floating-point
- **Q**—Quadword
- **S**—Signed
- **SS**—Signed saturation
- **U**—Unsigned
- **US**—Unsigned saturation
- **W**—Word
- ***x***—One or more variable characters in the mnemonic

For example, the mnemonic for the instruction that packs four words into eight unsigned bytes is PACKUSWB. In this mnemonic, the PACK designates 2x-to-1x conversion of vector elements, the US designates unsigned results with saturation, and the WB designates vector elements of the source as words and those of the result as bytes.

5.6.2 Exit Media State

The exit media state instructions are used to isolate the use of processor resources between 64-bit media instructions and x87 floating-point instructions.

- EMMS—Exit Media State
- FEMMS—Fast Exit Media State

These instructions initialize the contents of the x87 floating-point stack registers—called *clearing the MMX state*. Software should execute one of these instructions before leaving a 64-bit media procedure.

The EMMS and FEMMS instructions both clear the MMX state, as described in “Mixing Media Code with x87 Code” on page 280. The instructions differ in one respect: FEMMS leaves the data in the x87 stack registers undefined. By contrast, EMMS leaves the data in each such register as it was defined by the last x87 or 64-bit media instruction that wrote to the register. The FEMMS instruction is supported for backward-compatibility. Software that must be compatible with both AMD and non-AMD processors should use the EMMS instruction.

5.6.3 Data Transfer

The data-transfer instructions copy operands between a 32-bit or 64-bit memory location, an MMX register, an XMM register, or a GPR. The MOV mnemonic, which stands for *move*, is a misnomer. A copy function is actually performed instead of a move.

Move

- MOVD—Move Doubleword
- MOVQ—Move Quadword
- MOVDQ2Q—Move Double Quadword to Quadword
- MOVQ2DQ—Move Quadword to Double Quadword

The MOVD instruction copies a 32-bit or 64-bit value from a general-purpose register (GPR) or memory location to an MMX register, or from an MMX register to a GPR or memory location. If the source operand is 32 bits and the destination operand is 64 bits, the source is zero-extended to 64 bits in the destination. If the source is 64 bits and the destination is 32 bits, only the low-order 32 bits of the source are copied to the destination.

The MOVQ instruction copies a 64-bit value from an MMX register or 64-bit memory location to another MMX register, or from an MMX register to another MMX register or 64-bit memory location.

The MOVDQ2Q instruction copies the low-order 64-bit value in an XMM register to an MMX register.

The MOVQ2DQ instruction copies a 64-bit value from an MMX register to the low-order 64 bits of an XMM register, with zero-extension to 128 bits.

The MOVD and MOVQ instructions—along with the PUNPCK*x* instructions—are often among the most frequently used instructions in 64-bit media procedures (both integer and floating-point). The move instructions are similar to the assignment operator in high-level languages.

5.6.3.1 Move Non-Temporal

The move non-temporal instructions are called *streaming-store* instructions. They minimize pollution of the cache. The assumption is that the data they reference will be used only once, and is therefore not subject to cache-related overhead such as write-allocation. For further information, see “Memory Optimization” on page 98.

- MOVNTQ—Move Non-temporal Quadword
- MASKMOVQ—Mask Move Quadword

The MOVNTQ instruction stores a 64-bit MMX register value into a 64-bit memory location. The MASKMOVQ instruction stores bytes from the first operand, as selected by the mask value (most-significant bit of each byte) in the second operand, to a memory location specified in the rDI and DS registers. The first operand is an MMX register, and the second operand is another MMX register. The

size of the store is determined by the effective address size. Figure 5-11 on page 257 shows the MASKMOVQ operation.

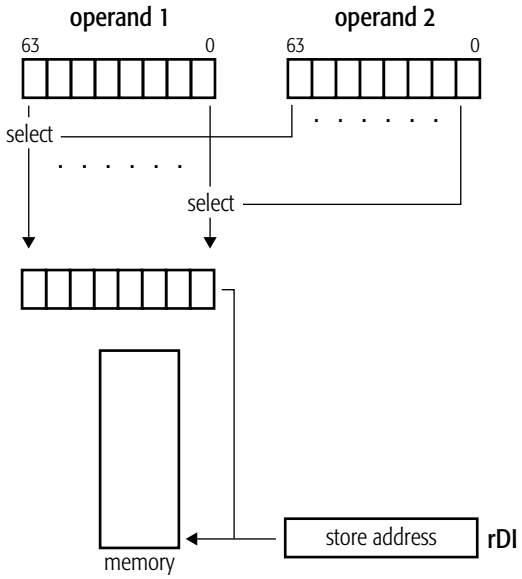

Figure 5-11. MASKMOVQ Move Mask Operation

The MOVNTQ and MASKMOVQ instructions use weakly-ordered, write-combining buffering of write data and they minimize cache pollution. The exact method by which cache pollution is minimized depends on the hardware implementation of the instruction. For further information, see “Memory Optimization” on page 98.

A typical case benefitting from streaming stores occurs when data written by the processor is never read by the processor, such as data written to a graphics frame buffer. MASKMOVQ is useful for the handling of end cases in block copies and block fills based on streaming stores.

Move Mask

- PMOVMSKB—Packed Move Mask Byte

The PMOVMSKB instruction moves the most-significant bit of each byte in an MMX register to the low-order byte of a 32-bit or 64-bit general-purpose register, with zero-extension. It is useful for extracting bits from a mask, or extracting zero-point values from quantized data such as signal samples, resulting in a byte that can be used for data-dependent branching.

5.6.4 Data Conversion

The integer data-conversion instructions convert operands from integer formats to floating-point formats. They take 64-bit integer source operands. For data-conversion instructions that take 32-bit and 64-bit floating-point source operands, see “Data Conversion” on page 271. For data-conversion

instructions that take 128-bit source operands, see “Data Conversion” on page 155 and “Data Conversion” on page 190.

5.6.4.1 Convert Integer to Floating-Point

These instructions convert integer data types into floating-point data types.

- CVTPI2PS—Convert Packed Doubleword Integers to Packed Single-Precision Floating-Point
- CVTPI2PD—Convert Packed Doubleword Integers to Packed Double-Precision Floating-Point
- PI2FW—Packed Integer To Floating-Point Word Conversion
- PI2FD—Packed Integer to Floating-Point Doubleword Conversion

The CVTPI2Px instructions convert two 32-bit signed integer values in the second operand (an MMX register or 64-bit memory location) to two single-precision (CVTPI2PS) or double-precision (CVTPI2PD) floating-point values. The instructions then write the converted values into the low-order 64 bits of an XMM register (CVTPI2PS) or the full 128 bits of an XMM register (CVTPI2PD). The CVTPI2PS instruction does not modify the high-order 64 bits of the XMM register.

The PI2Fx instructions are 3DNow! instructions. They convert two 16-bit (PI2FW) or 32-bit (PI2FD) signed integer values in the second operand to two single-precision floating-point values. The instructions then write the converted values into the destination. If a PI2FD conversion produces an inexact value, the value is truncated (rounded toward zero).

5.6.5 Data Reordering

The integer data-reordering instructions pack, unpack, interleave, extract, insert, shuffle, and swap the elements of vector operands.

5.6.5.1 Pack with Saturation

These instructions pack 2x-sized data types into 1x-sized data types, thus halving the precision of each element in a vector operand.

- PACKSSDW—Pack with Saturation Signed Doubleword to Word
- PACKSSWB—Pack with Saturation Signed Word to Byte
- PACKUSWB—Pack with Saturation Signed Word to Unsigned Byte

The PACKSSDW instruction converts each 32-bit signed integer in its two source operands (an MMX register or 64-bit memory location and another MMX register) into a 16-bit signed integer and packs the converted values into the destination MMX register. The PACKSSWB instruction does the analogous operation between word elements in the source vectors and byte elements in the destination vector. The PACKUSWB instruction does the same as PACKSSWB except that it converts word integers into unsigned (rather than signed) bytes.

Figure 5-12 on page 259 shows an example of a PACKSSDW instruction. The operation merges vector elements of 2x size (doubleword-size) into vector elements of 1x size (word-size), thus reducing the precision of the vector-element data types. Any results that would otherwise overflow or

underflow are saturated (clamped) at the maximum or minimum representable value, respectively, as described in “Saturation” on page 250.

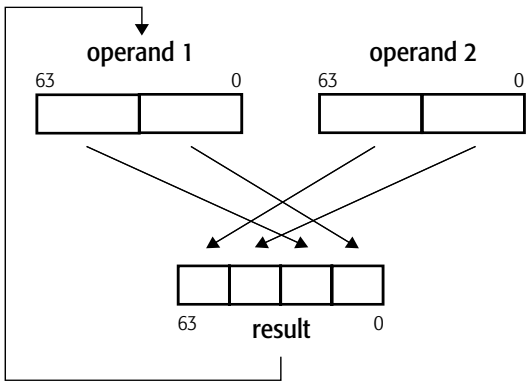

Figure 5-12. PACKSSDW Pack Operation

Conversion from higher-to-lower precision may be needed, for example, after an arithmetic operation which requires the higher-precision format to prevent possible overflow, but which requires the lower-precision format for a subsequent operation.

5.6.5.2 Unpack and Interleave

These instructions interleave vector elements from the high or low half of two source operands. They can be used to double the precision of operands.

- PUNPCKHBW—Unpack and Interleave High Bytes
- PUNPCKHWD—Unpack and Interleave High Words
- PUNPCKHDQ—Unpack and Interleave High Doublewords
- PUNPCKLBW—Unpack and Interleave Low Bytes
- PUNPCKLWD—Unpack and Interleave Low Words
- PUNPCKLDQ—Unpack and Interleave Low Doublewords

The PUNPCKHBW instruction unpacks the four high-order bytes from its two source operands and interleaves them into the bytes in the destination operand. The bytes in the low-order half of the source operand are ignored. The PUNPCKHWD and PUNPCKHDQ instructions perform analogous operations for words and doublewords in the source operands, packing them into interleaved words and interleaved doublewords in the destination operand.

The PUNPCKLBW, PUNPCKLWD, and PUNPCKLDQ instructions are analogous to their high-element counterparts except that they take elements from the low doubleword of each source vector

and ignore elements in the high doubleword. If the source operand for PUNPCKL*x* instructions is in memory, only the low 32 bits of the operand are loaded.

Figure 5-13 on page 260 shows an example of the PUNPCKLWD instruction. The elements are taken from the low half of the source operands. In this register image, elements from *operand2* are placed to the left of elements from *operand1*.

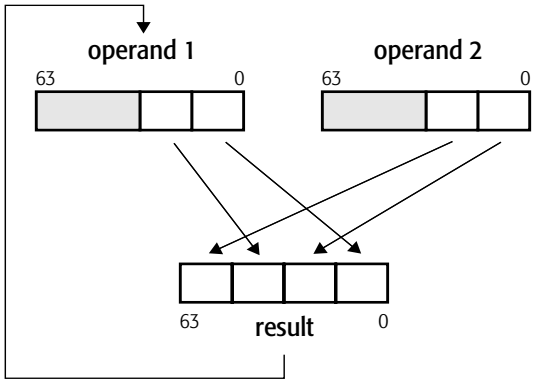

Figure 5-13. PUNPCKLWD Unpack and Interleave Operation

If one of the two source operands is a vector consisting of all zero-valued elements, the unpack instructions perform the function of expanding vector elements of 1x size into vector elements of 2x size (for example, word-size to doubleword-size). If both source operands are of identical value, the unpack instructions can perform the function of duplicating adjacent elements in a vector.

The PUNPCK*x* instructions—along with MOVD and MOVQ—are among the most frequently used instructions in 64-bit media procedures (both integer and floating-point).

5.6.5.3 Extract and Insert

These instructions copy a word element from a vector, in a manner specified by an immediate operand.

- PEXTRW—Packed Extract Word
- PINSRW—Packed Insert Word

The PEXTRW instruction extracts a 16-bit value from an MMX register, as selected by the immediate-byte operand, and writes it to the low-order word of a 32-bit or 64-bit general-purpose register, with zero-extension to 32 or 64 bits. PEXTRW is useful for loading computed values, such as table-lookup indices, into general-purpose registers where the values can be used for addressing tables in memory.

The PINSRW instruction inserts a 16-bit value from a the low-order word of a 32-bit or 64-bit general purpose register or a 16-bit memory location into an MMX register. The location in the destination

register is selected by the immediate-byte operand. The other words in the destination register operand are not modified.

5.6.5.4 Shuffle and Swap

These instructions reorder the elements of a vector.

- PSHUFW—Packed Shuffle Words
- PSWAPD—Packed Swap Doubleword

The PSHUFW instruction moves any one of the four words in its second operand (an MMX register or 64-bit memory location) to specified word locations in its first operand (another MMX register). The ordering of the shuffle can occur in any of 256 possible ways, as specified by the immediate-byte operand. Figure 5-14 shows one of the 256 possible shuffle operations. PSHUFW is useful, for example, in color imaging when computing alpha saturation of RGB values. In this case, PSHUFW can replicate an alpha value in a register so that parallel comparisons with three RGB values can be performed.

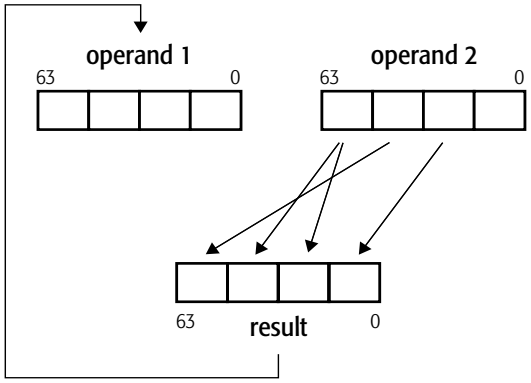

Figure 5-14. PSHUFW Shuffle Operation

The PSWAPD instruction swaps (reverses) the order of two 32-bit values in the second operand and writes each swapped value in the corresponding doubleword of the destination. Figure 5-15 shows a swap operation. PSWAPD is useful, for example, in complex-number multiplication in which the elements of one source operand must be swapped (see “Accumulation” on page 272 for details). PSWAPD supports independent source and result operands so that it can also perform a load function.

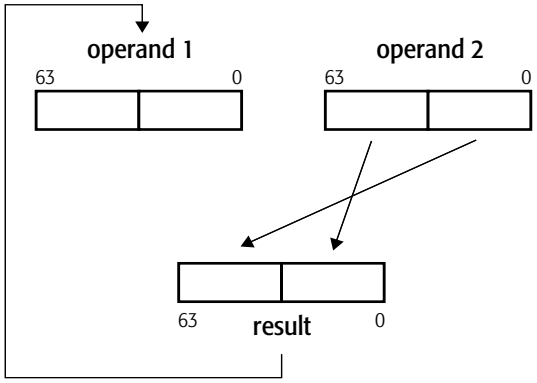

Figure 5-15. PSWAPD Swap Operation

5.6.6 Arithmetic

The integer vector-arithmetic instructions perform an arithmetic operation on the elements of two source vectors. Arithmetic instructions that are not specifically named as unsigned perform signed two's-complement arithmetic.

Addition

- PADDB—Packed Add Bytes
- PADDW—Packed Add Words
- PADDD—Packed Add Doublewords
- PADDQ—Packed Add Quadwords
- PADDSB—Packed Add with Saturation Bytes
- PADDSW—Packed Add with Saturation Words
- PADDUSB—Packed Add Unsigned with Saturation Bytes
- PADDUSW—Packed Add Unsigned with Saturation Words

The PADDB, PADDW, PADDD, and PADDQ instructions add each 8-bit (PADDB), 16-bit (PADDW), 32-bit (PADDD), or 64-bit (PADDQ) integer element in the second operand to the corresponding, same-sized integer element in the first operand. The instructions then write the integer result of each addition to the corresponding, same-sized element of the destination. These instructions operate on both signed and unsigned integers. However, if the result overflows, only the low-order byte, word, doubleword, or quadword of each result is written to the destination. The PADDD instruction can be used together with PMADDWD (page 264) to implement dot products.

The PADDSB and PADDSW instructions perform additions analogous to the PADDB and PADDW instructions, except with saturation. For each result in the destination, if the result is larger than the

largest, or smaller than the smallest, representable 8-bit (PADDSB) or 16-bit (PADDSW) signed integer, the result is saturated to the largest or smallest representable value, respectively.

The PADDUSB and PADDUSW instructions perform saturating additions analogous to the PADDSB and PADDSW instructions, except on unsigned integer elements.

Subtraction

- PSUBB—Packed Subtract Bytes
- PSUBW—Packed Subtract Words
- PSUBD—Packed Subtract Doublewords
- PSUBQ—Packed Subtract Quadword
- PSUBSB—Packed Subtract with Saturation Bytes
- PSUBSW—Packed Subtract with Saturation Words
- PSUBUSB—Packed Subtract Unsigned and Saturate Bytes
- PSUBUSW—Packed Subtract Unsigned and Saturate Words

The subtraction instructions perform operations analogous to the addition instructions.

The PSUBB, PSUBW, PSUBD, and PSUBQ instructions subtract each 8-bit (PSUBB), 16-bit (PSUBW), 32-bit (PSUBD), or 64-bit (PSUBQ) integer element in the second operand from the corresponding, same-sized integer element in the first operand. The instructions then write the integer result of each subtraction to the corresponding, same-sized element of the destination. These instructions operate on both signed and unsigned integers. However, if the result underflows, only the low-order byte, word, doubleword, or quadword of each result is written to the destination.

The PSUBSB and PSUBSW instructions perform subtractions analogous to the PSUBB and PSUBW instructions, except with saturation. For each result in the destination, if the result is larger than the largest, or smaller than the smallest, representable 8-bit (PSUBSB) or 16-bit (PSUBSW) signed integer, the result is saturated to the largest or smallest representable value, respectively.

The PSUBUSB and PSUBUSW instructions perform saturating subtractions analogous to the PSUBSB and PSUBSW instructions, except on unsigned integer elements.

Multiplication

- PMULHW—Packed Multiply High Signed Word
- PMULLW—Packed Multiply Low Signed Word
- PMULHRW—Packed Multiply High Rounded Word
- PMULHUW—Packed Multiply High Unsigned Word
- PMULUDQ—Packed Multiply Unsigned Doubleword and Store Quadword

The PMULHW instruction multiplies each 16-bit signed integer value in first operand by the corresponding 16-bit integer in the second operand, producing a 32-bit intermediate result. The instruction then writes the high-order 16 bits of the 32-bit intermediate result of each multiplication to

the corresponding word of the destination. The PMULLW instruction performs the same multiplication as PMULHW but writes the low-order 16 bits of the 32-bit intermediate result to the corresponding word of the destination.

The PMULHRW instruction performs the same multiplication as PMULHW but with rounding. After the multiplication, PMULHRW adds 8000h to the lower word of the doubleword result, thus rounding the high-order word which is returned as the result.

The PMULHUW instruction performs the same multiplication as PMULHW but on unsigned operands. The instruction is useful in 3D rasterization, which operates on unsigned pixel values.

The PMULUDQ instruction, unlike the other PMUL*x* instructions, preserves the full precision of the result. It multiplies 32-bit unsigned integer values in the first and second operands and writes the full 64-bit result to the destination.

See “Shift” on page 266 for shift instructions that can be used to perform multiplication and division by powers of 2.

Multiply-Add

- PMADDWD—Packed Multiply Words and Add Doublewords

The PMADDWD instruction multiplies each 16-bit signed value in the first operand by the corresponding 16-bit signed value in the second operand. The instruction then adds the adjacent 32-bit intermediate results of each multiplication, and writes the 32-bit result of each addition into the corresponding doubleword of the destination. PMADDWD thus performs two signed (16 × 16 = 32) + (16 × 16 = 32) multiply-adds in parallel. Figure 5-16 shows the PMADDWD operation.

The only case in which overflow can occur is when all four of the 16-bit source operands used to produce a 32-bit multiply-add result have the value 8000h. In this case, the result returned is 8000_0000h, because the maximum negative 16-bit value of 8000h multiplied by itself equals 4000_0000h, and 4000_0000h added to 4000_0000h equals 8000_0000h. The result of multiplying two negative numbers should be a positive number, but 8000_0000h is the maximum possible 32-bit negative number rather than a positive number.

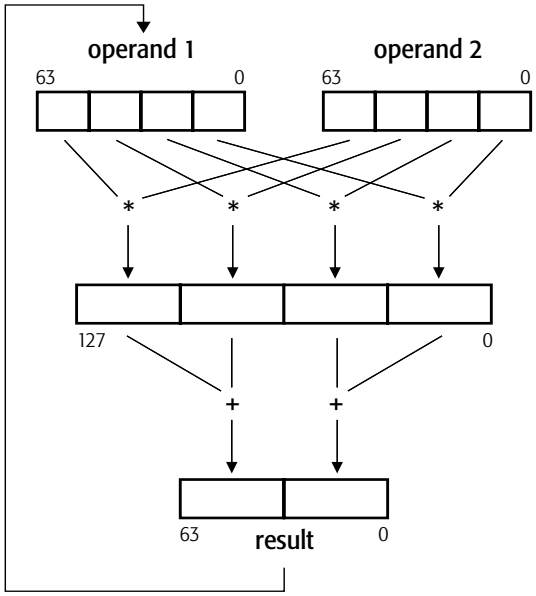

Figure 5-16. PMADDWD Multiply-Add Operation

PMADDWD can be used with one source operand (for example, a coefficient) taken from memory and the other source operand (for example, the data to be multiplied by that coefficient) taken from an MMX register. The instruction can also be used together with the PADDD instruction (page 262) to compute dot products, such as those required for finite impulse response (FIR) filters, one of the commonly used DSP algorithms. Scaling can be done, before or after the multiply, using a vector-shift instruction (page 266).

For floating-point multiplication operations, see the PFMUL instruction on page 272. For floating-point accumulation operations, see the PFACC, PFNACC, and PFPNACC instructions on page 272.

Average

- PAVGB—Packed Average Unsigned Bytes
- PAVGW—Packed Average Unsigned Words
- PAVGUSB—Packed Average Unsigned Packed Bytes

The PAVGx instructions compute the rounded average of each unsigned 8-bit (PAVGB) or 16-bit (PAVGW) integer value in the first operand and the corresponding, same-sized unsigned integer in the second operand. The instructions then write each average in the corresponding, same-sized element of the destination. The rounded average is computed by adding each pair of operands, adding 1 to the temporary sum, and then right-shifting the temporary sum by one bit.

The PAVGB instruction is useful for MPEG decoding, in which motion compensation performs many byte-averaging operations between and within macroblocks. In addition to speeding up these operations, PAVGB can free up registers and make it possible to unroll the averaging loops.

The PAVGUSB instruction (a 3DNow! instruction) performs a function identical to the PAVGB instruction, described on page 265, although the two instructions have different opcodes.

Sum of Absolute Differences

- PSADBW—Packed Sum of Absolute Differences of Bytes into a Word

The PSADBW instruction computes the absolute values of the differences of corresponding 8-bit signed integer values in the first and second operands. The instruction then sums the differences and writes an unsigned 16-bit integer result in the low-order word of the destination. The remaining bytes in the destination are cleared to all 0s.

Sums of absolute differences are used to compute the L1 norm in motion-estimation algorithms for video compression.

5.6.7 Shift

The vector-shift instructions are useful for scaling vector elements to higher or lower precision, packing and unpacking vector elements, and multiplying and dividing vector elements by powers of 2.

Left Logical Shift

- PSLLW—Packed Shift Left Logical Words
- PSLLD—Packed Shift Left Logical Doublewords
- PSLLQ—Packed Shift Left Logical Quadwords

The PSLLx instructions left-shift each of the 16-bit (PSLLW), 32-bit (PSLLD), or 64-bit (PSLLQ) values in the first operand by the number of bits specified in the second operand. The instructions then write each shifted value into the corresponding, same-sized element of the destination. The first and second operands are either an MMX register and another MMX register or 64-bit memory location, or an MMX register and an immediate-byte value. The low-order bits that are emptied by the shift operation are cleared to 0.

In integer arithmetic, left logical shifts effectively multiply unsigned operands by positive powers of 2.

Right Logical Shift

- PSRLW—Packed Shift Right Logical Words
- PSRLD—Packed Shift Right Logical Doublewords
- PSRLQ—Packed Shift Right Logical Quadwords

The PSRLx instructions right-shift each of the 16-bit (PSRLW), 32-bit (PSRLD), or 64-bit (PSRLQ) values in the first operand by the number of bits specified in the second operand. The instructions then write each shifted value into the corresponding, same-sized element of the destination. The first and

second operands are either an MMX register and another MMX register or 64-bit memory location, or an MMX register and an immediate-byte value. The high-order bits that are emptied by the shift operation are cleared to 0. In integer arithmetic, right logical shifts effectively divide unsigned operands or positive signed operands by positive powers of 2.

PSRLQ can be used to move the high 32 bits of an MMX register to the low 32 bits of the register.

Right Arithmetic Shift

- PSRAW—Packed Shift Right Arithmetic Words
- PSRAD—Packed Shift Right Arithmetic Doublewords

The PSRAx instructions right-shifts each of the 16-bit (PSRAW) or 32-bit (PSRAD) values in the first operand by the number of bits specified in the second operand. The instructions then write each shifted value into the corresponding, same-sized element of the destination. The high-order bits that are emptied by the shift operation are filled with the sign bit of the initial value.

In integer arithmetic, right arithmetic shifts effectively divide signed operands by positive powers of 2.

5.6.8 Compare

The integer vector-compare instructions compare two operands, and they either write a mask or they write the maximum or minimum value.

Compare and Write Mask

- PCMPEQB—Packed Compare Equal Bytes
- PCMPEQW—Packed Compare Equal Words
- PCMPEQD—Packed Compare Equal Doublewords
- PCMPGTB—Packed Compare Greater Than Signed Bytes
- PCMPGTW—Packed Compare Greater Than Signed Words
- PCMPGTD—Packed Compare Greater Than Signed Doublewords

The PCMPEQx and PCMPGTx instructions compare corresponding bytes, words, or doubleword in the first and second operands. The instructions then write a mask of all 1s or 0s for each compare into the corresponding, same-sized element of the destination.

For the PCMPEQx instructions, if the compared values are equal, the result mask is all 1s. If the values are not equal, the result mask is all 0s. For the PCMPGTx instructions, if the signed value in the first operand is greater than the signed value in the second operand, the result mask is all 1s. If the value in the first operand is less than or equal to the value in the second operand, the result mask is all 0s. PCMPEQx can be used to set the bits in an MMX register to all 1s by specifying the same register for both operands.

By specifying the same register for both operands, PCMPEQx can be used to set the bits in an MMX register to all 1s.

Figure 5-5 on page 244 shows an example of a non-branching sequence that implements a two-way multiplexer—one that is equivalent to the following sequence of ternary operators in C or C++:

```
r0 = a0 > b0 ? a0 : b0
r1 = a1 > b1 ? a1 : b1
r2 = a2 > b2 ? a2 : b2
r3 = a3 > b3 ? a3 : b3
```

Assuming `mmx0` contains `a`, and `mmx1` contains `b`, the above C sequence can be implemented with the following assembler sequence:

```
MOVQ        mmx3, mmx0
PCMPGTW     mmx3, mmx2  ; a > b ? 0xffff : 0
PAND        mmx0, mmx3  ; a > b ? a: 0
PANDN       mmx3, mmx1  ; a > b > 0 : b
POR         mmx0, mmx3  ; r = a > b ? a: b
```

In the above sequence, PCMPGTW, PAND, PANDN, and POR operate, in parallel, on all four elements of the vectors.

Compare and Write Minimum or Maximum

- PMAXUB—Packed Maximum Unsigned Bytes
- PMINUB—Packed Minimum Unsigned Bytes
- PMAXSW—Packed Maximum Signed Words
- PMINSW—Packed Minimum Signed Words

The PMAXUB and PMINUB instructions compare each of the 8-bit unsigned integer values in the first operand with the corresponding 8-bit unsigned integer values in the second operand. The instructions then write the maximum (PMAXUB) or minimum (PMINUB) of the two values for each comparison into the corresponding byte of the destination.

The PMAXSW and PMINSW instructions perform operations analogous to the PMAXUB and PMINUB instructions, except on 16-bit signed integer values.

5.6.9 Logical

The vector-logic instructions perform Boolean logic operations, including AND, OR, and exclusive OR.

And

- PAND—Packed Logical Bitwise AND
- PANDN—Packed Logical Bitwise AND NOT

The PAND instruction performs a bitwise logical AND of the values in the first and second operands and writes the result to the destination.

The PANDN instruction inverts the first operand (creating a one's complement of the operand), ANDs it with the second operand, and writes the result to the destination, and writes the result to the destination. Table 5-5 shows an example.

Table 5-5. Example PANDN Bit Values

Operand1 Bit	Operand1 Bit (Inverted)	Operand2 Bit	PANDN Result Bit
1	0	1	0
1	0	0	0
0	1	1	1
0	1	0	0

PAND can be used with the value 7FFFFFFF7FFFFFFFh to compute the absolute value of the elements of a 64-bit media floating-point vector operand. This method is equivalent to the x87 FABS (floating-point absolute value) instruction.

Or

- POR—Packed Logical Bitwise OR

The POR instruction performs a bitwise logical OR of the values in the first and second operands and writes the result to the destination.

Exclusive Or

- PXOR—Packed Logical Bitwise Exclusive OR

The PXOR instruction performs a bitwise logical exclusive OR of the values in the first and second operands and writes the result to the destination. PXOR can be used to clear all bits in an MMX register by specifying the same register for both operands. PXOR can also used with the value 8000000080000000h to change the sign bits of the elements of a 64-bit media floating-point vector operand. This method is equivalent to the x87 floating-point change sign (FCHS) instruction.

5.6.10 Save and Restore State

These instructions save and restore the processor state for 64-bit media instructions.

Save and Restore 64-Bit Media and x87 State

- FSAVE—Save x87 and MMX State
- FNSAVE—Save No-Wait x87 and MMX State
- FRSTOR—Restore x87 and MMX State

These instructions save and restore the entire processor state for x87 floating-point instructions and 64-bit media instructions. The instructions save and restore either 94 or 108 bytes of data, depending on the effective operand size.

Assemblers issue FSAVE as an FWAIT instruction followed by an FNSAVE instruction. Thus, FSAVE (but not FNSAVE) reports pending unmasked x87 floating-point exceptions before saving the state. After saving the state, the processor initializes the x87 state by performing the equivalent of an FINIT instruction.

Save and Restore 128-Bit, 64-Bit, and x87 State

- FXSAVE—Save XMM, MMX, and x87 State
- FXRSTOR—Restore XMM, MMX, and x87 State

The FXSAVE and FXRSTOR instructions save and restore the entire 512-byte processor state for 128-bit media instructions, 64-bit media instructions, and x87 floating-point instructions. The architecture supports two memory formats for FXSAVE and FXRSTOR, a 512-byte 32-bit legacy format and a 512-byte 64-bit format. Selection of the 32-bit or 64-bit format is determined by the effective operand size for the FXSAVE and FXRSTOR instructions. For details on the FXSAVE and FXRSTOR Instructions, see the “64-bit Media Instruction Reference” in Volume 5.

FXSAVE and FXRSTOR execute faster than FSAVE/FNSAVE and FRSTOR. However, unlike FSAVE and FNSAVE, FXSAVE does not initialize the x87 state, and like FNSAVE it does not report pending unmasked x87 floating-point exceptions. For details, see “Saving and Restoring State” on page 280.

5.7 Instruction Summary—Floating-Point Instructions

This section summarizes the functions of the floating-point (3DNow! and a few SSE and SSE2) instructions in the 64-bit media instruction subset. These include floating-point instructions that use an MMX register for source or destination and data-conversion instructions that convert from floating-point to integers formats. For a summary of the integer instructions in the 64-bit media instruction subset, including data-conversion instructions that convert from integer to floating-point formats, see “Instruction Summary—Integer Instructions” on page 253.

For a summary of the 128-bit media floating-point instructions, see “Instruction Summary—Floating-Point Instructions” on page 184. For a summary of the x87 floating-point instructions, see Section 6.4. “Instruction Summary” on page 310.

The instructions are organized here by functional group—such as data-transfer, vector arithmetic, and so on. Software running at any privilege level can use any of these instructions, if the CPUID instruction reports support for the instructions (see “Feature Detection” on page 276). More detail on individual instructions is given in the alphabetically organized “64-Bit Media Instruction Reference” in Volume 5.

5.7.1 Syntax

The 64-bit media floating-point instructions have the same syntax rules as those for the 64-bit media integer instructions, described in “Syntax” on page 254, except that the mnemonics of most floating-point instructions begin with the following prefix:

- PF—Packed floating-point

5.7.2 Data Conversion

These data-conversion instructions convert operands from floating-point to integer formats. The instructions take 32-bit or 64-bit floating-point source operands. For data-conversion instructions that take 64-bit integer source operands, see “Data Conversion” on page 257. For data-conversion instructions that take 128-bit source operands, see “Data Conversion” on page 155 and “Data Conversion” on page 190.

Convert Floating-Point to Integer

- CVTPS2PI—Convert Packed Single-Precision Floating-Point to Packed Doubleword Integers
- CVTTPS2PI—Convert Packed Single-Precision Floating-Point to Packed Doubleword Integers, Truncated
- CVTPD2PI—Convert Packed Double-Precision Floating-Point to Packed Doubleword Integers
- CVTTPD2PI—Convert Packed Double-Precision Floating-Point to Packed Doubleword Integers, Truncated
- PF2IW—Packed Floating-Point to Integer Word Conversion
- PF2ID—Packed Floating-Point to Integer Doubleword Conversion

The CVTPS2PI and CVTTPS2PI instructions convert two single-precision (32-bit) floating-point values in the second operand (the low-order 64 bits of an XMM register or a 64-bit memory location) to two 32-bit signed integers, and write the converted values into the first operand (an MMX register). For the CVTPS2PI instruction, if the conversion result is an inexact value, the value is rounded as specified in the rounding control (RC) field of the MXCSR register (“MXCSR Register” on page 115), but for the CVTTPS2PI instruction such a result is truncated (rounded toward zero).

The CVTPD2PI and CVTTPD2PI instructions perform conversions analogous to CVTPS2PI and CVTTPS2PI but for two double-precision (64-bit) floating-point values.

The 3DNow! PF2IW instruction converts two single-precision floating-point values in the second operand (an MMX register or a 64-bit memory location) to two 16-bit signed integer values, sign-extended to 32-bits, and writes the converted values into the first operand (an MMX register). The 3DNow! PF2ID instruction converts two single-precision floating-point values in the second operand to two 32-bit signed integer values, and writes the converted values into the first operand. If the result of either conversion is an inexact value, the value is truncated (rounded toward zero).

As described in “Floating-Point Data Types” on page 251, PF2IW and PF2ID do not fully comply with the IEEE-754 standard. Conversion of some source operands of the C type *float* (IEEE-754 single-precision)—specifically NaNs, infinities, and denormals—are not supported. Attempts to convert such source operands produce undefined results, and no exceptions are generated.

5.7.3 Arithmetic

The floating-point vector-arithmetic instructions perform an arithmetic operation on two floating-point operands. For a description of 3DNow! instruction saturation on overflow and underflow conditions, see “Floating-Point Data Types” on page 251.

Addition

- PFADD—Packed Floating-Point Add

The PFADD instruction adds each single-precision floating-point value in the first operand (an MMX register) to the corresponding single-precision floating-point value in the second operand (an MMX register or 64-bit memory location). The instruction then writes the result of each addition into the corresponding doubleword of the destination.

Subtraction

- PFSUB—Packed Floating-Point Subtract
- PFSUBR—Packed Floating-Point Subtract Reverse

The PFSUB instruction subtracts each single-precision floating-point value in the second operand from the corresponding single-precision floating-point value in the first operand. The instruction then writes the result of each subtraction into the corresponding quadword of the destination.

The PFSUBR instruction performs a subtraction that is the reverse of the PFSUB instruction. It subtracts each value in the first operand from the corresponding value in the second operand. The provision of both the PFSUB and PFSUBR instructions allows software to choose which source operand to overwrite during a subtraction.

Multiplication

- PFMUL—Packed Floating-Point Multiply

The PFMUL instruction multiplies each of the two single-precision floating-point values in the first operand by the corresponding single-precision floating-point value in the second operand and writes the result of each multiplication into the corresponding doubleword of the destination.

Division

For a description of floating-point division techniques, see “Reciprocal Estimation” on page 273. Division is equivalent to multiplication of the dividend by the reciprocal of the divisor.

Accumulation

- PFACC—Packed Floating-Point Accumulate
- PFNACC—Packed Floating-Point Negative Accumulate
- PFPNACC—Packed Floating-Point Positive-Negative Accumulate

The PFACC instruction adds the two single-precision floating-point values in the first operand and writes the result into the low-order word of the destination, and it adds the two single-precision values

in the second operand and writes the result into the high-order word of the destination. Figure 5-17 illustrates the operation.

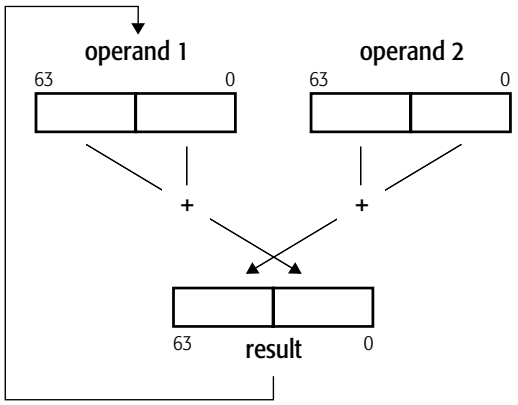

Figure 5-17. PFACC Accumulate Operation

The PFNACC instruction subtracts the first operand's high-order single-precision floating-point value from its low-order single-precision floating-point value and writes the result into the low-order doubleword of the destination, and it subtracts the second operand's high-order single-precision floating-point value from its low-order single-precision floating-point value and writes the result into the high-order doubleword of the destination.

The PFPNACC instruction *subtracts* the first operand's high-order single-precision floating-point value from its low-order single-precision floating-point value and writes the result into the low-order doubleword of the destination, and it *adds* the two single-precision values in the second operand and writes the result into the high-order doubleword of the destination.

PFPNACC is useful in complex-number multiplication, in which mixed positive-negative accumulation must be performed. Assuming that complex numbers are represented as two-element vectors (one element is the real part, the other element is the imaginary part), there is a need to swap the elements of one source operand to perform the multiplication, and there is a need for mixed positive-negative accumulation to complete the parallel computation of real and imaginary results. The PSWAPD instruction can swap elements of one source operand and the PFPNACC instruction can perform the mixed positive-negative accumulation to complete the computation.

Reciprocal Estimation

- PFRCP—Packed Floating-Point Reciprocal Approximation
- PFRCPIT1—Packed Floating-Point Reciprocal, Iteration 1
- PFRCPIT2—Packed Floating-Point Reciprocal or Reciprocal Square Root, Iteration 2

The PFRCP instruction computes the approximate reciprocal of the single-precision floating-point value in the low-order 32 bits of the second operand and writes the result into both doublewords of the first operand.

The PFRCPIT1 instruction performs the first intermediate step in the Newton-Raphson iteration to refine the reciprocal approximation produced by the PFRCP instruction. The first operand contains the input to a previous PFRCP instruction, and the second operand contains the result of the same PFRCP instruction.

The PFRCPIT2 instruction performs the second and final step in the Newton-Raphson iteration to refine the reciprocal approximation produced by the PFRCP instruction or the reciprocal square-root approximation produced by the PFSQRT instructions. The first operand contains the result of a previous PFRCPIT1 or PFRSQIT1 instruction, and the second operand contains the result of a PFRCP or PFRSQRT instruction.

The PFRCP instruction can be used together with the PFRCPIT1 and PFRCPIT2 instructions to increase the accuracy of a single-precision significand.

Reciprocal Square Root

- PFRSQRT—Packed Floating-Point Reciprocal Square Root Approximation
- PFRSQIT1—Packed Floating-Point Reciprocal Square Root, Iteration 1

The PFRSQRT instruction computes the approximate reciprocal square root of the single-precision floating-point value in the low-order 32 bits of the second operand and writes the result into each doubleword of the first operand. The second operand is a single-precision floating-point value with a 24-bit significand. The result written to the first operand is accurate to 15 bits. Negative operands are treated as positive operands for purposes of reciprocal square-root computation, with the sign of the result the same as the sign of the source operand.

The PFRSQIT1 instruction performs the first step in the Newton-Raphson iteration to refine the reciprocal square-root approximation produced by the PFSQRT instruction. The first operand contains the input to a previous PFRSQRT instruction, and the second operand contains the square of the result of the same PFRSQRT instruction.

The PFRSQRT instruction can be used together with the PFRSQIT1 instruction and the PFRCPIT2 instruction (described in “Reciprocal Estimation” on page 273) to increase the accuracy of a single-precision significand.

5.7.4 Compare

The floating-point vector-compare instructions compare two operands, and they either write a mask or they write the maximum or minimum value.

Compare and Write Mask

- PFCMPEQ—Packed Floating-Point Compare Equal
- PFCMPGT—Packed Floating-Point Compare Greater Than

- PFCMPGE—Packed Floating-Point Compare Greater or Equal

The PFCMP*x* instructions compare each of the two single-precision floating-point values in the first operand with the corresponding single-precision floating-point value in the second operand. The instructions then write the result of each comparison into the corresponding doubleword of the destination. If the comparison test (equal, greater than, greater or equal) is true, the result is a mask of all 1s. If the comparison test is false, the result is a mask of all 0s.

Compare and Write Minimum or Maximum

- PFMAX—Packed Floating-Point Maximum
- PFMIN—Packed Floating-Point Minimum

The PFMAX and PFMIN instructions compare each of the two single-precision floating-point values in the first operand with the corresponding single-precision floating-point value in the second operand. The instructions then write the maximum (PFMAX) or minimum (PFMIN) of the two values for each comparison into the corresponding doubleword of the destination.

The PFMIN and PFMAX instructions are useful for clamping, such as color clamping in 3D geometry and rasterization. They can also be used to avoid branching.

5.8 Instruction Effects on Flags

The 64-bit media instructions do not read or write any flags in the rFLAGS register, nor do they write any exception-status flags in the x87 status-word register, nor is their execution dependent on any mask bits in the x87 control-word register. The only x87 state affected by the 64-bit media instructions is described in “Actions Taken on Executing 64-Bit Media Instructions” on page 278.

5.9 Instruction Prefixes

Instruction prefixes, in general, are described in “Instruction Prefixes” on page 76. The following restrictions apply to the use of instruction prefixes with 64-bit media instructions.

5.9.1 Supported Prefixes

The following prefixes can be used with 64-bit media instructions:

- *Address-Size Override*—The 67h prefix affects only operands in memory. The prefix is ignored by all other 64-bit media instructions.
- *Operand-Size Override*—The 66h prefix is used to form the opcodes of certain 64-bit media instructions. The prefix is ignored by all other 64-bit media instructions.
- *Segment Overrides*—The 2Eh (CS), 36h (SS), 3Eh (DS), 26h (ES), 64h (FS), and 65h (GS) prefixes affect only operands in memory. In 64-bit mode, the contents of the CS, DS, ES, SS segment registers are ignored.

- *REP*—The F2 and F3h prefixes do not function as repeat prefixes for 64-bit media instructions. Instead, they are used to form the opcodes of certain 64-bit media instructions. The prefixes are ignored by all other 64-bit media instructions.
- *REX*—The REX prefixes affect operands that reference a GPR or XMM register when running in 64-bit mode. It allows access to the full 64-bit width of any of the 16 extended GPRs and to any of the 16 extended XMM registers. The REX prefix also affects the FXSAVE and FXRSTOR instructions, in which it selects between two types of 512-byte memory-image format, as described in "Media and x87 Processor State" in Volume 2. The prefix is ignored by all other 64-bit media instructions.

5.9.2 Special-Use and Reserved Prefixes

The following prefixes are used as opcode bytes in some 64-bit media instructions and are reserved in all other 64-bit media instructions:

- *Operand-Size Override*—The 66h prefix.
- *REP*—The F2 and F3h prefixes.

5.9.3 Prefixes That Cause Exceptions

The following prefixes cause an exception:

- *LOCK*—The F0h prefix causes an invalid-opcode exception when used with 64-bit media instructions.

5.10 Feature Detection

Before executing 64-bit media instructions, software should determine whether the processor supports the technology by executing the CPUID instruction. "Feature Detection" on page 79 describes how software uses the CPUID instruction to detect feature support. For full support of the 64-bit media instructions documented here, the following features require detection:

- MMX instructions, indicated by bit 23 of CPUID function 1 and function 8000_0001h.
- 3DNow! instructions, indicated by bit 31 of CPUID function 8000_0001h.
- MMX extensions, indicated by bit 22 of CPUID function 8000_0001h.
- 3DNow! extensions, indicated by bit 30 of CPUID function 8000_0001h.
- SSE instructions, indicated by bit 25 of CPUID function 8000_0001h.
- SSE2 instruction extensions, indicated by bit 26 of CPUID function 8000_0001h.
- SSE3 instruction extensions, indicated by bit 0 of CPUID function 0000_0001h.
- SSE4A instruction extensions, indicated by bit 6 of CPUID function 8000_0001h.

Software may also wish to check for the following support, because the FXSAVE and FXRSTOR instructions execute faster than FSAVE and FRSTOR:

- FXSAVE and FXRSTOR, indicated by bit 24 of CPUID function 1 and function 8000_0001h.

Software that runs in long mode should also check for the following support:

- Long Mode, indicated by bit 29 of CPUID function 8000_0001h.

See “CPUID” in Volume 3 for details on the CPUID instruction and Appendix D of that volume for information on detemining support for specific instruction subsets.

If the FXSAVE and FXRSTOR instructions are to be used, the operating system must support these instructions by having set CR4.OSFXSR = 1. If the MMX floating-point-to-integer data-conversion instructions (CVTPS2PI, CVTTPS2PI, CVTPD2PI, or CVTTPD2PI) are used, the operating system must support the FXSAVE and FXRSTOR instructions and SIMD floating-point exceptions (by having set CR4.OSXMMEXCPT = 1). For details, see “System-Control Registers” in Volume 2.

5.11 Exceptions

64-bit media instructions can generate two types of exceptions:

- *General-Purpose Exceptions*, described below in “General-Purpose Exceptions”
- *x87 Floating-Point Exceptions (#MF)*, described in “x87 Floating-Point Exceptions (#MF)” on page 278

All exceptions that occur while executing 64-bit media instructions can be handled by legacy exception handlers used for general-purpose instructions and x87 floating-point instructions.

5.11.1 General-Purpose Exceptions

The sections below list exceptions generated and not generated by general-purpose instructions. For a summary of the general-purpose exception mechanism, see “Interrupts and Exceptions” on page 91. For details about each exception and its potential causes, see “Exceptions and Interrupts” in Volume 2.

5.11.1.1 Exceptions Generated

The 64-bit media instructions can generate the following general-purpose exceptions:

- #DB—Debug Exception (Vector 1)
- #UD—Invalid-Opcode Exception (Vector 6)
- #DF—Double-Fault Exception (Vector 8)
- #SS—Stack Exception (Vector 12)
- #GP—General-Protection Exception (Vector 13)
- #PF—Page-Fault Exception (Vector 14)
- #MF—x87 Floating-Point Exception-Pending (Vector 16)
- #AC—Alignment-Check Exception (Vector 17)
- #MC—Machine-Check Exception (Vector 18)
- #XF—SIMD Floating-Point Exception (Vector 19)—Only by the CVTPS2PI, CVTTPS2PI, CVTPD2PI, and CVTTPD2PI instructions.

An invalid-opcode exception (#UD) can occur if a required CPUID feature flag is not set (see "Feature Detection" on page 276), or if an attempt is made to execute a 64-bit media instruction and the operating system has set the floating-point software-emulation (EM) bit in control register 0 to 1 (CR0.EM = 1).

For details on the system control-register bits, see "System-Control Registers" in Volume 2. For details on the machine-check mechanism, see "Machine Check Mechanism" in Volume 2.

For details on #MF exceptions, see "x87 Floating-Point Exceptions (#MF)" on page 278.

5.11.1.2 Exceptions Not Generated

The 64-bit media instructions do not generate the following general-purpose exceptions:

- #DE—Divide-By-Zero-Error Exception (Vector 0)
- Non-Maskable-Interrupt Exception (Vector 2)
- #BP—Breakpoint Exception (Vector 3)
- #OF—Overflow Exception (Vector 4)
- #BR—Bound-Range Exception (Vector 5)
- #NM—Device-Not-Available Exception (Vector 7)
- Coprocessor-Segment-Overrun Exception (Vector 9)
- #TS—Invalid-TSS Exception (Vector 10)
- #NP—Segment-Not-Present Exception (Vector 11)

For details on all general-purpose exceptions, see "Exceptions and Interrupts" in Volume 2.

5.11.2 x87 Floating-Point Exceptions (#MF)

The 64-bit media instructions do not generate x87 floating-point (#MF) exceptions as a consequence of their own computations. However, an #MF exception can occur during the execution of a 64-bit media instruction, due to a prior x87 floating-point instruction. Specifically, if an unmasked x87 floating-point exception is pending at the instruction boundary of the next 64-bit media instruction, the processor asserts the FERR# output signal. For details about the x87 floating-point exceptions and the FERR# output signal, see Section 6.8.2. "x87 Floating-Point Exception Causes" on page 329.

5.12 Actions Taken on Executing 64-Bit Media Instructions

The MMX registers are mapped onto the low 64 bits of the 80-bit x87 floating-point physical registers, FPR0–FPR7, described in Section 6.2. "Registers" on page 286. The MMX instructions do not use the x87 stack-addressing mechanism. However, 64-bit media instructions write certain values in the x87 top-of-stack pointer, tag bits, and high bits of the FPR0–FPR7 data registers.

Specifically, the processor performs the following x87-related actions atomically with the execution of 64-bit media instructions:

- *Top-Of-Stack Pointer (TOP)*—The processor clears the x87 top-of-stack pointer (bits 13–11 in the x87 status word register) to all 0s during the execution of every 64-bit media instruction, causing it to point to the *mmx0* register.
- *Tag Bits*—During the execution of every 64-bit media instruction, except the EMMS and FEMMS instructions, the processor changes the tag state for all eight MMX registers to *full*, as described below. In the case of EMMS and FEMMS, the processor changes the tag state for all eight MMX registers to *empty*, thus initializing the stack for an x87 floating-point procedure.
- *Bits 79:64*—During the execution of every 64-bit media instruction that writes a result to an MMX register, the processor writes the result data to a 64-bit MMX register (the low 64 bits of the associated 80-bit x87 floating-point physical register) and sets the exponent and sign bits (the high 16 bits of the associated 80-bit x87 floating-point physical register) to all 1s. In the x87 environment, the effect of setting the high 16 bits to all 1s indicates that the contents of the low 64 bits are not finite numbers. Such a designation prevents an x87 floating-point instruction from interpreting the data as a finite x87 floating-point number.

The rest of the x87 floating-point processor state—the entire x87 control-word register, the remaining fields of the status-word register, and the error pointers (instruction pointer, data pointer, and last opcode register)—is not affected by the execution of 64-bit media instructions.

The 2-bit tag fields defined by the x87 architecture for each x87 data register, and stored in the x87 tag-word register (also called the floating-point tag word, or FTW), characterize the contents of the MMX registers. The tag bits are visible to software only after an FSAVE or FNSAVE (but not FXSAVE) instruction, as described in “Media and x87 Processor State” in Volume 2. Internally, however, the processor maintains only a one-bit representation of each 2-bit tag field. This single bit indicates whether the associated register is *empty* or *full*. Table 5-6 on page 279 shows the mapping between the 1-bit internal tag—which is referred to in this chapter by its *empty* or *full* state—and the 2-bit architectural tag.

Table 5-6. Mapping Between Internal and Software-Visible Tag Bits

Architectural State		Internal State[1]
State	Binary Value	
Valid	00	Full (0)
Zero	01	
Special (NaN, infinity, denormal)[2]	10	
Empty	11	Empty (1)

Note:
1. *For a more detailed description of this mapping, see “Deriving FSAVE Tag Field from FXSAVE Tag Field” in Volume 2.*
2. *The 64-bit media floating point (3DNow!™) instructions do not support NaNs, infinities, and denormals.*

When the processor executes an FSAVE or FNSAVE (but not FXSAVE) instruction, it changes the internal 1-bit tag state to its 2-bit architectural tag by reading the data in all 80 bits of the physical data

registers and using the mapping in Table 5-6. For example, if the value in the high 16 bits of the 80-bit physical register indicate a NaN, the two tag bits for that register are changed to a binary value of 10 before the x87 status word is written to memory.

The tag bits have no effect on the execution of 64-bit media instructions or their interpretation of the contents of the MMX registers. However, the converse is not true: execution of 64-bit media instructions that write to an MMX register alter the tag bits and thus may affect execution of subsequent x87 floating-point instructions.

For a more detailed description of the mapping shown in Table 5-6, see “Deriving FSAVE Tag Field from FXSAVE Tag Field” in Volume 2 and its accompanying text.

5.13 Mixing Media Code with x87 Code

5.13.1 Mixing Code

Software may freely mix 64-bit media instructions (integer or floating-point) with 128-bit media instructions (integer or floating-point) and general-purpose instructions in a single procedure. However, before transitioning from a 64-bit media procedure—or a 128-bit media procedure that accesses an MMX™ register—to an x87 procedure, or to software that may eventually branch to an x87 procedure, software should clear the MMX state, as described immediately below.

5.13.2 Clearing MMX™ State

Software should separate 64-bit media procedures, 128-bit media procedures, or dynamic link libraries (DLLs) that access MMX registers from x87 floating-point procedures or DLLs by clearing the MMX state with the EMMS or FEMMS instruction before leaving a 64-bit media procedure, as described in “Exit Media State” on page 255.

The 64-bit media instructions and x87 floating-point instructions interpret the contents of their aliased MMX and x87 registers differently. Because of this, software should not exchange register data between 64-bit media and x87 floating-point procedures, or use conditional branches at the end of loops that might jump to code of the other type. Software must not rely on the contents of the aliased MMX and x87 registers across such code-type transitions. If a transition to an x87 procedure occurs from a 64-bit media procedure that does not clear the MMX state, the x87 stack may overflow.

5.14 State-Saving

5.14.1 Saving and Restoring State

In general, system software should save and restore MMX™ and x87 state between task switches or other interventions in the execution of 64-bit media procedures. Virtually all modern operating systems running on x86 processors implement preemptive multitasking that handle saving and restoring of state across task switches, independent of hardware task-switch support.

No changes are needed to the x87 register-saving performed by 32-bit operating systems, exception handlers, or device drivers. The same support provided in a 32-bit operating system's device-not-available (#NM) exception handler by any of the x87-register save/restore instructions described below also supports saving and restoring the MMX registers.

However, application procedures are also free to save and restore MMX and x87 state at any time they deem useful.

5.14.2 State-Saving Instructions

Software running at any privilege level may save and restore 64-bit media and x87 state by executing the FSAVE, FNSAVE, or FXSAVE instruction. Alternatively, software may use move instructions for saving only the contents of the MMX registers, rather than the complete 64-bit media and x87 state. For example, when saving MMX register values, use eight MOVQ instructions.

5.14.2.1 FSAVE/FNSAVE and FRSTOR Instructions

The FSAVE, FNSAVE, and FRSTOR instructions are described in "Save and Restore 64-Bit Media and x87 State" on page 269. After saving state with FSAVE or FNSAVE, the tag bits for all MMX and x87 registers are changed to *empty* and thus available for a new procedure. Thus, FSAVE and FNSAVE also perform the state-clearing function of EMMS or FEMMS.

5.14.2.2 FXSAVE and FXRSTOR Instructions

The FSAVE, FNSAVE, and FRSTOR instructions are described in "Save and Restore 128-Bit, 64-Bit, and x87 State" on page 270. The FXSAVE and FXRSTOR instructions execute faster than FSAVE/FNSAVE and FRSTOR because they do not save and restore the x87 error pointers (described in Section 6.2.5. "Pointers and Opcode State" on page 295) except in the relatively rare cases in which the exception-summary (ES) bit in the x87 status word (register image for FXSAVE, memory image for FXRSTOR) is set to 1, indicating that an unmasked x87 exception has occurred.

Unlike FSAVE and FNSAVE, however, FXSAVE does not alter the tag bits (thus, it does not perform the state-clearing function of EMMS or FEMMS). The state of the saved MMX and x87 registers is retained, thus indicating that the registers may still be valid (or whatever other value the tag bits indicated prior to the save). To invalidate the contents of the MMX and x87 registers after FXSAVE, software must explicitly execute an FINIT instruction. Also, FXSAVE (like FNSAVE) and FXRSTOR do not check for pending unmasked x87 floating-point exceptions. An FWAIT instruction can be used for this purpose.

For details about the FXSAVE and FXRSTOR memory formats, see "Media and x87 Processor State" in Volume 2.

5.15 Performance Considerations

In addition to typical code optimization techniques, such as those affecting loops and the inlining of function calls, the following considerations may help improve the performance of application programs written with 64-bit media instructions.

These are implementation-independent performance considerations. Other considerations depend on the hardware implementation. For information about such implementation-dependent considerations and for more information about application performance in general, see the data sheets and the software-optimization guides relating to particular hardware implementations.

5.15.1 Use Small Operand Sizes

The performance advantages available with 64-bit media operations is to some extent a function of the data sizes operated upon. The smaller the data size, the more data elements that can be packed into single 64-bit vectors. The parallelism of computation increases as the number of elements per vector increases.

5.15.2 Reorganize Data for Parallel Operations

Much of the performance benefit from the 64-bit media instructions comes from the parallelism inherent in vector operations. It can be advantageous to reorganize data before performing arithmetic operations so that its layout after reorganization maximizes the parallelism of the arithmetic operations.

The speed of memory access is particularly important for certain types of computation, such as graphics rendering, that depend on the regularity and locality of data-memory accesses. For example, in matrix operations, performance is high when operating on the rows of the matrix, because row bytes are contiguous in memory, but lower when operating on the columns of the matrix, because column bytes are not contiguous in memory and accessing them can result in cache misses. To improve performance for operations on such columns, the matrix should first be transposed. Such transpositions can, for example, be done using a sequence of unpacking or shuffle instructions.

5.15.3 Remove Branches

Branch can be replaced with 64-bit media instructions that simulate predicated execution or conditional moves, as described in “Branch Removal” on page 244. Where possible, break long dependency chains into several shorter dependency chains which can be executed in parallel. This is especially important for floating-point instructions because of their longer latencies.

5.15.4 Align Data

Data alignment is particularly important for performance when data written by one instruction is read by a subsequent instruction soon after the write, or when accessing streaming (non-temporal) data—data that will not be reused and therefore should not be cached. These cases may occur frequently in 64-bit media procedures.

Accesses to data stored at unaligned locations may benefit from on-the-fly software alignment or from repetition of data at different alignment boundaries, as required by different loops that process the data.

5.15.5 Organize Data for Cacheability

Pack small data structures into cache-line-size blocks. Organize frequently accessed constants and coefficients into cache-line-size blocks and prefetch them. Procedures that access data arranged in memory-bus-sized blocks, or memory-burst-sized blocks, can make optimum use of the available memory bandwidth.

For data that will be used only once in a procedure, consider using non-cacheable memory. Accesses to such memory are not burdened by the overhead of cache protocols.

5.15.6 Prefetch Data

Media applications typically operate on large data sets. Because of this, they make intensive use of the memory bus. Memory latency can be substantially reduced—especially for data that will be used only once—by prefetching such data into various levels of the cache hierarchy. Software can use the PREFETCH*x* instructions very effectively in such cases, as described in “Cache and Memory Management” on page 71.

Some of the best places to use prefetch instructions are inside loops that process large amounts of data. If the loop goes through less than one cache line of data per iteration, partially unroll the loop to obtain multiple iterations of the loop within a cache line. Try to use virtually all of the prefetched data. This usually requires unit-stride memory accesses—those in which all accesses are to contiguous memory locations.

5.15.7 Retain Intermediate Results in MMX™ Registers

Keep intermediate results in the MMX registers as much as possible, especially if the intermediate results are used shortly after they have been produced. Avoid spilling intermediate results to memory and reusing them shortly thereafter.

6 x87 Floating-Point Programming

This chapter describes the x87 floating-point programming model. This model supports all aspects of the legacy x87 floating-point model and complies with the IEEE 754 and 854 standards for binary floating-point arithmetic. In hardware implementations of the AMD64 architecture, support for specific features of the x87 programming model are indicated by the CPUID feature bits, as described in “Feature Detection” on page 327.

6.1 Overview

Floating-point software is typically written to manipulate numbers that are very large or very small, that require a high degree of precision, or that result from complex mathematical operations, such as transcendentals. Applications that take advantage of floating-point operations include geometric calculations for graphics acceleration, scientific, statistical, and engineering applications, and process control.

6.1.1 Capabilities

The advantages of using x87 floating-point instructions include:

- Representation of all numbers in common IEEE-754/854 formats, ensuring replicability of results across all platforms that conform to IEEE-754/854 standards.
- Availability of separate floating-point registers. Depending on the hardware implementation of the architecture, this may allow execution of x87 floating-point instructions in parallel with execution of general-purpose and 128-bit media instructions.
- Availability of instructions that compute absolute value, change-of-sign, round-to-integer, partial remainder, and square root.
- Availability of instructions that compute transcendental values, including 2^x-1, cosine, partial arc tangent, partial tangent, sine, sine with cosine, y*$\log_2$x, and y*$\log_2$(x+1). The cosine, partial arc tangent, sine, and sine with cosine instructions use angular values expressed in radians for operands and results.
- Availability of instructions that load common constants, such as $\log_2$e, $\log_2$10, $\log_{10}$2, $\log_e$2, Pi, 1, and 0.

x87 instructions operate on data in three floating-point formats—32-bit single-precision, 64-bit double-precision, and 80-bit double-extended-precision (sometimes called extended precision)—as well as integer, and 80-bit packed-BCD formats.

x87 instructions carry out all computations using the 80-bit double-extended-precision format. When an x87 instruction reads a number from memory in 80-bit double-extended-precision format, the number can be used directly in computations, without conversion. When an x87 instruction reads a number in a format other than double-extended-precision format, the processor first converts the

number into double-extended-precision format. The processor can convert numbers back to specific formats, or leave them in double-extended-precision format when writing them to memory.

Most x87 operations for addition, subtraction, multiplication, and division specify two source operands, the first of which is replaced by the result. Instructions for subtraction and division have reverse forms which swap the ordering of operands.

6.1.2 Origins

In 1979, AMD introduced the first floating-point coprocessor for microprocessors—the AM9511 arithmetic circuit. This coprocessor performed 32-bit floating-point operations under microprocessor control. In 1980, AMD introduced the AM9512, which performed 64-bit floating-point operations. These coprocessors were second-sourced as the 8231 and 8232 coprocessors. Before then, programmers working with general-purpose microprocessors had to use much slower, vendor-supplied software libraries for their floating-point needs.

In 1985, the Institute of Electrical and Electronics Engineers published the *IEEE Standard for Binary Floating-Point Arithmetic*, also referred to as the *ANSI/IEEE Std 754-1985* standard, or *IEEE 754*. This standard defines the data types, operations, and exception-handling methods that are the basis for the x87 floating-point technology implemented in the legacy x86 architecture. In 1987, the IEEE published a more general radix-independent version of that standard, called the ANSI/IEEE Std 854-1987 standard, or *IEEE 854* for short. The AMD64 architecture complies with both the IEEE 754 and IEEE 854 standards.

6.1.3 Compatibility

x87 floating-point instructions can be executed in any of the architecture's operating modes. Existing x87 binary programs run in legacy and compatibility modes without modification. The support provided by the AMD64 architecture for such binaries is identical to that provided by legacy x86 architectures.

To run in 64-bit mode, x87 floating-point programs must be recompiled. The recompilation has no side effects on such programs, other than to make available the extended general-purpose registers and 64-bit virtual address space.

6.2 Registers

Operands for the x87 instructions are located in x87 registers or memory. Figure 6-1 on page 287 shows an overview of the x87 registers.

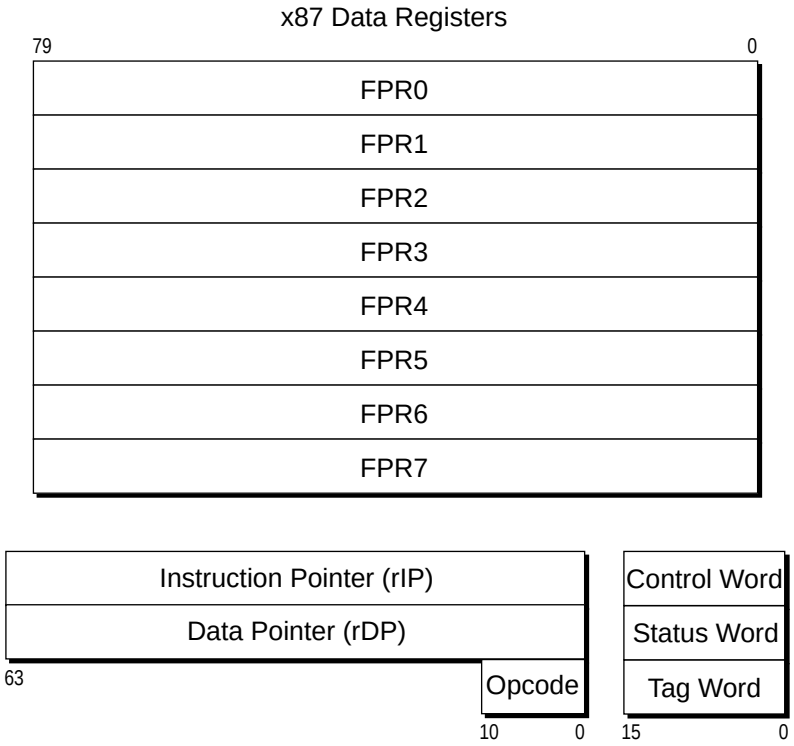

Figure 6-1. x87 Registers

These registers include eight 80-bit data registers, three 16-bit registers that hold the x87 control word, status word, and tag word, two 64-bit registers that hold instruction and data pointers, and an 11-bit register that holds a permutation of an x87 opcode.

6.2.1 x87 Data Registers

Figure 6-2 on page 288 shows the eight 80-bit data registers in more detail. Typically, x87 instructions reference these registers as a stack. x87 instructions store operands only in these 80-bit registers or in memory. They do not (with two exceptions) access the GPR registers, and they do not access the YMM/XMM registers.

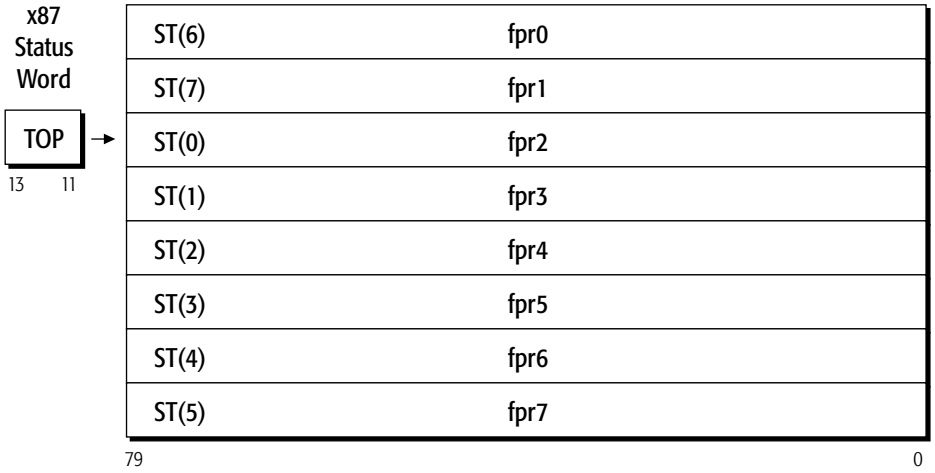

Figure 6-2. x87 Physical and Stack Registers

6.2.1.1 Stack Organization

The bank of eight physical data registers, FPR0–FPR7, are organized internally as a stack, ST(0)–ST(7). The stack functions like a circular modulo-8 buffer. The stack top can be set by software to start at any register position in the bank. Many instructions access the top of stack as well as individual registers relative to the top of stack.

6.2.1.2 Stack Pointer

Bits 13:11 of the x87 status word (“x87 Status Word Register (FSW)” on page 289) are the top-of-stack pointer (TOP). The TOP specifies the mapping of the stack registers onto the physical registers. The TOP contains the physical-register index of the location of the top of stack, ST(0). Instructions that load operands from memory into an x87 register first decrement the stack pointer and then copy the operand (often with conversion to the double-extended-precision format) from memory into the decremented top-of-stack register. Instructions that store operands from an x87 register to memory copy the operand (often with conversion from the double-extended-precision format) in the top-of-stack register to memory and then increment the stack pointer.

Figure 6-2 shows the mapping between stack registers and physical registers when the TOP has the value 2. Modulo-8 wraparound addressing is used. Pushing a new element onto this stack—for example with the FLDZ (floating-point load +0.0) instruction—decrements the TOP to 1, so that ST(0) refers to FPR1, and the new top-of-stack is loaded with +0.0.

The architecture provides alternative versions of many instructions that either modify or do not modify the TOP as a side effect. For example, FADDP (floating-point add and pop) behaves exactly like FADD (floating-point add), except that it pops the stack after completion. Programs that use the x87 registers as a flat register file rather than as a stack would use non-popping versions of instructions to

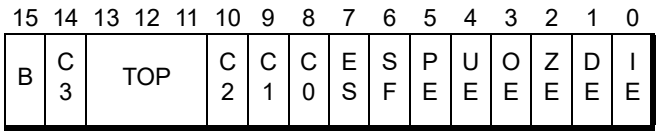
ensure that the TOP remains unchanged. However, loads (pushes) without corresponding pops can cause the stack to overflow, which occurs when a value is pushed or loaded into an x87 register that is not empty (as indicated by the register's tag bits). To prevent overflow, the FXCH (floating-point exchange) instruction can be used to access stack registers, giving the appearance of a flat register file, but all x87 programs must be aware of the register file's stack organization.

The FINCSTP and FDECSTP instructions can be used to increment and decrement, respectively, the TOP, modulo-8, allowing the stack top to wrap around to the bottom of the eight-register file when incremented beyond the top of the file, or to wrap around to the top of the register file when decremented beyond the bottom of the file. Neither the x87 tag word nor the contents of the floating-point stack itself is updated when these instructions are used.

6.2.2 x87 Status Word Register (FSW)

The 16-bit x87 status word register contains information about the state of the floating-point unit, including the top-of-stack pointer (TOP), four condition-code bits, exception-summary flag, stack-fault flag, and six x87 floating-point exception flags. Figure 6-3 on page 290 shows the format of this register. All bits can be read and written, however values written to the B and ES bits (bits 15 and 7) are ignored.

The FRSTOR and FXRSTOR instructions load the status word from memory. The FSTSW, FNSTSW, FSAVE, FNSAVE, FXSAVE, FSTENV, and FNSTENV instructions store the status word to memory. The FCLEX and FNCLEX instructions clear the exception flags. The FINIT and FNINIT instructions clear all bits in the status-word.



Bits	Mnemonic	Description
15	B	x87 Floating-Point Unit Busy
14	C3	Condition Code
13:11	TOP	Top of Stack Pointer 000 = FPR0 111 = FPR7
10	C2	Condition Code
9	C1	Condition Code
8	C0	Condition Code
7	ES	Exception Status
6	SF	Stack Fault
	Exception Flags	
5	PE	Precision Exception
4	UE	Underflow Exception
3	OE	Overflow Exception
2	ZE	Zero-Divide Exception
1	DE	Denormalized-Operand Exception
0	IE	Invalid-Operation Exception

Figure 6-3. x87 Status Word Register (FSW)

The bits in the x87 status word are defined immediately below, starting with bit 0. The six exception flags (IE, DE, ZE, OE, UE, PE) plus the stack fault (SF) flag are sticky bits. Once set by the processor, such a bit remains set until software clears it. For details about the causes of x87 exceptions indicated by bits 6:0, see “x87 Floating-Point Exception Causes” on page 329. For details about the masking of x87 exceptions, see “x87 Floating-Point Exception Masking” on page 333.

6.2.2.1 Invalid-Operation Exception (IE)

Bit 0. The processor sets this bit to 1 when an invalid-operation exception occurs. These exceptions are caused by many types of errors, such as an invalid operand or by stack faults. When a stack fault causes an IE exception, the stack fault (SF) exception bit is also set.

6.2.2.2 Denormalized-Operand Exception (DE)

Bit 1. The processor sets this bit to 1 when one of the source operands of an instruction is in denormalized form. (See “Denormalized (Tiny) Numbers” on page 303.)

6.2.2.3 Zero-Divide Exception (ZE)

Bit 2. The processor sets this bit to 1 when a non-zero number is divided by zero.

6.2.2.4 Overflow Exception (OE)

Bit 3. The processor sets this bit to 1 when the absolute value of a rounded result is larger than the largest representable normalized floating-point number for the destination format. (See “Normalized Numbers” on page 303.)

6.2.2.5 Underflow Exception (UE)

Bit 4. The processor sets this bit to 1 when the absolute value of a rounded non-zero result is too small to be represented as a normalized floating-point number for the destination format. (See “Normalized Numbers” on page 303.)

The underflow exception has an unusual behavior. When masked by the UM bit (bit 4 of the x87 control word), the processor only reports a UE exception if the UE occurs *together with* a precision exception (PE).

6.2.2.6 Precision Exception (PE)

Bit 5. The processor sets this bit to 1 when a floating-point result, after rounding, differs from the infinitely precise result and thus cannot be represented exactly in the specified destination format. The PE exception is also called the *inexact-result* exception.

6.2.2.7 Stack Fault (SF)

Bit 6. The processor sets this bit to 1 when a stack overflow (due to a push or load into a non-empty stack register) or stack underflow (due to referencing an empty stack register) occurs in the x87 stack-register file. When either of these conditions occur, the processor also sets the invalid-operation exception (IE) flag, and the processor distinguishes overflow from underflow by writing the condition-code 1 (C1) bit (C1 = 1 for overflow, C1 = 0 for underflow). Unlike the flags for the other x87 exceptions, the SF flag does not have a corresponding mask bit in the x87 control word.

If, subsequent to the instruction that caused the SF bit to be set, a second invalid-operation exception (IE) occurs due to an invalid operand in an arithmetic instruction (i.e., not a stack fault), and if software has not cleared the SF bit between the two instructions, the SF bit will remain set.

6.2.2.8 Exception Status (ES)

Bit 7. The processor calculates the value of this bit at each instruction boundary and sets the bit to 1 when one or more unmasked floating-point exceptions occur. If the ES bit has already been set by the action of some prior instruction, the processor invokes the #MF exception handler when the next non-control x87 or 64-bit media instruction is executed. (See “Control” on page 323 for a definition of control instructions).

The ES bit can be written, but the written value is ignored. Like the SF bit, the ES bit does not have a corresponding mask bit in the x87 control word.

6.2.2.9 Top-of-Stack Pointer (TOP)

Bits 13:11. The TOP contains the physical register index of the location of the top of stack, ST(0). It thus specifies the mapping of the x87 stack registers, ST(0)–ST(7), onto the x87 physical registers, FPR0–FPR7. The processor changes the TOP during any instructions that pushes or pops the stack. For details on how the stack works, see “Stack Organization” on page 288.

6.2.2.10 Condition Codes (C3–C0)

Bits 14 and 10:8. The processor sets these bits according to the result of arithmetic, compare, and other instructions. In certain cases, other status-word flags can be used together with the condition codes to determine the result of an operation, including stack overflow, stack underflow, sign, least-significant quotient bits, last-rounding direction, and out-of-range operand. For details on how each instruction sets the condition codes, see “x87 Floating-Point Instruction Reference” in Volume 5.

6.2.2.11 x87 Floating-Point Unit Busy (B)

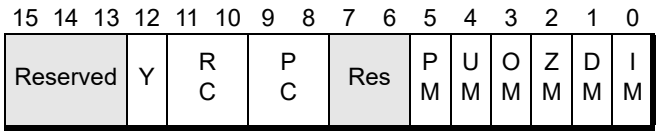
Bit 15. The processor sets the value of this bit equal to the calculated value of the ES bit, bit 7. This bit can be written, but the written value is ignored. The bit is included only for backward-compatibility with the 8087 coprocessor, in which it indicates that the coprocessor is busy.

For further details about the x87 floating-point exceptions, see “x87 Floating-Point Exception Causes” on page 329.

6.2.3 x87 Control Word Register (FCW)

The 16-bit x87 control word register allows software to manage certain x87 processing options, including rounding, precision, and masking of the six x87 floating-point exceptions (any of which is reported as an #MF exception). Figure 6-4 shows the format of the control word. All bits, except reserved bits, can be read and written.

The FLDCW, FRSTOR, and FXRSTOR instructions load the control word from memory. The FSTCW, FNSTCW, FSAVE, FNSAVE, and FXSAVE instructions store the control word to memory. The FINIT and FNINIT instructions initialize the control word with the value 037Fh, which specifies round-to-nearest, all exceptions masked, and double-extended precision (64-bit).



Bits	Mnemonic	Description
12	Y	Infinity Bit (80287 compatibility)
11:10	RC	Rounding Control
9:8	PC	Precision Control
		#MF Exception Masks
5	PM	Precision Exception Mask
4	UM	Underflow Exception Mask
3	OM	Overflow Exception Mask
2	ZM	Zero-Divide Exception Mask
1	DM	Denormalized-Operand Exception Mask
0	IM	Invalid-Operation Exception Mask

Figure 6-4. x87 Control Word Register (FCW)

Starting from bit 0, the bits are:

6.2.3.1 Exception Masks (PM, UM, OM, ZM, DM, IM)

Bits 5:0. Software can set these bits to mask, or clear these bits to unmask, the corresponding six types of x87 floating-point exceptions (PE, UE, OE, ZE, DE, IE), which are reported in the x87 status word as described in “x87 Status Word Register (FSW)” on page 289. A bit masks its exception type when set to 1, and unmasks it when cleared to 0.

Masking a type of exception causes the processor to handle all subsequent instances of the exception type in a default way. Unmasking the exception type causes the processor to branch to the #MF exception service routine when an exception occurs. For details about the processor’s responses to masked and unmasked exceptions, see “x87 Floating-Point Exception Causes” on page 329.

6.2.3.2 Precision Control (PC)

Bits 9:8. Software can set this field to specify the precision of x87 floating-point calculations, as shown in Table 6-1. Details on each precision are given in “Data Types” on page 299. The default precision is double-extended-precision. Precision control affects only the F(I)ADDx, F(I)SUB*x*, F(I)MULx, F(I)DIV*x*, and FSQRT instructions. For further details on precision, see “Precision” on page 309.

Table 6-1. Precision Control (PC) Summary

PC Value (binary)	Data Type
00	Single precision
01	*reserved*
10	Double precision
11	Double-extended precision (default)

6.2.3.3 Rounding Control (RC)

Bits 11:10. Software can set this field to specify how the results of x87 instructions are to be rounded. Table 6-2 lists the four rounding modes, which are defined by the IEEE 754 standard.

Table 6-2. Types of Rounding

RC Value	Mode	Type of Rounding
00 (default)	Round to nearest	The rounded result is the representable value closest to the infinitely precise result. If equally close, the even value (with least-significant bit 0) is taken.
01	Round down	The rounded result is closest to, but no greater than, the infinitely precise result.
10	Round up	The rounded result is closest to, but no less than, the infinitely precise result.
11	Round toward zero	The rounded result is closest to, but no greater in absolute value than, the infinitely precise result.

Round-to-nearest is the default rounding mode. It provides a statistically unbiased estimate of the true result, and is suitable for most applications. Rounding modes apply to all arithmetic operations except comparison and remainder. They have no effect on operations that produce not-a-number (NaN) results. For further details on rounding, see “Rounding” on page 309.

6.2.3.4 Infinity Bit (Y)

Bit 12. This bit is obsolete. It can be read and written, but the value has no meaning. On pre-386 processor implementations, the bit specified the affine (Y = 1) or projective (Y = 0) infinity. The AMD64 architecture uses only the affine infinity, which specifies distinct positive and negative infinity values.

6.2.4 x87 Tag Word Register (FTW)

The x87 tag word register contains a 2-bit tag field for each x87 physical data register. These tag fields characterize the register’s data. Figure 6-5 shows the format of the tag word.

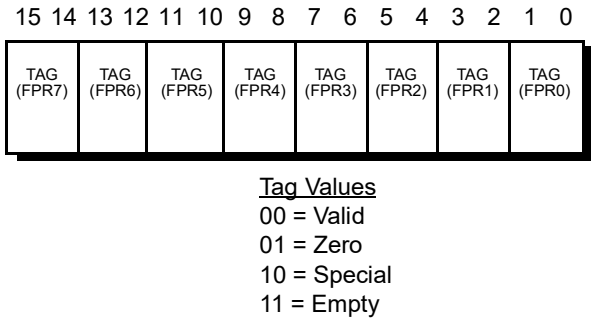


Figure 6-5. x87 Tag Word Register (FTW)

In the memory image saved by the instructions described in "x87 Environment" on page 297, each x87 physical data register has two tag bits which are encoded according to the *Tag Values* shown in Figure 6-5. Internally, the hardware may maintain only a single bit that indicates whether the associated register is *empty* or *full*. The mapping between such a 1-bit internal tag and the 2-bit software-visible architectural representation saved in memory is shown in Table 6-3 on page 295. In such a mapping, whenever software saves the tag word, the processor expands the internal 1-bit tag state to the 2-bit architectural representation by examining the contents of the x87 registers, as described in "SSE, MMX, and x87 Programming" in Volume 2.

Table 6-3. Mapping Between Internal and Software-Visible Tag Bits

Architectural State (Software-Visible)		Hardware State
State	Bit Value	
Valid	00	Full
Zero	01	
Special (NaN, infinity, denormal, or unsupported)	10	
Empty	11	Empty

The FINIT and FNINIT instructions write the tag word so that it specifies all floating-point registers as *empty*. Execution of 64-bit media instructions that write to an MMX™ register alter the tag bits by setting all the registers to *full*, and thus they may affect execution of subsequent x87 floating-point instructions. For details, see "Mixing Media Code with x87 Code" on page 280.

6.2.5 Pointers and Opcode State

The x87 instruction pointer, instruction opcode, and data pointer are part of the x87 environment (non-data processor state) that is loaded and stored by the instructions described in "x87 Environment" on page 297. Figure 6-6 illustrates the pointer and opcode state. Execution of all x87 instructions—except control instructions (see "Control" on page 323)—causes the processor to store this state in hardware.

For convenience, the pointer and opcode state is illustrated here as registers. However, the manner of storing this state in hardware depends on the hardware implementation. The AMD64 architecture specifies only the software-visible state that is saved in memory. (See “Media and x87 Processor State” in Volume 2 for details of the memory images.)

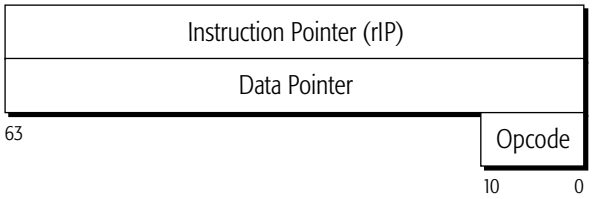

Figure 6-6. x87 Pointers and Opcode State

6.2.5.1 Last x87 Instruction Pointer

The contents of the 64-bit last-instruction pointer depends on the operating mode, as follows:

- *64-Bit Mode*—The pointer contains the 64-bit RIP offset of the last *non-control* x87 instruction executed (see “Control” on page 323 for a definition of control instructions). The 16-bit code-segment (CS) selector is not saved. (It is the operating system’s responsibility to ensure that the 64-bit state-restoration is executed in the same code segment as the preceding 64-bit state-store.)
- *Legacy Protected Mode and Compatibility Mode*—The pointer contains the 16-bit code-segment (CS) selector and the 16-bit or 32-bit eIP of the last non-control x87 instruction executed.
- *Legacy Real Mode and Virtual-8086 Mode*—The pointer contains the 20-bit or 32-bit linear address (CS base + eIP) of the last non-control x87 instruction executed.

The FINIT and FNINIT instructions clear all bits in this pointer.

6.2.5.2 Last x87 Opcode

The 11-bit instruction opcode holds a permutation of the two-byte instruction opcode from the last non-control x87 floating-point instruction executed by the processor. The opcode field is formed as follows:

- Opcode Field[10:8] = First x87-opcode byte[2:0].
- Opcode Field[7:0] = Second x87-opcode byte[7:0].

For example, the x87 opcode D9 F8 (floating-point partial remainder) is stored as 001_1111_1000b. The low-order three bits of the first opcode byte, D9 (1101_1001b), are stored in bits 10:8. The second opcode byte, F8 (1111_1000b), is stored in bits 7:0. The high-order five bits of the first opcode byte (1101_1b) are not needed because they are identical for all x87 instructions.

6.2.5.3 Last x87 Data Pointer

The operating mode determines the value of the 64-bit data pointer, as follows:

- *64-Bit Mode*—The pointer contains the 64-bit offset of the last memory operand accessed by the last non-control x87 instruction executed.
- *Legacy Protected Mode and Compatibility Mode*—The pointer contains the 16-bit data-segment selector and the 16-bit or 32-bit offset of the last memory operand accessed by an executed non-control x87 instruction.
- *Legacy Real Mode and Virtual-8086 Mode*—The pointer contains the 20-bit or 32-bit linear address (segment base + offset) of the last memory operand accessed by an executed non-control x87 instruction.

The FINIT and FNINIT instructions clear all bits in this pointer.

6.2.6 x87 Environment

The x87 environment—or non-data processor state—includes the following processor state:

- x87 control word register (FCW)
- x87 status word register (FSW)
- x87 tag word (FTW)
- last x87 instruction pointer
- last x87 data pointer
- last x87 opcode

Table 6-4 lists the x87 instructions can access this x87 processor state.

Table 6-4. Instructions that Access the x87 Environment

Instruction	Description	State Accessed
FINIT	Floating-Point Initialize	Entire Environment
FNINIT	Floating-Point No-Wait Initialize	Entire Environment
FNSAVE	Floating-Point No-Wait Save State	Entire Environment
FRSTOR	Floating-Point Restore State	Entire Environment
FSAVE	Floating-Point Save State	Entire Environment
FLDCW	Floating-Point Load x87 Control Word	x87 Control Word
FNSTCW	Floating-Point No-Wait Store Control Word	x87 Control Word
FSTCW	Floating-Point Store Control Word	x87 Control Word
FNSTSW	Floating-Point No-Wait Store Status Word	x87 Status Word
FSTSW	Floating-Point Store Status Word	x87 Status Word

Table 6-4. Instructions that Access the x87 Environment (continued)

Instruction	Description	State Accessed
FLDENV	Floating-Point Load x87 Environment	Environment, Not Including x87 Data Registers
FNSTENV	Floating-Point No-Wait Store Environment	Environment, Not Including x87 Data Registers
FSTENV	Floating-Point Store Environment	Environment, Not Including x87 Data Registers

For details on how the x87 environment is stored in memory, see “Media and x87 Processor State” in Volume 2.

6.2.7 Floating-Point Emulation (CR0.EM)

The operating system can set the floating-point software-emulation (EM) bit in control register 0 (CR0) to 1 to allow software emulation of x87 instructions. If the operating system has set CR0.EM = 1, the processor does not execute x87 instructions. Instead, a device-not-available exception (#NM) occurs whenever an attempt is made to execute such an instruction, except that setting CR0.EM to 1 does not cause an #NM exception when the WAIT or FWAIT instruction is executed. For details, see “System-Control Registers” in Volume 2.

6.3 Operands

6.3.1 Operand Addressing

Operands for x87 instructions are referenced by the opcodes. Operands can be located either in x87 registers or memory. Immediate operands are not used in x87 floating-point instructions, and I/O ports cannot be directly addressed by x87 floating-point instructions.

6.3.1.1 Memory Operands

Most x87 floating-point instructions can take source operands from memory, and a few of the instructions can write results to memory. The following sections describe the methods and conditions for addressing memory operands:

- “Memory Addressing” on page 14 describes the general methods and conditions for addressing memory operands.
- “Instruction Prefixes” on page 326 describes the use of address-size instruction overrides by 64-bit media instructions.

6.3.1.2 Register Operands

Most x87 floating-point instructions can read source operands from and write results to x87 registers. Most instructions access the ST(0)–ST(7) register stack. For a few instructions, the register types also include the x87 control word register, the x87 status word register, and (for FSTSW and FNSTSW) the AX general-purpose register.

6.3.2 Data Types

Figure 6-7 shows register images of the x87 data types. These include three scalar floating-point formats (80-bit double-extended-precision, 64-bit double-precision, and 32-bit single-precision), three scalar signed-integer formats (quadword, doubleword, and word), and an 80-bit packed binary-coded decimal (BCD) format. Although Figure 6-7 shows register images of the data types, the three signed-integer data types can exist only in memory. All data types are converted into an 80-bit format when they are loaded into an x87 register.

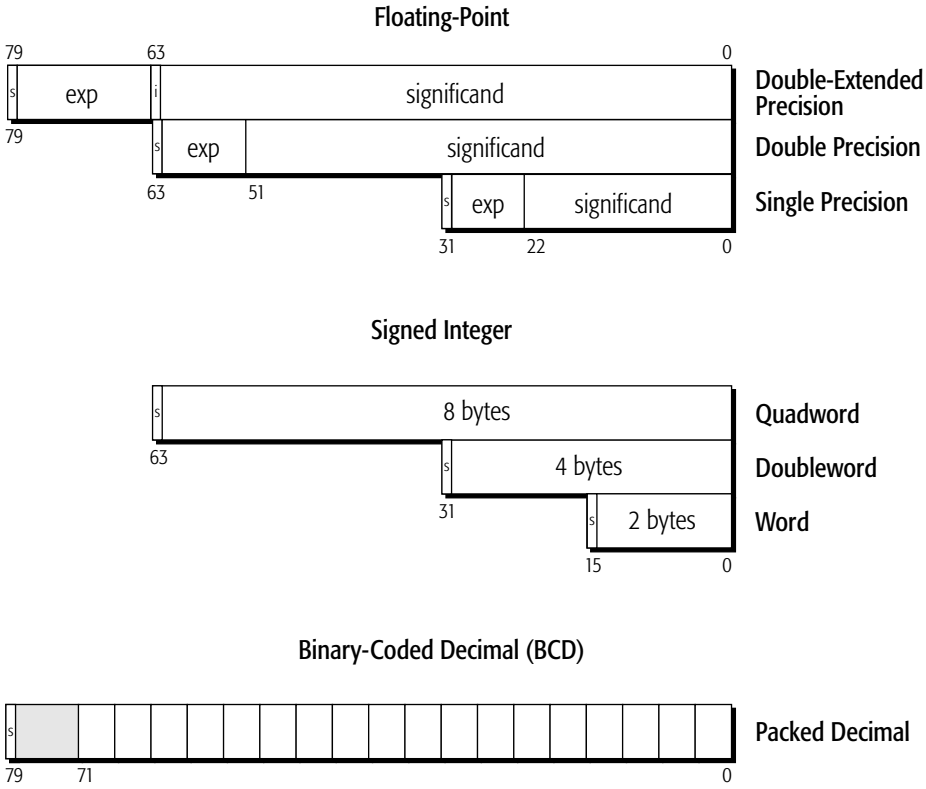

Figure 6-7. x87 Data Types

6.3.2.1 Floating-Point Data Types

The floating-point data types, shown in Figure 6-8 on page 300, include 32-bit single precision, 64-bit double precision, and 80-bit double-extended precision. The default precision is double-extended precision, and all operands loaded into registers are converted into double-extended precision format.

All three floating-point formats are compatible with the *IEEE Standard for Binary Floating-Point Arithmetic* (ANSI/IEEE Std 754 and 854).

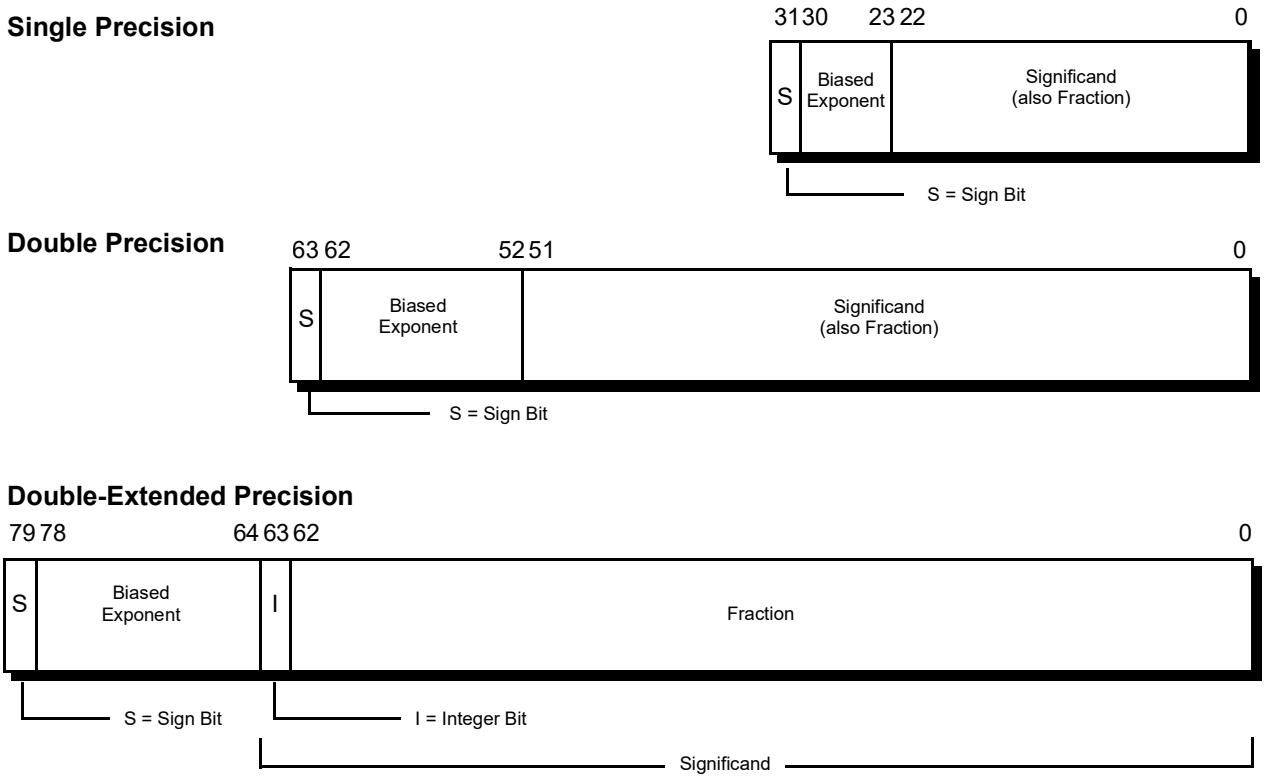

Figure 6-8. x87 Floating-Point Data Types

All of the floating-point data types consist of a sign (0 = positive, 1 = negative), a biased exponent (base-2), and a significand, which represents the integer and fractional parts of the number. The integer bit (also called the *J bit)* is either implied (called a *hidden integer bit*) or explicit, depending on the data type. The value of an implied integer bit can be inferred from number encodings, as described in "Number Encodings" on page 305. The bias of the exponent is a constant which makes the exponent always positive and allows reciprocation, without overflow, of the smallest normalized number representable by that data type.

Specifically, the data types are formatted as follows:

- *Single-Precision Format*—This format includes a 1-bit sign, an 8-bit biased exponent whose value is 127, and a 23-bit significand. The integer bit is implied, making a total of 24 bits in the significand.
- *Double-Precision Format*—This format includes a 1-bit sign, an 11-bit biased exponent whose value is 1023, and a 52-bit significand. The integer bit is implied, making a total of 53 bits in the significand.
- *Double-Extended-Precision Format*—This format includes a 1-bit sign, a 15-bit biased exponent whose value is 16,383, and a 64-bit significand, which includes one explicit integer bit.

Table 6-5 shows the range of finite values representable by the three x87 floating-point data types.

Table 6-5. Range of Finite Floating-Point Values

Data Type	Range of Finite Values[1]		Precision
	Base 2	Base 10	
Single Precision	2^{-126} to $2^{127} * (2 - 2^{-23})$	$1.17 * 10^{-38}$ to $+3.40 * 10^{38}$	24 bits
Double Precision	2^{-1022} to $2^{1023} * (2 - 2^{-52})$	$2.23 * 10^{-308}$ to $+1.79 * 10^{308}$	53 bits
Double-Extended Precision	2^{-16382} to $2^{16383} * (2 - 2^{-63})$	$3.37 * 10^{-4932}$ to $+1.18 * 10^{4932}$	64 bits

Note:
1. See “Number Representation” on page 302.

For example, in the single-precision format, the largest normal number representable has an exponent of FEh and a significand of 7FFFFFh, with a numerical value of $2^{127} * (2 - 2^{-23})$. Results that overflow above the maximum representable value return either the maximum representable normalized number (see “Normalized Numbers” on page 303) or infinity, with the sign of the true result, depending on the rounding mode specified in the rounding control (RC) field of the x87 control word. Results that underflow below the minimum representable value return either the minimum representable normalized number or a denormalized number (see “Denormalized (Tiny) Numbers” on page 303), with the sign of the true result, or a result determined by the x87 exception handler, depending on the rounding mode, precision mode, and underflow-exception mask (UM) in the x87 control word (see “Unmasked Responses” on page 337).

6.3.2.2 Integer Data Type

The integer data types, shown in Figure 6-7 on page 299, include two’s-complement 16-bit word, 32-bit doubleword, and 64-bit quadword. These data types are used in x87 instructions that convert signed integer operands into floating-point values. The integers can be loaded from memory into x87 registers and stored from x87 registers into memory. The data types cannot be moved between x87 registers and other registers.

For details on the format and number-representation of the integer data types, see “Fundamental Data Types” on page 36.

6.3.2.3 Packed-Decimal Data Type

The 80-bit packed-decimal data type, shown in Figure 6-9 on page 302, represents an 18-digit decimal integer using the binary-coded decimal (BCD) format. Each of the 18 digits is a 4-bit representation of an integer. The 18 digits use a total of 72 bits. The next-higher seven bits in the 80-bit format are reserved (ignored on loads, zeros on stores). The high bit (bit 79) is a sign bit.

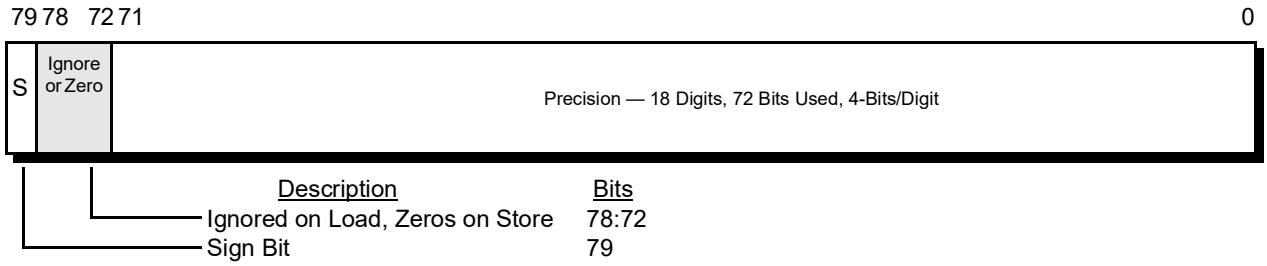

Figure 6-9. x87 Packed Decimal Data Type

Two x87 instructions operate on the packed-decimal data type. The FBLD (floating-point load binary-coded decimal) and FBSTP (floating-point store binary-coded decimal integer and pop) instructions push and pop, respectively, a packed-decimal memory operand between the floating-point stack and memory. FBLD converts the value being pushed to a double-extended-precision floating-point value. FBSTP rounds the value being popped to an integer.

For details on the format and use of 4-bit BCD integers, see “Binary-Coded-Decimal (BCD) Digits” on page 40.

6.3.3 Number Representation

Of the following types of floating-point values, six are supported by the architecture and three are not supported:

- *Supported Values*
  - Normal
  - Denormal (Tiny)
  - Pseudo-Denormal
  - Zero
  - Infinity
  - Not a Number (NaN)
- *Unsupported Values*
  - Unnormal
  - Pseudo-Infinity
  - Pseudo-NaN

The supported values can be used as operands in x87 floating-point instructions. The unsupported values cause an invalid-operation exception (IE) when used as operands.

In common engineering and scientific usage, floating-point numbers—also called *real numbers*—are represented in base (radix) 10. A non-zero number consists of a *sign*, a normalized *significand*, and a signed *exponent*, as in:

```
+2.71828 e0
```

Both large and small numbers are representable in this notation, subject to the limits of data-type precision. For example, a million in base-10 notation appears as +1.00000 e6 and -0.0000383 is represented as -3.83000 e-5. A non-zero number can always be written in *normalized form*—that is, with a leading non-zero digit immediately before the decimal point. Thus, a normalized significand in base-10 notation is a number in the range [1,10). The signed exponent specifies the number of positions that the decimal point is shifted.

Unlike the common engineering and scientific usage described above, x87 floating-point numbers are represented in base (radix) 2. Like its base-10 counterpart, a normalized base-2 significand is written with its leading non-zero digit immediately to the left of the radix point. In base-2 arithmetic, a non-zero digit is always a one, so the range of a binary significand is [1,2):

```
+1.fraction ±exponent
```

The leading non-zero digit is called the *integer bit*, and in the x87 double-extended-precision floating-point format this integer bit is explicit, as shown in Figure 6-8. In the x87 single-precision and the double-precision floating-point formats, the integer bit is simply omitted (and called the *hidden integer bit)*, because its implied value is always 1 in a normalized significand (0 in a denormalized significand), and the omission allows an extra bit of precision.

The following sections describe the supported number representations.

6.3.3.1 Normalized Numbers

Normalized floating-point numbers are the most frequent operands for x87 instructions. These are finite, non-zero, positive or negative numbers in which the integer bit is 1, the biased exponent is non-zero and non-maximum, and the fraction is any representable value. Thus, the significand is within the range of [1, 2). Whenever possible, the processor represents a floating-point result as a normalized number.

6.3.3.2 Denormalized (Tiny) Numbers

Denormalized numbers (also called *tiny* numbers) are smaller than the smallest representable normalized numbers. They arise through an underflow condition, when the exponent of a result lies below the representable minimum exponent. These are finite, non-zero, positive or negative numbers in which the integer bit is 0, the biased exponent is 0, and the fraction is non-zero.

The processor generates a denormalized-operand exception (DE) when an instruction uses a denormalized *source operand*. The processor may generate an underflow exception (UE) when an instruction produces a rounded, non-zero *result* that is too small to be represented as a normalized

floating-point number in the destination format, and thus is represented as a denormalized number. If a result, after rounding, is too small to be represented as the minimum denormalized number, it is represented as zero. (See “Exceptions” on page 327 for specific details.)

Denormalization may correct the exponent by placing leading zeros in the significand. This may cause a loss of precision, because the number of significant bits in the fraction is reduced by the leading zeros. In the single-precision floating-point format, for example, normalized numbers have biased exponents ranging from 1 to 254 (the unbiased exponent range is from –126 to +127). A true result with an exponent of, say, –130, undergoes denormalization by right-shifting the significand by the difference between the normalized exponent and the minimum exponent, as shown in Table 6-6.

Table 6-6. Example of Denormalization

Significand (base 2)	Exponent	Result Type
1.0011010000000000	–130	True result
0.0001001101000000	–126	Denormalized result

6.3.3.3 Pseudo-Denormalized Numbers

Pseudo-denormalized numbers are positive or negative numbers in which the integer bit is 1, the biased exponent is 0, and the fraction is any value. The processor accepts pseudo-denormal source operands but it does not produce pseudo-denormal results. When a pseudo-denormal number is used as a source operand, the processor treats the arithmetic value of its biased exponent as 1 rather than 0, and the processor generates a denormalized-operand exception (DE).

6.3.3.4 Zero

The floating-point zero is a finite, positive or negative number in which the integer bit is 0, the biased exponent is 0, and the fraction is 0. The sign of a zero result depends on the operation being performed and the selected rounding mode. It may indicate the direction from which an underflow occurred, or it may reflect the result of a division by +∞ or –∞.

6.3.3.5 Infinity

Infinity is a positive or negative number, +∞ and –∞, in which the integer bit is 1, the biased exponent is maximum, and the fraction is 0. The infinities are the maximum numbers that can be represented in floating-point format. Negative infinity is less than any finite number and positive infinity is greater than any finite number (i.e., the affine sense).

An infinite result is produced when a non-zero, non-infinite number is divided by 0 or multiplied by infinity, or when infinity is added to infinity or to 0. Arithmetic on infinities is exact. For example, adding any floating-point number to +∞ gives a result of +∞. Arithmetic comparisons work correctly on infinities. Exceptions occur only when the use of an infinity as a source operand constitutes an invalid operation.

6.3.3.6 Not a Number (NaN)

NaNs are non-numbers, lying outside the range of representable floating-point values. The integer bit is 1, the biased exponent is maximum, and the fraction is non-zero. NaNs are of two types:

- *Signaling NaN (SNaN)*
- *Quiet NaN (QNaN)*

A QNaN is a NaN with the most-significant fraction bit set to 1, and an SNaN is a NaN with the most-significant fraction bit cleared to 0. When the processor encounters an SNaN as a source operand for an instruction, an invalid-operation exception (IE) occurs and a QNaN is produced as the result, if the exception is masked. In general, when the processor encounters a QNaN as a source operand for an instruction—in an instruction other than FxCOM*x*, FISTx, or FSTx—the processor does not generate an exception but generates a QNaN as the result.

The processor never generates an SNaN as a result of a floating-point operation. When an invalid-operation exception (IE) occurs due to an SNaN operand, the invalid-operation exception mask (IM) bit determines the processor's response, as described in "x87 Floating-Point Exception Masking" on page 333.

When a floating-point operation or exception produces a QNaN result, its value is derived from the source operands according to the rules shown in Table 6-7.

6.3.4 Number Encodings

6.3.4.1 Supported Encodings

Table 6-8 on page 307 shows the floating-point encodings of supported numbers and non-numbers. The number categories are ordered from large to small. In this affine ordering, positive infinity is larger than any positive normalized number, which in turn is larger than any positive denormalized number, which is larger than positive zero, and so forth. Thus, the ordinary rules of comparison apply between categories as well as within categories, so that comparison of any two numbers is well-defined.

The actual exponent field length is 8, 11, or 15 bits, and the fraction field length is 23, 52, or 63 bits, depending on operand precision.

Table 6-7. NaN Results from NaN Source Operands

Source Operand (in either order)[1]		NaN Result[2]
QNaN	Any non-NaN floating-point value (or single-operand instruction)	Value of QNaN
SNaN	Any non-NaN floating-point value (or single-operand instruction)	Value of SNaN, converted to a QNaN[3]
QNaN	QNaN	Value of QNaN with the larger significand[4]
QNaN	SNaN	Value of QNaN
SNaN	QNaN	Value of QNaN
SNaN	SNaN	Value of SNaN with the larger significand[4]

Note:

1. *This table does not include NaN source operands used in FxCOMx, FISTx, or FSTx instructions.*
2. *A NaN result is produced when the floating-point invalid-operation exception is masked.*
3. *The conversion is done by changing the most-significant fraction bit to 1.*
4. *If the significands of the source operands are equal but their signs are different, the NaN result is undefined.*

The single-precision and double-precision formats do not include the integer bit in the significand (the value of the integer bit can be inferred from number encodings). The double-extended-precision format explicitly includes the integer in bit 63 and places the most-significant fraction bit in bit 62. Exponents of all three types are encoded in biased format, with respective biasing constants of 127, 1023, and 16,383.

Table 6-8. Supported Floating-Point Encodings

Classification		Sign	Biased Exponent[1]	Significand[2]
Positive Non-Numbers	SNaN	0	111 ... 111	1.011 ... 111 to 1.000 ... 001
	QNaN	0	111 ... 111	1.111 ... 111 to 1.100 ... 000
Positive Floating-Point Numbers	Positive Infinity (+∞)	0	111 ... 111	1.000 ... 000
	Positive Normal	0	111 ... 110 to 000 ... 001	1.111 ... 111 to 1.000 ... 000
	Positive Pseudo-Denormal[3]	0	000 ... 000	1.111 ... 111 to 1.000 ... 001
	Positive Denormal	0	000 ... 000	0.111 ... 111 to 0.000 ... 001
	Positive Zero	0	000 ... 000	0.000 ... 000
Negative Floating-Point Numbers	Negative Zero	1	000 ... 000	0.000 ... 000
	Negative Denormal	1	000 ... 000	0.000 ... 001 to 0.111 ... 111
	Negative Pseudo-Denormal[3]	1	000 ... 000	1.000 ... 001 to 1.111 ... 111
	Negative Normal	1	000 ... 001 to 111 ... 110	1.000 ... 000 to 1.111 ... 111
	Negative Infinity (-∞)	1	111 ... 111	1.000 ... 000
Negative Non-Numbers	SNaN	1	111 ... 111	1.000 ... 001 to 1.011 ... 111
	QNaN[4]	1	111 ... 111	1.100 ... 000 to 1.111 ... 111

Note:

1. *The actual exponent field length is 8, 11, or 15 bits, depending on operand precision.*
2. *The "1." and "0." prefixes represent the implicit or explicit integer bit. The actual fraction field length is 23, 52, or 63 bits, depending on operand precision.*
3. *Pseudo-denormals can only occur in double-extended-precision format, because they require an explicit integer bit.*
4. *The floating-point indefinite value is a QNaN with a negative sign and a significand whose value is 1.100 ... 000.*

6.3.4.2 Unsupported Encodings

Table 6-9 on page 308 shows the encodings of unsupported values. These values can exist only in the double-extended-precision format, because they require an explicit integer bit. The processor does not generate them as results, and they cause an invalid-operation exception (IE) when used as source operands.

6.3.4.3 Indefinite Values

Floating-point, integer, and packed-decimal data types each have a unique encoding that represents an *indefinite value*. The processor returns an indefinite value when a masked invalid-operation exception (IE) occurs. The indefinite values for various data types are provided in Table 4-7 on page 129.

For example, if a floating-point arithmetic operation is attempted using a source operand which is in an unsupported format, and IE exceptions are masked, the floating-point indefinite value is returned as the result. Or, if an integer store instruction overflows its destination data type, and IE exceptions are masked, the integer indefinite value is returned as the result.

Table 6-9. Unsupported Floating-Point Encodings

Classification	Sign	Biased Exponent[1]	Significand[2]
Positive Pseudo-NaN	0	111 ... 111	0.111 ... 111 to 0.000 ... 001
Positive Pseudo-Infinity	0	111 ... 111	0.000 ... 000
Positive Unnormal	0	111 ... 110 to 000 ... 001	0.111 ... 111 to 0.000 ... 000
Negative Unnormal	1	000 ... 001 to 111 ... 110	0.000 ... 000 to 0.111 ... 111
Negative Pseudo-Infinity	1	111 ... 111	0.000 ... 000
Negative Pseudo-NaN	1	111 ... 111	0.000 ... 001 to 0.111 ... 111

Note:
1. *The actual exponent field length is 15 bits.*
2. *The "0." prefix represent the explicit integer bit. The actual fraction field length is 63 bits.*

Table 6-10 shows the encodings of the indefinite values for each data type. For floating-point numbers, the indefinite value is a special form of QNaN. For integers, the indefinite value is the largest representable negative two's-complement number, 80...00h. (This value is interpreted as the largest representable negative number, except when a masked IE exception occurs, in which case it is interpreted as an indefinite value.) For packed-decimal numbers, the indefinite value has no other meaning than indefinite.

Table 6-10. Indefinite-Value Encodings

Data Type	Indefinite Encoding
Single-Precision Floating-Point	FFC0_0000h
Double-Precision Floating-Point	FFF8_0000_0000_0000h
Extended-Precision Floating-Point	FFFF_C000_0000_0000_0000h
16-Bit Integer	8000h
32-Bit Integer	8000_0000h
64-Bit Integer	8000_0000_0000_0000h
80-Bit BCD	FFFF_C000_0000_0000_0000h

6.3.5 Precision

The Precision control (PC) field comprises bits [9:8] of the x87 control word ("x87 Control Word Register (FCW)" on page 292). This field specifies the precision of floating-point calculations for the FADDx, FSUB*x*, FMUL*x*, FDIV*x*, and FSQRT instructions, as shown in Table 6-11.

Table 6-11. Precision Control Field (PC) Values and Bit Precision

PC Field	Data Type	Precision (bits)
00	Single precision	24[1]
01	*reserved*	
10	Double precision	53[1]
11	Double-extended precision	64

Note:
1. The single-precision and double-precision bit counts include the implied integer bit.

The default precision is double-extended-precision. Selecting double-precision or single-precision reduces the size of the significand to 53 bits or 24 bits, but keeps the exponent in double extended range. The reduced precision is provided to support the IEEE 754 standard. When using reduced precision, rounding clears the unused bits on the right of the significand to 0s.

6.3.6 Rounding

The rounding control (RC) field comprises bits [11:10] of the x87 control word ("x87 Control Word Register (FCW)" on page 292). This field specifies how the results of x87 floating-point computations are rounded. Rounding modes apply to most arithmetic operations but not to comparison or remainder. They have no effect on operations that produce NaN results.

The IEEE 754 standard defines the four rounding modes as shown in Table 6-12.

Table 6-12. Types of Rounding

RC Value	Mode	Type of Rounding
00 (default)	Round to nearest	The rounded result is the representable value closest to the infinitely precise result. If equally close, the even value (with least-significant bit 0) is taken.
01	Round down	The rounded result is closest to, but no greater than, the infinitely precise result.
10	Round up	The rounded result is closest to, but no less than, the infinitely precise result.
11	Round toward zero	The rounded result is closest to, but no greater in absolute value than, the infinitely precise result.

Round to nearest is the default (reset) rounding mode. It provides a statistically unbiased estimate of the true result, and is suitable for most applications. The other rounding modes are directed roundings: round up (toward +∞), round down (toward –∞), and round toward zero. Round up and round down are used in interval arithmetic, in which upper and lower bounds bracket the true result of a computation. Round toward zero takes the smaller in magnitude, that is, always truncates.

The processor produces a floating-point result defined by the IEEE standard to be infinitely precise. This result may not be representable exactly in the destination format, because only a subset of the continuum of real numbers finds exact representation in any particular floating-point format. Rounding modifies such a result to conform to the destination format, thereby making the result inexact and also generating a precision exception (PE), as described in “x87 Floating-Point Exception Causes” on page 329.

Suppose, for example, the following 24-bit result is to be represented in single-precision format, where “E_2 1010” represents the biased exponent:

$$1.0011\ 0101\ 0000\ 0001\ 0010\ 0111\ E_2\ 1010$$

This result has no exact representation, because the least-significant 1 does not fit into the single-precision format, which allows for only 23 bits of fraction. The rounding control field determines the direction of rounding. Rounding introduces an error in a result that is less than one *unit in the last place (ulp)*, that is, the least-significant bit position of the floating-point representation.

6.4 Instruction Summary

This section summarizes the functions of the x87 floating-point instructions. The instructions are organized here by functional group—such as data-transfer, arithmetic, and so on. More detail on individual instructions is given in the alphabetically organized “x87 Floating-Point Instruction Reference” in Volume 5.

Software running at any privilege level can use any of these instructions, if the CPUID instruction reports support for the instructions (see “Feature Detection” on page 327). Most x87 instructions take

floating-point data types for both their source and destination operands, although some x87 data-conversion instructions take integer formats for their source or destination operands.

6.4.1 Syntax

Each instruction has a *mnemonic syntax* used by assemblers to specify the operation and the operands to be used for source and destination (result) data. Many of x87 instructions have the following syntax:

```
MNEMONIC st(j), st(i)
```

Figure 6-10 on page 311 shows an example of the mnemonic syntax for a floating-point add (FADD) instruction.

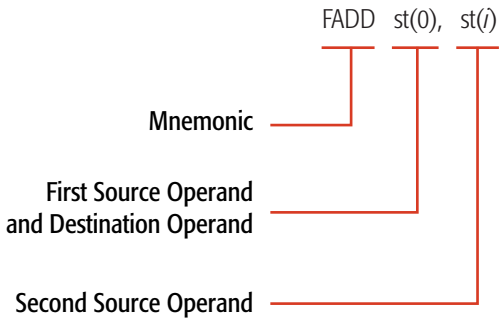

Figure 6-10. Mnemonic Syntax for Typical Instruction

This example shows the FADD mnemonic followed by two operands, both of which are 80-bit stack-register operands. Most instructions take source operands from an x87 stack register and/or memory and write their results to a stack register or memory. Only two of the instructions (FSTSW and FNSTSW) can access a general-purpose registers (GPR), and none access the 128-bit media (XMM) registers. Although the MMX registers map to the x87 registers, the contents of the MMX registers cannot be accessed meaningfully using x87 instructions.

Instructions can have one or more prefixes that modify default operand properties. These prefixes are summarized in “Instruction Prefixes” on page 76.

6.4.1.1 Mnemonics

The following characters are used as prefixes in the mnemonics of integer instructions:

- **F**—x87 Floating-point

In addition to the above prefix characters, the following characters are used elsewhere in the mnemonics of x87 instructions:

- **B**—Below, or BCD
- **BE**—Below or Equal

- **CMOV**—Conditional Move
- **c**—Variable condition
- **E**—Equal
- **I**—Integer
- **LD**—Load
- **N**—No Wait
- **NB**—Not Below
- **NBE**—Not Below or Equal
- **NE**—Not Equal
- **NU**—Not Unordered
- **P**—Pop
- **PP**—Pop Twice
- **R**—Reverse
- **ST**—Store
- **U**—Unordered
- ***x***—One or more variable characters in the mnemonic

For example, the mnemonic for the store instruction that stores the top-of-stack and pops the stack is FSTP. In this mnemonic, the F means a floating-point instruction, the ST means a store, and the P means pop the stack.

6.4.2 Data Transfer and Conversion

The data transfer and conversion instructions copy data—in some cases with data conversion—between x87 stack registers and memory or between stack positions.

Load or Store Floating-Point

- FLD—Floating-Point Load
- FST—Floating-Point Store Stack Top
- FSTP—Floating-Point Store Stack Top and Pop

The FLD instruction pushes the source operand onto the top-of-stack, ST(0). The source operand may be a single-precision, double-precision, or double-extended-precision floating-point value in memory or the contents of a specified stack position, ST(i).

The FST instruction copies the value at the top-of-stack, ST(0), to a specified stack position, ST(i), or to a 32-bit or 64-bit memory location. If the destination is a memory location, the value copied is converted to the precision allowed by the destination and rounded, as specified by the rounding control (RC) field of the x87 control word. If the top-of-stack value is a NaN or an infinity, FST truncates the stack-top exponent and significand to fit the destination size. (For details, see “FST FSTP” in *AMD64*

Architecture Programmer's Manual Volume 5: 64-bit Media and x87 Floating-Point Instructions, order# 26569.

The FSTP instruction is similar to FST, except that FSTP can also store to an 80-bit memory location and it pops the stack after the store. FSTP can be used to clean up the x87 stack at the end of an x87 procedure by removing one register of preloaded data from the stack.

Convert and Load or Store Integer

- FILD—Floating-Point Load Integer
- FIST—Floating-Point Integer Store
- FISTP—Floating-Point Integer Store and Pop
- FISTTP—Floating-Point Integer Truncate and Store

The FILD instruction converts the 16-bit, 32-bit, or 64-bit source signed integer in memory into a double-extended-precision floating-point value and pushes the result onto the top-of-stack, ST(0).

The FIST instruction converts and rounds the source value in the top-of-stack, ST(0), to a signed integer and copies it to the specified 16-bit or 32-bit memory location. The type of rounding is determined by the rounding control (RC) field of the x87 control word.

The FISTP instruction is similar to FIST, except that FISTP can also store the result to a 64-bit memory location and it pops ST(0) after the store.

The FISTTP instruction converts a floating-point value in ST(0) to an integer by truncating the fractional part of the number and storing the integer result to the memory address specified by the destination operand. FISTTP then pops the floating point register stack. The FISTTP instruction ignores the rounding mode specified by the x87 control word.

Convert and Load or Store BCD

- FBLD—Floating-Point Load Binary-Coded Decimal
- FBSTP—Floating-Point Store Binary-Coded Decimal Integer and Pop

The FBLD and FBSTP instructions, respectively, push and pop an 80-bit packed BCD memory value on and off the top-of-stack, ST(0). FBLD first converts the value being pushed to a double-extended-precision floating-point value. FBSTP rounds the value being popped to an integer, using the rounding mode specified by the RC field, and converts the value to an 80-bit packed BCD value. Thus, no FRNDIT (round-to-integer) instruction is needed prior to FBSTP.

Conditional Move

- FCMOVB—Floating-Point Conditional Move If Below
- FCMOVBE—Floating-Point Conditional Move If Below or Equal
- FCMOVE—Floating-Point Conditional Move If Equal
- FCMOVNB—Floating-Point Conditional Move If Not Below
- FCMOVNBE—Floating-Point Conditional Move If Not Below or Equal

- FCMOVNE—Floating-Point Conditional Move If Not Equal
- FCMOVNU—Floating-Point Conditional Move If Not Unordered
- FCMOVU—Floating-Point Conditional Move If Unordered

The FCMOV*cc* instructions copy the contents of a specified stack position, ST(i), to the top-of-stack, ST(0), if the specified rFLAGS condition is met. Table 6-13 on page 314 specifies the flag combinations for each conditional move.

Table 6-13. rFLAGS Conditions for FCMOV*cc*

Condition	Mnemonic	rFLAGS Register State
Below	B	Carry flag is set (CF = 1)
Below or Equal	BE	Either carry flag or zero flag is set (CF = 1 or ZF = 1)
Equal	E	Zero flag is set (ZF = 1)
Not Below	NB	Carry flag is not set (CF = 0)
Not Below or Equal	NBE	Neither carry flag nor zero flag is set (CF = 0, ZF = 0)
Not Equal	NE	Zero flag is not set (ZF = 0)
Not Unordered	NU	Parity flag is not set (PF = 0)
Unordered	U	Parity flag is set (PF = 1)

Exchange

- FXCH—Floating-Point Exchange

The FXCH instruction exchanges the contents of a specified stack position, ST(i), with the top-of-stack, ST(0). The top-of-stack pointer is left unchanged. In the form of the instruction that specifies no operand, the contents of ST(1) and ST(0) are exchanged.

Extract

- FXTRACT—Floating-Point Extract Exponent and Significand

The FXTRACT instruction copies the unbiased exponent of the original value in the top-of-stack, ST(0), and writes it as a floating-point value to ST(1), then copies the significand and sign of the original value in the top-of-stack and writes it as a floating-point value with an exponent of zero to the top-of-stack, ST(0).

6.4.3 Load Constants

Load 0, 1, or Pi

- FLDZ—Floating-Point Load +0.0
- FLD1—Floating-Point Load +1.0
- FLDPI—Floating-Point Load Pi

The FLDZ, FLD1, and FLDPI instructions, respectively, push the floating-point constant value, +0.0, +1.0, and Pi (3.141592653...), onto the top-of-stack, ST(0).

Load Logarithm

- FLDL2E—Floating-Point Load Log2 e
- FLDL2T—Floating-Point Load Log2 10
- FLDLG2—Floating-Point Load Log10 2
- FLDLN2—Floating-Point Load Ln 2

The FLDL2E, FLDL2T, FLDLG2, and FLDLN2 instructions, respectively, push the floating-point constant value, $\log_2 e$, $\log_2 10$, $\log_{10} 2$, and $\log_e 2$, onto the top-of-stack, ST(0).

6.4.4 Arithmetic

The arithmetic instructions support addition, subtraction, multiplication, division, change-sign, round, round to integer, partial remainder, and square root. In most arithmetic operations, one of the source operands is the top-of-stack, ST(0). The other source operand can be another stack entry, ST(*i*), or a floating-point or integer operand in memory.

The non-commutative operations of subtraction and division have two forms, the direct FSUB and FDIV, and the reverse FSUBR and FDIVR. FSUB, for example, subtracts the right operand from the left operand, and writes the result to the left operand. FSUBR subtracts the left operand from the right operand, and writes the result to the left operand. The FADD and FMUL operations have no reverse counterparts.

Addition

- FADD—Floating-Point Add
- FADDP—Floating-Point Add and Pop
- FIADD—Floating-Point Add Integer to Stack Top

The FADD instruction syntax has forms that include one or two explicit source operands. In the one-operand form, the instruction reads a 32-bit or 64-bit floating-point value from memory, converts it to the double-extended-precision format, adds it to ST(0), and writes the result to ST(0). In the two-operand form, the instruction adds both source operands from stack registers and writes the result to the first operand.

The FADDP instruction syntax has forms that include zero or two explicit source operands. In the zero-operand form, the instruction adds ST(0) to ST(1), writes the result to ST(1), and pops the stack. In the two-operand form, the instruction adds both source operands from stack registers, writes the result to the first operand, and pops the stack.

The FIADD instruction reads a 16-bit or 32-bit integer value from memory, converts it to the double-extended-precision format, adds it to ST(0), and writes the result to ST(0).

Subtraction

- FSUB—Floating-Point Subtract
- FSUBP—Floating-Point Subtract and Pop
- FISUB—Floating-Point Integer Subtract
- FSUBR—Floating-Point Subtract Reverse
- FSUBRP—Floating-Point Subtract Reverse and Pop
- FISUBR—Floating-Point Integer Subtract Reverse

The FSUB instruction syntax has forms that include one or two explicit source operands. In the one-operand form, the instruction reads a 32-bit or 64-bit floating-point value from memory, converts it to the double-extended-precision format, subtracts it from ST(0), and writes the result to ST(0). In the two-operand form, both source operands are located in stack registers. The instruction subtracts the second operand from the first operand and writes the result to the first operand.

The FSUBP instruction syntax has forms that include zero or two explicit source operands. In the zero-operand form, the instruction subtracts ST(0) from ST(1), writes the result to ST(1), and pops the stack. In the two-operand form, both source operands are located in stack registers. The instruction subtracts the second operand from the first operand, writes the result to the first operand, and pops the stack.

The FISUB instruction reads a 16-bit or 32-bit integer value from memory, converts it to the double-extended-precision format, subtracts it from ST(0), and writes the result to ST(0).

The FSUBR and FSUBRP instructions perform the same operations as FSUB and FSUBP, respectively, except that the source operands are reversed. Instead of subtracting the second operand from the first operand, FSUBR and FSUBRP subtract the first operand from the second operand.

Multiplication

- FMUL—Floating-Point Multiply
- FMULP—Floating-Point Multiply and Pop
- FIMUL—Floating-Point Integer Multiply

The FMUL instruction has three forms. One form of the instruction multiplies two double-extended precision floating-point values located in ST(0) and another floating-point stack register and leaves the product in ST(0). The second form multiplies two double-extended precision floating-point values located in ST(0) and another floating-point stack destination register and leaves the product in the destination register. The third form converts a floating-point value in a specified memory location to double-extended-precision format, multiplies the result by the value in ST(0) and writes the product to ST(0).

The FMULP instruction syntax is similar to the form of FMUL described in the previous paragraph. This instruction pops the floating-point register stack after performing the multiplication operation. This instruction cannot take a memory operand.

The FIMUL instruction reads a 16-bit or 32-bit integer value from memory, converts it to the double-extended-precision format, multiplies ST(0) by the memory operand, and writes the result to ST(0).

Division

- FDIV—Floating-Point Divide
- FDIVP—Floating-Point Divide and Pop
- FIDIV—Floating-Point Integer Divide
- FDIVR—Floating-Point Divide Reverse
- FDIVRP—Floating-Point Divide Reverse and Pop
- FIDIVR—Floating-Point Integer Divide Reverse

The FDIV instruction syntax has forms that include one or two source explicit operands that may be single-precision or double-precision floating-point values or 16-bit or 32-bit integer values. In the one-operand form, the instruction reads a value from memory, divides ST(0) by the memory operand, and writes the result to ST(0). In the two-operand form, both source operands are located in stack registers. The instruction divides the first operand by the second operand and writes the result to the first operand.

The FDIVP instruction syntax has forms that include zero or two explicit source operands. In the zero-operand form, the instruction divides ST(1) by ST(0), writes the result to ST(1), and pops the stack. In the two-operand form, both source operands are located in stack registers. The instruction divides the first operand by the second operand, writes the result to the first operand, and pops the stack.

The FIDIV instruction reads a 16-bit or 32-bit integer value from memory, converts it to the double-extended-precision format, divides ST(0) by the memory operand, and writes the result to ST(0).

The FDIVR and FDIVRP instructions perform the same operations as FDIV and FDIVP, respectively, except that the source operands are reversed. Instead of dividing the first operand by the second operand, FDIVR and FDIVRP divide the second operand by the first operand.

Change Sign

- FABS—Floating-Point Absolute Value
- FCHS—Floating-Point Change Sign

The FABS instruction changes the top-of-stack value, ST(0), to its absolute value by clearing its sign bit to 0. The top-of-stack value is always positive following execution of the FABS instruction. The FCHS instruction complements the sign bit of ST(0). For example, if ST(0) was +0.0 before the execution of FCHS, it is changed to -0.0.

Round

- FRNDINT—Floating-Point Round to Integer

The FRNDINT instruction rounds the top-of-stack value, ST(0), to an integer value, although the value remains in double-extended-precision floating-point format. Rounding takes place according to the setting of the rounding control (RC) field in the x87 control word.

Partial Remainder

- FPREM—Floating-Point Partial Remainder
- FPREM1—Floating-Point Partial Remainder

The FPREM instruction returns the remainder obtained by dividing ST(0) by ST(1) and stores it in ST(0). If the exponent difference between ST(0) and ST(1) is less than 64, all integer bits of the quotient are calculated, guaranteeing that the remainder returned is less in magnitude than the divisor in ST(1). If the exponent difference is equal to or greater than 64, only a subset of the integer quotient bits, numbering between 32 and 63, are calculated and a partial remainder is returned. FPREM can be repeated on a partial remainder until reduction is complete. It can be used to bring the operands of transcendental functions into their proper range. FPREM is supported for software written for early x87 coprocessors. Unlike the FPREM1 instruction, FPREM does not calculate the partial remainder as specified in IEEE Standard 754.

The FPREM1 instruction works like FPREM, except that the FPREM1 quotient is rounded using round-to-nearest mode, whereas FPREM truncates the quotient.

Square Root

- FSQRT—Floating-Point Square Root

The FSQRT instruction replaces the contents of the top-of-stack, ST(0), with its square root.

6.4.5 Transcendental Functions

The transcendental instructions compute trigonometric functions, inverse trigonometric functions, logarithmic functions, and exponential functions.

Trigonometric Functions

- FSIN—Floating-Point Sine
- FCOS—Floating-Point Cosine
- FSINCOS—Floating-Point Sine and Cosine
- FPTAN—Floating-Point Partial Tangent
- FPATAN—Floating-Point Partial Arctangent

The FSIN instruction replaces the contents of ST(0) (in radians) with its sine.

The FCOS instruction replaces the contents of ST(0) (in radians) with its cosine.

The FSINCOS instruction computes both the sine and cosine of the contents of ST(0) (in radians) and writes the sine to ST(0) and pushes the cosine onto the stack. Frequently, a piece of code that needs to compute the sine of an argument also needs to compute the cosine of that same argument. In such

cases, use the FSINCOS instruction to compute both functions concurrently, which is faster than using separate FSIN and FCOS instructions.

The FPTAN instruction replaces the contents of the ST(0) (in radians), with its tangent, in radians, and pushes the value 1.0 onto the stack.

The FPATAN instruction computes θ = arctan (Y/X), in which X is located in ST(0) and Y in ST(1). The result, θ, is written over Y in ST(1), and the stack is popped.

FSIN, FCOS, FSINCOS, and FPTAN are architecturally restricted in their argument range. Only arguments with a magnitude of less than 2^{63} can be evaluated. If the argument is out of range, the C2 condition-code bit in the x87 status word is set to 1, and the argument is returned as the result. If software detects an out-of-range argument, the FPREM or FPREM1 instruction can be used to reduce the magnitude of the argument before using the FSIN, FCOS, FSINCOS, or FPTAN instruction again.

Logarithmic Functions

- F2XM1—Floating-Point Compute 2^x-1
- FSCALE—Floating-Point Scale
- FYL2X—Floating-Point y * log2x
- FYL2XP1—Floating-Point y * log2(x +1)

The F2XM1 instruction computes $Y = 2^X - 1$. X is located in ST(0) and must fall between –1 and +1. Y replaces X in ST(0). If ST(0) is out of range, the instruction returns an undefined result but no x87 status-word exception bits are affected.

The FSCALE instruction replaces ST(0) with ST(0) times 2^n, where n is the value in ST(1) truncated to an integer. This provides a fast method of multiplying by integral powers of 2.

The FYL2X instruction computes $Z = Y * \log_2 X$. X is located in ST(0) and Y is located in ST(1). X must be greater than 0. The result, Z, replaces Y in ST(1), which becomes the new top-of-stack because X is popped off the stack.

The FYL2XP1 instruction computes $Z = Y * \log_2(X + 1)$. X located in ST(0) and must be in the range $0 < |X| < (1 - 2^{½} / 2)$. Y is taken from ST(1). The result, Z, replaces Y in ST(1), which becomes the new top-of-stack because X is popped off the stack.

6.4.5.1 Accuracy of Transcendental Results

x87 computations are carried out in double-extended-precision format, so that the transcendental functions provide results accurate to within one *unit in the last place (ulp)* for each of the floating-point data types.

6.4.5.2 Argument Reduction Using Pi

The FPREM and FPREM1 instructions can be used to reduce an argument of a trigonometric function by a multiple of Pi. The following example shows a reduction by 2π:

```
sin(n*2π+x) = sin(x) for all integral n
```

In this example, the range is $0 \le x < 2\pi$ in the case of FPREM or $-\pi \le x \le \pi$ in the case of FPREM1. Negative arguments are reduced by repeatedly subtracting -2π. See “Partial Remainder” on page 318 for details of the instructions.

6.4.6 Compare and Test

The compare-and-test instructions set and clear flags in the rFLAGS register to indicate the relationship between two operands (less, equal, greater, or unordered).

Floating-Point Ordered Compare

- FCOM—Floating-Point Compare
- FCOMP—Floating-Point Compare and Pop
- FCOMPP—Floating-Point Compare and Pop Twice
- FCOMI—Floating-Point Compare and Set Flags
- FCOMIP—Floating-Point Compare and Set Flags and Pop

The FCOM instruction syntax has forms that include zero or one explicit source operands. In the zero-operand form, the instruction compares ST(1) with ST(0) and writes the x87 status-word condition codes accordingly. In the one-operand form, the instruction reads a 32-bit or 64-bit value from memory, compares it with ST(0), and writes the x87 condition codes accordingly.

The FCOMP instruction performs the same operation as FCOM but also pops ST(0) after writing the condition codes.

The FCOMPP instruction performs the same operation as FCOM but also pops both ST(0) and ST(1). FCOMPP can be used to initialize the x87 stack at the end of an x87 procedure by removing two registers of preloaded data from the stack.

The FCOMI instruction compares the contents of ST(0) with the contents of another stack register and writes the ZF, PF, and CF flags in the rFLAGS register as shown in Table 6-14. If no source is specified, ST(0) is compared to ST(1). If ST(0) or the source operand is a NaN or in an unsupported format, the flags are set to indicate an unordered condition.

The FCOMIP instruction performs the same comparison as FCOMI but also pops ST(0) after writing the rFLAGS bits.

Table 6-14. rFLAGS Values for FCOMI Instruction

Flag	ST(0) > ST(i)	ST(0) < ST(i)	ST(0) = ST(i)	Unordered
ZF	0	0	1	1
PF	0	0	0	1
CF	0	1	0	1

For comparison-based branches, the combination of FCOMI and FCMOV*cc* is faster than the classical method of using F*x*STSW AX to copy condition codes through the AX register to the rFLAGS register, where they can provide branch direction for conditional operations.

The FCOM*x* instructions perform ordered compares, as opposed to the FUCOM*x* instructions. See the description of ordered vs. unordered compares immediately below.

Floating-Point Unordered Compare

- FUCOM—Floating-Point Unordered Compare
- FUCOMP—Floating-Point Unordered Compare and Pop
- FUCOMPP—Floating-Point Unordered Compare and Pop Twice
- FUCOMI—Floating-Point Unordered Compare and Set Flags
- FUCOMIP—Floating-Point Unordered Compare and Set Flags and Pop

The FUCOM*x* instructions perform the same operations as the FCOM*x* instructions, except that the FUCOM*x* instructions generate an invalid-operation exception (IE) only if any operand is an unsupported data type or a signaling NaN (SNaN), whereas the ordered-compare FCOM*x* instructions generate an invalid-operation exception if any operand is an unsupported data type or any type of NaN. For a description of NaNs, see “Number Representation” on page 302.

Integer Compare

- FICOM—Floating-Point Integer Compare
- FICOMP—Floating-Point Integer Compare and Pop

The FICOM instruction reads a 16-bit or 32-bit integer value from memory, compares it with ST(0), and writes the condition codes in the same way as the FCOM instruction.

The FICOMP instruction performs the same operations as FICOM but also pops ST(0).

Test

- FTST—Floating-Point Test with Zero

The FTST instruction compares ST(0) with zero and writes the condition codes in the same way as the FCOM instruction.

Classify

- FXAM—Floating-Point Examine

The FXAM instruction determines the type of value in ST(0) and sets the condition codes accordingly, as shown in Table 6-15.

Table 6-15. Condition-Code Settings for FXAM

C3	C2	C0	C1[1]	Meaning
0	0	0	0	+unsupported
0	0	0	1	-unsupported
0	0	1	0	+NAN
0	0	1	1	-NAN
0	1	0	0	+normal
0	1	0	1	-normal
0	1	1	0	+infinity
0	1	1	1	-infinity
1	0	0	0	+0
1	0	0	1	-0
1	0	1	0	+empty
1	0	1	1	-empty
1	1	0	0	+denormal
1	1	0	1	-denormal

Note:
1. C1 is the sign of ST(0).

6.4.7 Stack Management

The stack management instructions move the x87 top-of-stack pointer (TOP) and clear the contents of stack registers.

Stack Control

- FDECSTP—Floating-Point Decrement Stack-Top Pointer
- FINCSTP—Floating-Point Increment Stack-Top Pointer

The FINCSTP and FDECSTP instructions increment and decrement, respectively, the TOP, modulo-8. Neither the x87 tag word nor the contents of the floating-point stack itself is updated.

Clear State

- FFREE—Free Floating-Point Register

The FFREE instruction frees a specified stack register by setting the x87 tag-word bits for the register to all 1s, indicating *empty*. Neither the stack-register contents nor the stack pointer is modified by this instruction.

6.4.8 No Operation

This instruction uses processor cycles but generates no result.

- FNOP—Floating-Point No Operation

The FNOP instruction has no operands and writes no result. Its purpose is simply to delay execution of a sequence of instructions.

6.4.9 Control

The control instructions are used to initialize, save, and restore x87 processor state and to manage x87 exceptions.

Initialize

- FINIT—Floating-Point Initialize
- FNINIT—Floating-Point No-Wait Initialize

The FINIT and FNINIT instructions set all bits in the x87 control-word, status-word, and tag word registers to their default values. Assemblers issue FINIT as an FWAIT instruction followed by an FNINIT instruction. Thus, FINIT (but not FNINIT) reports pending unmasked x87 floating-point exceptions before performing the initialization.

Both FINIT and FNINIT write the control word with its initialization value, 037Fh, which specifies round-to-nearest, all exceptions masked, and double-extended-precision. The tag word indicates that the floating-point registers are *empty*. The status word and the four condition-code bits are cleared to 0. The x87 pointers and opcode state (“Pointers and Opcode State” on page 295) are all cleared to 0.

The FINIT instruction should be used when pending x87 floating-point exceptions are being reported (unmasked). The no-wait instruction, FNINIT, should be used when pending x87 floating-point exceptions are not being reported (masked).

Wait for Exceptions

- FWAIT or WAIT—Wait for Unmasked x87 Floating-Point Exceptions

The FWAIT and WAIT instructions are synonyms. The instruction forces the processor to test for and handle any pending, unmasked x87 floating-point exceptions.

Clear Exceptions

- FCLEX—Floating-Point Clear Flags
- FNCLEX—Floating-Point No-Wait Clear Flags

These instructions clear the status-word exception flags, stack-fault flag, and busy flag. They leave the four condition-code bits undefined.

Assemblers issue FCLEX as an FWAIT instruction followed by an FNCLEX instruction. Thus, FCLEX (but not FNCLEX) reports pending unmasked x87 floating-point exceptions before clearing the exception flags.

The FCLEX instruction should be used when pending x87 floating-point exceptions are being reported (unmasked). The no-wait instruction, FNCLEX, should be used when pending x87 floating-point exceptions are not being reported (masked).

Save and Restore x87 Control Word

- FLDCW—Floating-Point Load x87 Control Word
- FSTCW—Floating-Point Store Control Word
- FNSTCW—Floating-Point No-Wait Store Control Word

These instructions load or store the x87 control-word register as a 2-byte value from or to a memory location.

The FLDCW instruction loads a control word. If the loaded control word unmasks any pending x87 floating-point exceptions, these exceptions are reported when the next non-control x87 or 64-bit media instruction is executed.

Assemblers issue FSTCW as an FWAIT instruction followed by an FNSTCW instruction. Thus, FSTCW (but not FNSTCW) reports pending unmasked x87 floating-point exceptions before storing the control word.

The FSTCW instruction should be used when pending x87 floating-point exceptions are being reported (unmasked). The no-wait instruction, FNSTCW, should be used when pending x87 floating-point exceptions are not being reported (masked).

Save x87 Status Word

- FSTSW—Floating-Point Store Status Word
- FNSTSW—Floating-Point No-Wait Store Status Word

These instructions store the x87 status word either at a specified 2-byte memory location or in the AX register. The second form, F*x*STSW AX, is used in older code to copy condition codes through the AX register to the rFLAGS register, where they can be used for conditional branching using general-purpose instructions. However, the combination of FCOMI and FCMOV*cc* provides a faster method of conditional branching.

Assemblers issue FSTSW as an FWAIT instruction followed by an FNSTSW instruction. Thus, FSTSW (but not FNSTSW) reports pending unmasked x87 floating-point exceptions before storing the status word.

The FSTSW instruction should be used when pending x87 floating-point exceptions are being reported (unmasked). The no-wait instruction, FNSTSW, should be used when pending x87 floating-point exceptions are not being reported (masked).

Save and Restore x87 Environment

- FLDENV—Floating-Point Load x87 Environment
- FNSTENV—Floating-Point No-Wait Store Environment

- FSTENV—Floating-Point Store Environment

These instructions load or store the entire x87 environment (non-data processor state) as a 14-byte or 28-byte block, depending on effective operand size, from or to memory.

When executing FLDENV, any exception flags are set in the new status word, and these exceptions are unmasked in the control word, a floating-point exception occurs when the next non-control x87 or 64-bit media instruction is executed.

Assemblers issue FSTENV as an FWAIT instruction followed by an FNSTENV instruction. Thus, FSTENV (but not FNSTENV) reports pending unmasked x87 floating-point exceptions before storing the status word.

The x87 environment includes the x87 control word register, x87 status word register, x87 tag word, last x87 instruction pointer, last x87 data pointer, and last x87 opcode. See “Media and x87 Processor State” in Volume 2 for details on how the x87 environment is stored in memory.

Save and Restore x87 and 64-Bit Media State

- FSAVE—Save x87 and MMX State.
- FNSAVE—Save No-Wait x87 and MMX State.
- FRSTOR—Restore x87 and MMX State.

These instructions save and restore the entire processor state for x87 floating-point instructions and 64-bit media instructions. The instructions save and restore either 94 or 108 bytes of data, depending on the effective operand size.

Assemblers issue FSAVE as an FWAIT instruction followed by an FNSAVE instruction. Thus, FSAVE (but not FNSAVE) reports pending unmasked x87 floating-point exceptions before saving the state.

After saving the state, the processor initializes the x87 state by performing the equivalent of an FINIT instruction. For details, see “State-Saving” on page 339.

Save and Restore x87, 128-Bit, and 64-Bit State

- FXSAVE—Save XMM, MMX, and x87 State.
- FXRSTOR—Restore XMM, MMX, and x87 State.

The FXSAVE and FXRSTOR instructions save and restore the entire 512-byte processor state for 128-bit media instructions, 64-bit media instructions, and x87 floating-point instructions. The architecture supports two memory formats for FXSAVE and FXRSTOR, a 512-byte 32-bit legacy format and a 512-byte 64-bit format. Selection of the 32-bit or 64-bit format is determined by the effective operand size for the FXSAVE and FXRSTOR instructions. For details, see “Media and x87 Processor State” in Volume 2.

FXSAVE and FXRSTOR execute faster than FSAVE/FNSAVE and FRSTOR. However, unlike FSAVE and FNSAVE, FXSAVE does not initialize the x87 state, and like FNSAVE it does not report pending unmasked x87 floating-point exceptions. For details, see “State-Saving” on page 339.

6.5 Instruction Effects on rFLAGS

The rFLAGS register is described in “Flags Register” on page 34. Table 6-16 on page 326 summarizes the effect that x87 floating-point instructions have on individual flags within the rFLAGS register. Only instructions that access the rFLAGS register are shown—all other x87 instructions have no effect on rFLAGS.

The following codes are used within the table:

- Mod—The flag is modified.
- Tst—The flag is tested.
- Gray shaded cells indicate the flag is not affected by the instruction.

Table 6-16. Instruction Effects on rFLAGS

Instruction Mnemonic	rFLAGS Mnemonic and Bit Number					
	OF 11	SF 7	ZF 6	AF 4	PF 2	CF 0
FCMOV*cc*			Tst		Tst	Tst
FCOMI FCOMIP FUCOMI FUCOMIP			Mod		Mod	Mod

6.6 Instruction Prefixes

Instruction prefixes, in general, are described in “Instruction Prefixes” on page 76. The following restrictions apply to the use of instruction prefixes with x87 instructions.

6.6.0.1 Supported Prefixes

The following prefixes can be used with x87 instructions:

- *Operand-Size Override*—The 66h prefix affects only the FLDENV, FSTENV, FNSTENV, FSAVE, FNSAVE, and FRSTOR instructions, in which it selects between a 16-bit and 32-bit memory-image format. The prefix is ignored by all other x87 instructions.
- *Address-Size Override*—The 67h prefix affects only operands in memory, in which it selects between a 16-bit and 32-bit addresses. The prefix is ignored by all other x87 instructions.
- *Segment Overrides*—The 2Eh (CS), 36h (SS), 3Eh (DS), 26h (ES), 64h (FS), and 65h (GS) prefixes specify a segment. They affect only operands in memory. In 64-bit mode, the CS, DS, ES, SS segment overrides are ignored.
- *REX*—The REX.W bit affects the FXSAVE and FXRSTOR instructions, in which it selects between two types of 512-byte memory-image formats, as described in "Saving Media and x87 Processor State" in Volume 2. The REX.W bit also affects the FLDENV, FSTENV, FSAVE, and

FRSTOR instructions, in which it selects the 32-bit memory-image format. The REX.R, REX.X, and REX.B bits only affect operands in memory, in which they are used to find the memory operand.

6.6.0.2 Ignored Prefixes

The following prefixes are ignored by x87 instructions:

- *REP*—The F3h and F2h prefixes.

6.6.0.3 Prefixes That Cause Exceptions

The following prefixes cause an exception:

- *LOCK*—The F0h prefix causes an invalid-opcode exception when used with x87 instructions.

6.7 Feature Detection

Before executing x87 floating-point instructions, software should determine if the processor supports the technology by executing the CPUID instruction. “Feature Detection” on page 79 describes how software uses the CPUID instruction to detect feature support. For full support of the x87 floating-point features, the following feature must be present:

- On-Chip Floating-Point Unit, indicated by bit 0 of CPUID function 1 and CPUID function 8000_0001h.
- CMOV*cc* (conditional moves), indicated by bit 15 of CPUID function 1 and CPUID function 8000_0001h. This bit indicates support for x87 floating-point conditional moves (FCMOV*cc*) whenever the On-Chip Floating-Point Unit bit (bit 0) is also set.

Software may also wish to check for the following support, because the FXSAVE and FXRSTOR instructions execute faster than FSAVE and FRSTOR:

- FXSAVE and FXRSTOR, indicated by bit 24 of CPUID function 1 and function 8000_0001h.

Software that runs in long mode should also check for the following support:

- Long Mode, indicated by bit 29 of CPUID function 8000_0001h.

See “CPUID” in Volume 3 for details on the CPUID instruction and Appendix D of that volume for information on detemining support for specific instruction subsets.

6.8 Exceptions

6.8.0.1 Types of Exceptions

x87 instructions can generate two types of exceptions:

- *General-Purpose Exceptions*, described below in “General-Purpose Exceptions”

- *x87 Floating-Point Exceptions (#MF)*, described in "x87 Floating-Point Exception Causes" on page 329

6.8.0.2 Relation to 128-Bit Media Exceptions

Although the x87 floating-point instructions and the 128-bit media instructions each have certain exceptions with the same names, the exception-reporting and exception-handling methods used by the two instruction subsets are distinct and independent of each other. If procedures using both types of instructions are run in the same operating environment, separate service routines should be provided for the exceptions of each type of instruction subset.

6.8.1 General-Purpose Exceptions

The sections below list general-purpose exceptions generated and not generated by x87 floating-point instructions. For a summary of the general-purpose exception mechanism, see "Interrupts and Exceptions" on page 91. For details about each exception and its potential causes, see "Exceptions and Interrupts" in Volume 2.

6.8.1.1 Exceptions Generated

x87 instructions can generate the following general-purpose exceptions:

- #DB—Debug Exception (Vector 1)
- #BP—Breakpoint Exception (Vector 3)
- #UD—Invalid-Opcode Exception (Vector 6)
- #NM—Device-Not-Available Exception (Vector 7)
- #DF—Double-Fault Exception (Vector 8)
- #SS—Stack Exception (Vector 12)
- #GP—General-Protection Exception (Vector 13)
- #PF—Page-Fault Exception (Vector 14)
- #MF—x87 Floating-Point Exception-Pending (Vector 16)
- #AC—Alignment-Check Exception (Vector 17)
- #MC—Machine-Check Exception (Vector 18)

For details on #MF exceptions, see "x87 Floating-Point Exception Causes" below.

6.8.1.2 Exceptions Not Generated

x87 instructions do not generate the following general-purpose exceptions:

- #DE—Divide-by-zero-error exception (Vector 0)
- Non-Maskable-Interrupt Exception (Vector 2)
- #OF—Overflow exception (Vector 4)
- #BR—Bound-range exception (Vector 5)

- Coprocessor-segment-overrun exception (Vector 9)
- #TS—Invalid-TSS exception (Vector 10)
- #NP—Segment-not-present exception (Vector 11)
- #MC—Machine-check exception (Vector 18)
- #XF—SIMD floating-point exception (Vector 19)

For details on all general-purpose exceptions, see “Exceptions and Interrupts” in Volume 2.

6.8.2 x87 Floating-Point Exception Causes

The x87 floating-point exception-pending (#MF) exception listed above in “General-Purpose Exceptions” is actually the logical OR of six exceptions that can be caused by x87 floating-point instructions. Each of the six exceptions has a status flag in the x87 status word and a mask bit in the x87 control word. A seventh exception, stack fault (SF), is reported together with one of the six maskable exceptions and does not have a mask bit.

If a #MF exception occurs when its mask bit is set to 1 (*masked*), the processor responds in a default way that does not invoke the #MF exception service routine. If an exception occurs when its mask bit is cleared to 0 (*unmasked*), the processor suspends processing of the faulting instruction (if possible) and, at the boundary of the next non-control x87 or 64-bit media instruction (see “Control” on page 323), determines that an unmasked exception is pending—by checking the exception status (ES) flag in the x87 status word—and invokes the #MF exception service routine.

6.8.2.1 #MF Exception Types and Flags

The #MF exceptions are of six types, five of which are mandated by the IEEE 754 standard. These six types and their bit-flags in the x87 status word are shown in Table 6-17. A stack fault (SF) exception is always accompanied by an invalid-operation exception (IE). A summary of each exception type is given in “x87 Status Word Register (FSW)” on page 289.

Table 6-17. x87 Floating-Point (#MF) Exception Flags

Exception and Mnemonic	x87 Status-Word Bit[1]	Comparable IEEE 754 Exception
Invalid-operation exception (IE)	0	Invalid Operation
Invalid-operation exception (IE) with stack fault (SF) exception	0 and 6	*none*
Denormalized-operand exception (DE)	1	*none*
Zero-divide exception (ZE)	2	Division by Zero
Overflow exception (OE)	3	Overflow
Underflow exception (UE)	4	Underflow
Precision exception (PE)	5	Inexact

Note:
1. *See “x87 Status Word Register (FSW)” on page 289 for a summary of each exception.*

The sections below describe the causes for the #MF exceptions. Masked and unmasked responses to the exceptions are described in "x87 Floating-Point Exception Masking" on page 333. The priority of #MF exceptions are described in "x87 Floating-Point Exception Priority" on page 332.

6.8.2.2 Invalid-Operation Exception (IE)

The IE exception occurs due to one of the attempted operations shown in Table 6-18 on page 330. An IE exception may also be accompanied by a stack fault (SF) exception. See "Stack Fault (SF)" on page 331.

Table 6-18. Invalid-Operation Exception (IE) Causes

Operation		Condition
Arithmetic (IE exception)	Any Arithmetic Operation	• A source operand is an SNaN, or • A source operand is an unsupported data type (pseudo-NaN, pseudo-infinity, or unnormal).
	FADD, FADDP	Source operands are infinities with opposite signs.
	FSUB, FSUBP, FSUBR, FSUBRP	Source operands are infinities with same sign.
	FMUL, FMULP	Source operands are zero and infinity.
	FDIV, FDIVP, FDIVR, FDIVRP	Source operands are both infinities or both zeros.
	FSQRT	Source operand is less than zero (except ±0 which returns ±0).
	FYL2X	Source operand is less than zero (except ±0 which returns ±∞).
	FYL2XP1	Source operand is less than minus one.
	FCOS, FPTAN, FSIN, FSINCOS	Source operand is infinity.
	FCOM, FCOMP, FCOMPP, FCOMI, FCOMIP	A source operand is a QNaN.
	FPREM, FPREM1	Dividend is infinity or divisor is zero.
	FIST, FISTP, FISTTP	Source operand overflows the destination size.
	FBSTP	Source operand overflows packed BCD data size.
Stack (IE and SF exceptions)		Stack overflow or underflow.[1]

Note:
1. *The processor sets condition code C1 = 1 for overflow, C1 = 0 for underflow.*

6.8.2.3 Denormalized-Operand Exception (DE)

The DE exception occurs in any of the following cases:

- *Denormalized Operand (any precision)*—An arithmetic instruction uses an operand of any precision that is in denormalized form, as described in "Denormalized (Tiny) Numbers" on page 303.
- *Denormalized Single-Precision or Double-Precision Load*—An instruction loads a single-precision or double-precision (but not double-extended-precision) operand, which is in denormalized form, into an x87 register.

6.8.2.4 Zero-Divide Exception (ZE)

The ZE exception occurs when:

- *Divisor is Zero*—An FDIV, FDIVP, FDIVR, FDIVRP, FIDIV, or FIDIVR instruction attempts to divide zero into a non-zero finite dividend.
- *Source Operand is Zero*—An FYL2X or FXTRACT instruction uses a source operand that is zero.

6.8.2.5 Overflow Exception (OE)

The OE exception occurs when the value of a rounded floating-point result is larger than the largest representable normalized positive or negative floating-point number in the destination format, as shown in Table 6-5 on page 301. An overflow can occur through computation or through conversion of higher-precision numbers to lower-precision numbers. See "Precision" on page 309. Integer and BCD overflow is reported via the invalid-operation exception.

6.8.2.6 Underflow Exception (UE)

The UE exception occurs when the value of a rounded, non-zero floating-point result is too small to be represented as a normalized positive or negative floating-point number in the destination format, as shown in Table 6-5 on page 301. Integer and BCD underflow is reported via the invalid-operation exception.

6.8.2.7 Precision Exception (PE)

The PE exception, also called the *inexact-result* exception, occurs when a floating-point result, after rounding, differs from the infinitely precise result and thus cannot be represented exactly in the specified destination format. Software that does not require exact results normally masks this exception. See "Precision" on page 309 and "Rounding" on page 309.

6.8.2.8 Stack Fault (SF)

The SF exception occurs when a stack overflow (due to a push or load into a non-empty stack register) or stack underflow (due to referencing an empty stack register) occurs in the x87 stack-register file. The empty and non-empty conditions are shown in Table 6-3 on page 295. When either of these conditions occur, the processor also sets the invalid-operation exception (IE) flag, and it sets or clears the condition-code 1 (C1) bit to indicate the direction of the stack fault (C1 = 1 for overflow, C1 = 0 for underflow). Unlike the flags for the other x87 exceptions, the SF flag does not have a corresponding mask bit in the x87 control word.

6.8.3 x87 Floating-Point Exception Priority

Table 6-19 shows the priority with which the processor recognizes multiple, simultaneous SIMD floating-point exceptions and operations involving QNaN operands. Each exception type is characterized by its timing, as follows:

- *Pre-Computation*—an exception that is recognized before an instruction begins its operation.
- *Post-Computation*—an exception that is recognized after an instruction completes its operation.

For post-computation exceptions, a result may be written to the destination, depending on the type of exception and whether the destination is a register or memory location. Operations involving QNaNs do not necessarily cause exceptions, but the processor handles them with the priority shown in Table 6-19 on page 332 relative to the handling of exceptions.

Table 6-19. Priority of x87 Floating-Point Exceptions

Priority	Exception or Operation	Timing
1	Invalid-operation exception (IE) with stack fault (SF) due to underflow	Pre-Computation
2	Invalid-operation exception (IE) with stack fault (SF) due to overflow	Pre-Computation
3	Invalid-operation exception (IE) when accessing unsupported data type	Pre-Computation
4	Invalid-operation exception (IE) when accessing SNaN operand	Pre-Computation
5	Operation involving a QNaN operand[1]	—
6	Any other type of invalid-operation exception (IE)	Pre-Computation
	Zero-divide exception (ZE)	Pre-Computation
7	Denormalized operation exception (DE)	Pre-Computation
8	Overflow exception (OE)	Post-Computation
	Underflow exception (UE)	Post-Computation
9	Precision (inexact) exception (PE)	Post-Computation

Note:
1. *Operations involving QNaN operands do not, in themselves, cause exceptions but they are handled with this priority relative to the handling of exceptions.*

For exceptions that occur before the associated operation (pre-operation, as shown in Table 6-19), if an unmasked exception occurs, the processor suspends processing of the faulting instruction but it waits until the boundary of the next non-control x87 or 64-bit media instruction to be executed before invoking the associated exception service routine. During this delay, non-x87 instructions may overwrite the faulting x87 instruction's source or destination operands in memory. If that occurs, the x87 service routine may be unable to perform its job.

To prevent such problems, analyze x87 procedures for potential exception-causing situations and insert a WAIT or other safe x87 instruction immediately after any x87 instruction that may cause a problem.

6.8.4 x87 Floating-Point Exception Masking

The six floating-point exception flags in the x87 status word have corresponding exception-flag masks in the x87 control word, as shown in Table 6-20 on page 333.

Table 6-20. x87 Floating-Point (#MF) Exception Masks

Exception Mask and Mnemonic	x87 Control-Word Bit[1]
Invalid-operation exception mask (IM)	0
Denormalized-operand exception mask (DM)	1
Zero-divide exception mask (ZM)	2
Overflow exception mask (OM)	3
Underflow exception mask (UM)	4
Precision exception mask (PM)	5

Note:
1. See "x87 Status Word Register (FSW)" on page 289 for a summary of each exception.

Each mask bit, when set to 1, inhibits invocation of the #MF exception handler and instead continues normal execution using the default response for the exception type. During initialization with FINIT or FNINIT, all exception-mask bits in the x87 control word are set to 1 (masked). At processor reset, all exception-mask bits are cleared to 0 (unmasked).

6.8.4.1 Masked Responses

The occurrence of a masked exception does not invoke its exception handler when the exception condition occurs. Instead, the processor handles masked exceptions in a default way, as shown in Table 6-21 on page 334.

Table 6-21. Masked Responses to x87 Floating-Point Exceptions

Exception and Mnemonic	Type of Operation[1]	Processor Response
Invalid-operation exception (IE)[2]	Any Arithmetic Operation: Source operand is an SNaN.	Set IE flag, and return a QNaN value.
	Any Arithmetic Operation: Source operand is an unsupported data type or FADD, FADDP: Source operands are infinities with opposite signs or FSUB, FSUBP, FSUBR, FSUBRP: Source operands are infinities with same sign or FMUL, FMULP: Source operands are zero and infinity or FDIV, FDIVP, FDIVR, FDIVRP: Source operands are both infinities or both are zeros or FSQRT: Source operand is less than zero (except ±0 which returns ±0) or FYL2X: Source operand is less than zero (except ±0 which returns ±∞) or FYL2XP1: Source operand is less than minus one.	Set IE flag, and return the floating-point indefinite value[3].

Note:
1. *See "Instruction Summary" on page 310 for the types of instructions.*
2. *Includes invalid-operation exception (IE) together with stack fault (SF).*
3. *See "Indefinite Values" on page 308.*

Table 6-21. Masked Responses to x87 Floating-Point Exceptions (continued)

Exception and Mnemonic	Type of Operation[1]	Processor Response
Invalid-operation exception (IE)[2]	FCOS, FPTAN, FSIN, FSINCOS: Source operand is ∞ or FPREM, FPREM1: Dividend is infinity or divisor is 0.	Set IE flag, return the floating-point indefinite value[3], and clear condition code C2 to 0.
	FCOM, FCOMP, or FCOMPP: One or both operands is a NaN or FUCOM, FUCOMP, or FUCOMPP: One or both operands is an SNaN.	Set IE flag, and set C3–C0 condition codes to reflect the result.
	FCOMI or FCOMIP: One or both operands is a NaN or FUCOMI or FUCOMIP: One or both operands is an SNaN.	Sets IE flag, and sets the result in eflags to "unordered."
	FIST, FISTP, FISTTP: Source operand overflows the destination size.	Set IE flag, and return the integer indefinite value[3].
	FXCH: A source register is specified *empty* by its tag bits.	Set IE flag, and perform exchange using floating-point indefinite value[3] as content for empty register(s).
	FBSTP: Source operand overflows packed BCD data size.	Set IE flag, and return the packed-decimal indefinite value[3].
Denormalized-operand exception (DE)		Set DE flag, and return the result using the denormal operand(s).
Zero-divide exception (ZE)	FDIV, FDIVP, FDIVR, FDIVRP, FIDIV, or FIDIVR: Divisor is 0.	Set ZE flag, and return signed ∞ with sign bit = XOR of the operand sign bits.
	FYL2X: ST(0) is 0 and ST(1) is a non-zero floating-point value.	Set ZE flag, and return signed ∞ with sign bit = complement of sign bit for ST(1) operand.
	FXTRACT: Source operand is 0.	Set ZE flag, write ST(0) = 0 with sign of operand, and write ST(1) = –∞.

Note:
1. *See "Instruction Summary" on page 310 for the types of instructions.*
2. *Includes invalid-operation exception (IE) together with stack fault (SF).*
3. *See "Indefinite Values" on page 308.*

Table 6-21. Masked Responses to x87 Floating-Point Exceptions (continued)

Exception and Mnemonic	Type of Operation[1]	Processor Response
Overflow exception (OE)	Round to nearest.	• If sign of result is positive, set OE flag, and return +∞. • If sign of result is negative, set OE flag, and return -∞.
	Round toward +∞.	• If sign of result is positive, set OE flag, and return +∞. • If sign of result is negative, set OE flag, and return finite negative number with largest magnitude.
	Round toward -∞.	• If sign of result is positive, set OE flag, and return finite positive number with largest magnitude. • If sign of result is negative, set OE flag, and return -∞.
	Round toward 0.	• If sign of result is positive, set OE flag and return finite positive number with largest magnitude. • If sign of result is negative, set OE flag and return finite negative number with largest magnitude.
Underflow exception (UE)		• If result is both denormal (tiny) and inexact, set UE flag and return denormalized result. • If result is denormal (tiny) but not inexact, return denormalized result but do not set UE flag.
Precision exception (PE)	Without overflow or underflow	Set PE flag, return rounded result, write C1 condition code to specify round-up (C1 = 1) or not round-up (C1 = 0).
	With masked overflow or underflow	Set PE flag and respond as for the OE or UE exceptions.
	With unmasked overflow or underflow for register destination	Set PE flag, respond to the OE or UE exception by calling the #MF service routine.
	With unmasked overflow or underflow for memory destination	Do not set PE flag, respond to the OE or UE exception by calling the #MF service routine. The destination and the TOP are not changed.

Note:
1. *See "Instruction Summary" on page 310 for the types of instructions.*
2. *Includes invalid-operation exception (IE) together with stack fault (SF).*
3. *See "Indefinite Values" on page 308.*

6.8.4.2 Unmasked Responses

The processor handles unmasked exceptions as shown in Table 6-22 on page 337.

Table 6-22. Unmasked Responses to x87 Floating-Point Exceptions

Exception and Mnemonic	Type of Operation	Processor Response[1]
Invalid-operation exception (IE)		Set IE and ES flags, and call the #MF service routine[2]. The destination and the TOP are not changed.
Invalid-operation exception (IE) with stack fault (SF)		
Denormalized-operand exception (DE)		Set DE and ES flags, and call the #MF service routine[2]. The destination and the TOP are not changed.
Zero-divide exception (ZE)		Set ZE and ES flags, and call the #MF service routine[2]. The destination and the TOP are not changed.
Overflow exception (OE)		• If the destination is memory, set OE and ES flags, and call the #MF service routine[2]. The destination and the TOP are not changed. • If the destination is an x87 register: - divide true result by 2^{24576}, - round significand according to PC precision control and RC rounding control (or round to double-extended precision for instructions not observing PC precision control), - write C1 condition code according to rounding (C1 = 1 for round up, C1 = 0 for round toward zero), - write result to destination, - pop or push stack if specified by the instruction, - set OE and ES flags, and call the #MF service routine[2].

Note:

1. For all unmasked exceptions, the processor's response also includes assertion of the FERR# output signal at the completion of the instruction that caused the exception.

2. When CR0.NE is set to 1, the #MF service routine is taken at the next non-control x87 instruction. If CR0.NE is cleared to zero, x87 floating-point instructions are handled by setting the FERR# input signal to 1, which external logic can use to handle the interrupt.

Table 6-22. Unmasked Responses to x87 Floating-Point Exceptions (continued)

Exception and Mnemonic	Type of Operation	Processor Response[1]
Underflow exception (UE)		• If the destination is memory, set UE and ES flags, and call the #MF service routine[2]. The destination and the TOP are not changed. • If the destination is an x87 register: - multiply true result by 2^{24576}, - round significand according to PC precision control and RC rounding control (or round to double-extended precision for instructions not observing PC precision control), - write C1 condition code according to rounding (C1 = 1 for round up, C1 = 0 for round toward zero), - write result to destination, - pop or push stack if specified by the instruction, - set UE and ES flags, and call the #MF service routine[2].
Precision exception (PE)	Without overflow or underflow	Set PE and ES flags, return rounded result, write C1 condition code to specify round-up (C1 = 1) or not round-up (C1 = 0), and call the #MF service routine[2].
	With masked overflow or underflow	Set PE and ES flags, respond as for the OE or UE exception, and call the #MF service routine[2].
	With unmasked overflow or underflow for register destination	
	With unmasked overflow or underflow for memory destination	Do not set PE flag, respond to the OE or UE exception by calling the #MF service routine. The destination and the TOP are not changed.

Note:
1. *For all unmasked exceptions, the processor's response also includes assertion of the FERR# output signal at the completion of the instruction that caused the exception.*
2. *When CR0.NE is set to 1, the #MF service routine is taken at the next non-control x87 instruction. If CR0.NE is cleared to zero, x87 floating-point instructions are handled by setting the FERR# input signal to 1, which external logic can use to handle the interrupt.*

6.8.4.3 FERR# and IGNNE# Signals

In all unmasked-exception responses, the processor also asserts the FERR# output signal at the completion of the instruction that caused the exception. The exception is serviced at the boundary of the next non-waiting x87 or 64-bit media instruction following the instruction that caused the exception. (See "Control" on page 323 for a definition of *control instructions*.)

System software controls x87 floating-point exception reporting using the numeric error (NE) bit in control register 0 (CR0), as follows:

- If CR0.NE = 1, internal processor control over x87 floating-point exception reporting is enabled. In this case, an #MF exception occurs immediately. The FERR# output signal is asserted, but is not

used externally. It is recommended that system software set NE to 1. This enables optimal performance in handling x87 floating-point exceptions.

- If CR0.NE = 0, internal processor control of x87 floating-point exceptions is disabled and the external IGNNE# input signal controls whether x87 floating-point exceptions are ignored, as follows:
  - When IGNNE# is 0, x87 floating-point exceptions are reported by asserting the FERR# output signal, then stopping program execution until an external interrupt is detected. External logic use the FERR# signal to generate the external interrupt.
  - When IGNNE# is 1, x87 floating-point exceptions do not stop program execution. After FERR# is asserted, instructions continue to execute.

6.8.4.4 Using NaNs in IE Diagnostic Exceptions

Both SNaNs and QNaNs can be encoded with many different values to carry diagnostic information. By means of appropriate masking and unmasking of the invalid-operation exception (IE), software can use signaling NaNs to invoke an exception handler. Within the constraints imposed by the encoding of SNaNs and QNaNs, software may freely assign the bits in the significand of a NaN. See the section "Not a Number (NaN)" on page 305 for format details.

For example, software can pre-load each element of an array with a signaling NaN that encodes the array index. When an application accesses an uninitialized array element, the invalid-operation exception is invoked and the service routine can identify that element. A service routine can store debug information in memory as the exceptions occur. The routine can create a QNaN that references its associated debug area in memory. As the program runs, the service routine can create a different QNaN for each error condition, so that a single test-run can identify a collection of errors.

6.9 State-Saving

In general, system software should save and restore x87 state between task switches or other interventions in the execution of x87 floating-point procedures. Virtually all modern operating systems running on x86 processors implement preemptive multitasking that handle saving and restoring of state across task switches, independent of hardware task-switch support. However, application procedures are also free to save and restore x87 state at any time they deem useful.

6.9.1 State-Saving Instructions

6.9.1.1 FSAVE/FNSAVE and FRSTOR Instructions

Application software can save and restore the x87 state by executing the FSAVE (or FNSAVE) and FRSTOR instructions. Alternatively, software may use multiple F*x*ST*x* (floating-point store stack top) instructions for saving only the contents of the x87 data registers, rather than the complete x87 state.

The FSAVE instruction stores the state, but only after handling any pending unmasked x87 floating-point exceptions, whereas the FNSAVE instruction skips the handling of these exceptions. The state of all x87 data registers is saved, as well as all x87 environment state (the x87 control word register,

status word register, tag word, instruction pointer, data pointer, and last opcode register). After saving this state, the tag bits for all x87 registers are changed to *empty* and thus available for a new procedure.

6.9.1.2 FXSAVE and FXRSTOR Instructions

Application software can save and restore the 128-bit media state, 64-bit media state, and x87 floating-point state by executing the FXSAVE and FXRSTOR instructions. The FXSAVE and FXRSTOR instructions execute faster than FSAVE/FNSAVE and FRSTOR because they do not save and restore the x87 pointers (last instruction pointer, last data pointer, and last opcode, described in “Pointers and Opcode State” on page 295) except in the relatively rare cases in which the exception-summary (ES) bit in the x87 status word (the ES register image for FXSAVE, or the ES memory image for FXRSTOR) is set to 1, indicating that an unmasked x87 exception has occurred.

Unlike FSAVE and FNSAVE, however, FXSAVE does not alter the tag bits. The state of the saved x87 data registers is retained, thus indicating that the registers may still be valid (or whatever other value the tag bits indicated prior to the save). To invalidate the contents of the x87 data registers after FXSAVE, software must explicitly execute an FINIT instruction. Also, FXSAVE (like FNSAVE) and FXRSTOR do not check for pending unmasked x87 floating-point exceptions. An FWAIT instruction can be used for this purpose.

The architecture supports two memory formats for FXSAVE and FXRSTOR, a 512-byte 32-bit legacy format and a 512-byte 64-bit format, used in 64-bit mode. Selection of the 32-bit or 64-bit format is determined by the effective operand size for the FXSAVE and FXRSTOR instructions. For details, see “Media and x87 Processor State” in Volume 2.

6.10 Performance Considerations

In addition to typical code optimization techniques, such as those affecting loops and the inlining of function calls, the following considerations may help improve the performance of application programs written with x87 floating-point instructions.

These are implementation-independent performance considerations. Other considerations depend on the hardware implementation. For information about such implementation-dependent considerations and for more information about application performance in general, see the data sheets and the software-optimization guides relating to particular hardware implementations.

6.10.1 Replace x87 Code with 128-Bit Media Code

Code written with 128-bit media floating-point instructions can operate in parallel on four times as many single-precision floating-point operands as can x87 floating-point code. This achieves potentially four times the computational work of x87 instructions that use single-precision operands. Also, the higher density of 128-bit media floating-point operands may make it possible to remove local temporary variables that would otherwise be needed in x87 floating-point code. 128-bit media code is easier to write than x87 floating-point code, because the XMM register file is flat rather than stack-oriented, and, in 64-bit mode there are twice the number of XMM registers as x87 registers.

6.10.2 Use FCOMI-FCMOV*x* Branching

Depending on the hardware implementation of the architecture, the combination of FCOMI and FCMOV*cc* is often faster than the classical approach using FxSTSW AX instructions for comparison-based branches that depend on the condition codes for branch direction, because FNSTSW AX is often a serializing instruction.

6.10.3 Use FSINCOS Instead of FSIN and FCOS

Frequently, a piece of code that needs to compute the sine of an argument also needs to compute the cosine of that same argument. In such cases, use the FSINCOS instruction to compute both trigonometric functions concurrently, which is faster than using separate FSIN and FCOS instructions to accomplish the same task.

6.10.4 Break Up Dependency Chains

Parallelism can be increased by breaking up dependency chains or by evaluating multiple dependency chains simultaneously (explicitly switching execution between them). Depending on the hardware implementation of the architecture, the FXCH instruction may prove faster than FST/FLD pairs for switching execution between dependency chains.

Revision History

Date	Revision	Description
November 2021	3.38	Added corrections/clarifications to: Address generation in Section 4.5.3. PCID behavior in Section 5.5. Machine Check Exception in Section 8.2.18. SEV Status MSR in Section 15.34.10. SEV_SNP in Sections 15.36.7, .10, .17. VMCB and VMSA contents in Appendix B. SVM Intercepts in Appendix C. Added new features: Chapter 5: Upper Address Ignore. Chapter 9, Section 3.2.6 and Appendix A: Machine Check Architecture Extension. Section 15.36: VMSA Register Protection, SEV-SNP VMSA Register Protection and Secure TSC.
March 2021	3.37	Added SPEC_CTRL and PRED_CMD support. Added x2APIC support. Added SMM Page Configuration Lock. Corrected the AMD64 Architecture SMM State-Save Area table. Add new section: APERF Read-only (AperfReadOnly). Updated the MSRs of the AMD64 Architecture table. Updated the Machine-Check MSR Cross-Reference table. Updated the Performance-Monitoring MSR Cross-Reference table. Updated the Secure Virtual Machine MSR Cross-Reference table. Added new section: Speculation Control MSRs.

Date	Revision	Description
August 2020	3.36	Added Shadow Stack support. Chapter 3: Section 3.1: Added content. Section 3.1.3: Added bit 23 and new content. Section 3.2.7: Added Shadow Stack Registers as new section 3.2.7. Chapter 5: Section 5.6: Updated content. Chapter 6: Added content to Table 6-1. Added section 6.7. Chapter 7: Table 7-3. Updated. Chapter 8: Table 8-1 and Table 8-2: Added content. Section 8.4: Updated content. Section 8.4.2: Added content. Added #CP as new section 8.2.20. Table 8-8: Added content. Added new Shadow Stack section 8.7.6. Section 8.9: Added bullet. Added new 8.9.4.1 section. Chapter 10: Updated Table 10-1. Section 10.4: Added bullet. Chapter 11: Section 11.5.2 and Figure 11-8: Updated table and figure. Section 11.5.8: Updated Table 11-3. Chapter 12: Section 12.2.2: Updated. Section 12.2.4: Updated Figure 12-6. Section 12.3.2: Updated content and added bullets. Chapter 15: Section 15.5.1: Updates. Section 15.15.3: Updated Figure 15-4. Section 15.25.6: Added bullet. Section 15.29.1. Updates. Section 15.29.4.1: Added content. Section 15.29.8.2: Added content. Added Chapter 18. Appendix A: Table A-1: Added content. Added new section A.10. Appendix B: Table B-1, Table B-2, and Table 4: Added content.
May 2020	3.35	Sections 5.6.1 and 5.6.6: Minor updates. Figure 5-16: Updated figure.

Date	Revision	Description
April 2020	3.34	Section 3.1.3: Updated register information. Added PCIDE and PKE registers. Updated (TCE) content. Section 5.3.2: Added Process Context Identifier register information and register figure. Section 5.3.3: Updated figure. Section 5.3.4: Updated figure. Section 5.3.5: Updated figure. Section 5.4.1: Added (MPK) register information. Section 5.5.1: Inserted Process Context Identifiers as Section 5.5.1. Section 5.5.3: Added bullets to Implicit Invalidations list. Section 5.6: Updated content. Section 8.2.15: Added bullet. Section 8.4.2: Updated register figure and added PK register information. Section 11.5.2: Updated register figure and table. Section 14.1.3: Updated table. Section 15.9: Updated table. Appendix B: Updated table. Appendix C: Updated table.

Date	Revision	Description
April 2020	3.33	Section 1.1.2: Clarification on address size support. Section 3.2.1: New feature enable bits in SYSCFG MSR. Section 7.6.5: Updated terminology. Section 7.10.6: Clarification to encrypted memory operation. Section 8.1.4: Clarification to IRET and NMI behavior. Tables 8-1 and 8-2: Added #HV exception. Inserted new 8.2.20 section for #HV exception. Section 8.4.2: Changes for SEV-SNP extension. Table 8-8: Added SEV-related exceptions. Figure 10-6: Updated I/O Restart DWORD. Section 15 and 15.1: General updates. Section 15.5.2: Relocated VMLOAD/VMSAVE documentation. Section 15.2.4 and 15.2.6: Updated content. Section 15.6: Added content. Table 15-7: Added content. Section 15.25.6: Clarification. Section 15.25.13: General clarifications. Section 15.33.1 and 15.33.2: General clarifications. Section 15.34.3, 15.34.7, and 15.34.10: Clarifications, and additions for SEV-SNP. Table 15-35: Added content. Section 15.35.8: Corrected terminology. Section 15.36: Added SEV-SNP extension documentation. Table A-1 and Table A-7: Added SEV-SNP related MSRs. Appendix B: Updates for SEV-SNP extension. Table C-1: Added exit code for SEV-SNP extension.
October 2019	3.32	Added UMIP, XSS, GMET, VTE, MCOMMIT, and RDPRU.
July 2019	3.31	Added CLWB and WBNOINVD details. Clarified FP error pointer save/restore behavior. Corrected description of APIC Software Enable functionality. Clarified canonical address checking behavior. Clarified fault generation. November 2021n for instructions that cross page or segment boundaries.

Date	Revision	Description
September 2018	3.30	Modified Section 7.4 Modified Section 7.6.4 Modified Section 8.5.2 Modified Section 9.2 Corrected Figure 9-4 Corrected Table 9-1 Modified Section 9.3.2 Corrected Figure 9-6 Corrected Table 9-4 Modified Section 14.2.3 Modified Section 14.4 Modified Section 15.6 Modified Section 15.7 Modified Section 15.34.9 Modified Section 15.34.10 Modified Section 15.35.2 Corrected Table B-4 in Appendix B
December 2017	3.29	Modified Sections 7.10.1 and 7.10.4. Modified Sections 15.34.1, 15.34.7. Added new Section 15.34.10. Modified Section 15.35.10. Modified Appendix A, Table A-7.
March 2017	3.28	Modified CR4 Register, Section 3.1.3. Removed UD2 in Table 6-1. Added new bullet in Section 7.1.1. Modified Note in Table 7-1. Added new Section 7.4.1. Clarified Self Modifying Code in Section 7.6.1. Added UD0 and UD1 instructions in Section 8.2.7. Added Instructions Retired Performance counter in Section 13.1.1. Modified Table in Section 15.34.9.

Date	Revision	Description
December 2016	3.27	Added Resume Flag (RF) Bit in Section 3.1.6, ”RFLAGS Register,” on page 52. Added Tom2ForceMemTypeWB in Section 3.2.1, ”System Configuration Register (SYSCFG),” on page 61. Clarified SYSCALL and SYSRET in Section 6.1.1, ”SYSCALL and SYSRET,” on page 171. Added Section 7.3.2, ”Access Atomicity,” on page 192. Updated Note b in Table 7-11 on page 222. Modified Table 8-1, “Interrupt Vector Source and Cause”, on page 237. Modified Table 8-2, “Interrupt Vector Classification”, on page 238. Added Section 8.2.22, ”#VC—VMM Communication Exception (Vector 29),” on page 252. Added a Note in Chapter 10, "System-Management Mode," on page 317. Added Section 10.5, ”Multiprocessor Considerations,” on page 334. Updated CPUID 8000_001F[EAX] and added CPUID 8000_001F[EDX] in Section 15.34.1, ”Determining Support for SEV,” on page 572. Added new Section 15.35, ”Encrypted State (SEV-ES),” on page 578. Clarified TSC Ratio MSR in Section 15.30.5 ”TSC Ratio MSR (C000_0104h)” on page 568. Modified Appendix B, ”Layout of VMCB” on page 679. Added Table B-3, “Swap Types”, on page 687. Added Codes 8Fh, 90h-9Fh, and 403h in Table C-1, “SVM Intercept Codes”, on page 693.
April 2016	3.26	Clarification on loading a null selector into FS or GS added in Section 4.5.3, ”Segment Registers in 64-Bit Mode,” on page 80 Translation table diagrams corrected for definition of bit 8 in Section 5.5, ”Translation-Lookaside Buffer (TLB),” on page 154 CR0.CD implementation-dependent behavior noted in Section 7.6.2, ”Cache Control Mechanisms,” on page 202 Added clarification on IST usage in Section 8.9.4, ”Interrupt-Stack Table,” on page 276. Added new Section 7.10, ”Secure Memory Encryption,” on page 228. Added guideline for secure AP startup in Section 15.27.8, ”Secure Multiprocessor Initialization,” on page 544 Added TLB maintenance requirement for multiprocessor VM's in Section 15.29.4, ”VMCB Changes in Support of AVIC,” on page 552. Added new Section 15.34, ”Secure Encrypted Virtualization,” on page 571

Date	Revision	Description
June 2015	3.25	Added new section 15.33 Nested Virtualization for coverage of VMSAVE and VMLOAD Virtualization and Virtual GIF. Various minor edits.
October 2013	3.24	Added description of Supervisor-Mode Execution Prevention. See Section 5.6.5 ”Supervisor-Mode Execution Prevention (CR4.SMEP) Bit” on page 160. Indicated the deprecation of the Processor Feedback Interface. See Section 17.4, ”Processor Feedback Interface,” on page 644. Added Section 17.5, ”Processor Core Power Reporting,” on page 644.
May 2013	3.23	Clarified guidelines for implementing cross-modifying code in the sub-section ”Cross-Modifying Code” on page 201. Added AVIC description. See Section 15.29, ”Advanced Virtual Interrupt Controller,” on page 546. Added L2I PMC architecture definition. See Section 13.2, ”Performance Monitoring Counters,” on page 400.
September 2012	3.22	Clarified processor behavior on write of EFER[LMA] bit in Section 3.1.7 ”Extended Feature Enable Register (EFER)” on page 56. Clarified difference between cold reset and warm reset in Section 9.3, ”Machine Check Architecture MSRs,” on page 291. Added information on FFXSR feature bit to Table 11-1 on page 336. Clarified SMM code responsibility to manage VMCB clean bits. See Section 15.15.2, ”Guidelines for Clearing VMCB Clean Bits,” on page 511. Added a note to Table 15-9 on page 514 to indicate that all encodings of TLB_CONTROL not defined are reserved. Corrected information concerning the assignment of logical APIC IDs in Section 16.6.1, ”Receiving System and IPI Interrupts,” on page 619.
March 2012	3.21	Added definition of processor feedback interface—frequency sensitivity monitor (See Section 17.4, ”Processor Feedback Interface,” on page 644) Added Instruction-Based Sampling in a new section of Chapter 13 (See Section 13.3, ”Instruction-Based Sampling,” on page 409.) Reworked Introduction and first section of Chapter 9, "Machine Check Architecture," on page 287 and added deferred error handling. Added description of CR4[FSGSBASE] bit. (See Section 3.1.3, ”CR4 Register,” on page 47.) Added references to the RDFSBASE, RDGSBASE, WRFSBASE, and WRGSBASE instructions in discussion of FS and GS segment descriptors. (See ”FS and GS Registers in 64-Bit Mode” on page 80) Added Section 6.3.2, ”Accessing Segment Register Hidden State,” on page 176.

Date	Revision	Description
December 2011	3.20	Clarified description of the Cache Disable (CD) memory type in Section 7.4 ”Memory Types” on page 192. Added caveat: an overflow of either APERF or MPERF can invalidate the effective frequency calculation. See Section 17.3, ”Determining Processor Effective Frequency,” on page 642. Other minor editorial changes.
September 2011	3.19	Added XSAVEOPT to discussions on XSAVE. Corrections to discussion on multiprocessor memory access ordering in Chapter 7. Added discussion of extended core and northbridge performance counters and feature indicators to Chapter 13. Added Lightweight Profiling (LWP) to Chapter 13. Added Global Timestamp Counter, Continuous Mode to LWP description Clarification: Function of pin A20M# is only defined in real mode. Statement added to Section 1.2.4, ”Real Addressing,” on page 10. Eliminated hardware P-state references
May 2011	3.18	Added information for OSXSAVE and XSAVE features. Added Cache Topology, Pause Filter Threshold, and XSETBV information. Updated TSC ratio information. Corrected description of FXSAVE/FXRSTOR exception behavior when CR0.EM=1
June 2010	3.17	Replaced missing figures in Chapter 8, "Exceptions and Interrupts," on page 233.
June 2010	3.16	Updated information on performance monitoring counters in ”Performance-Monitoring Counter Enable (PCE)” on page 50 and 6.2.5, ”Accessing Model-Specific Registers” on page 175. Revised Table 4-1, ”Segment Registers” on page 79. Add flush by ASID information to section 15.16, ”TLB Control” on page 513. Added information on VMCB clean field to Chapter15, ”Secure Virtual Machine” on page 483 and Appendix B, ”Layout of VMCB” on page 679. Added section 15.10, ”IOIO Intercepts” on page 501. Added section 15.30.5, ”TSC Ratio MSR (C000_0104h)” on page 568. Added section 17.2, ”Core Performance Boost” on page 641.

Date	Revision	Description
November 2009	3.15	Added section 7.5, ”Buffering and Combining Memory Writes” on page 197 Added MFENCE to list of ”Serializing Instructions” on page 206. Updated section 7.6.1, ”Cache Organization and Operation” on page 199. Updated Table 7-3, “Memory Access Ordering Rules”, on page 196 and notes. Updated 7.4, ”Memory Types” on page 192. Clarified 5.5.3, ”TLB Management” on page 155. Added ”Invalidation of Table Entry Upgrades.” on page 156. Updated ”Speculative Caching of Address Translations” on page 156. Update ”Handling of D-Bit Updates” on page 157. Revised and updated section 7.2, ”Multiprocessor Memory Access Ordering” on page 186 ff. Added information on long mode segment-limit checks in ”Extended Feature Enable Register (EFER)” on page 57table on page 57 and ”Long Mode Segment Limit Enable (LMSLE) bit” on page 58 on page 58. Added discussion of ”Data Limit Checks in 64-bit Mode” on page 123on page 123. Updated Table 6-1, “System Management Instructions”, on page 167. Updated ”Canonicalization and Consistency Checks” on page 489on page 489. Added information about the next sequential instruction pointer (nRIP) in 15.7.1, ”State Saved on Exit” on page 493. Updated priority definition of PAUSE instruction intercept in Table 15-7, “Instruction Intercepts”, on page 498. Added nRIP field to Table B-1, “VMCB Layout, Control Area”, on page 679. Clarified information on ICEBP event injection, on page 516. Deleted erroneous statement concerning the operation of the General Local Vector Table register Mask bit in section 16.4. Clarified the description of the Interrupt Command Register Delivery Status bit in section ”Interprocessor Interrupts (IPI)” on page 615on page 615.

Date	Revision	Description
September 2007	3.14	Added information on ”Speculative Caching of Address Translations,” ”Caching of Upper Level Translation Table Entries,” ”Use of Cached Entries When Reporting a Page Fault Exception,” ”Use of Cached Entries When Reporting a Page Fault Exception,” ”Handling of D-Bit Updates,” ”Invalidation of Cached Upper-level Entries by INVLPG” on page 157 and ”Handling of PDPT Entries in PAE Mode” on page 157to section 5.5.3, ”TLB Management” on page 155. Added 15.21.7, ”Interrupt Masking in Local APIC” on page 520. Added 16.3.6, ”Extended APIC Control Register” on page 607; clarified the use of the ICR DS bit in 16.5, ”Interprocessor Interrupts (IPI)” on page 615. Added minor clarifications and corrected typographical and formatting errors.
July 2007	3.13	Added 5.3.5, ”1-Gbyte Page Translation” on page 147. Added 7.2, ”Multiprocessor Memory Access Ordering” on page 186 Added divide-by-zero exception to Table 8-9, “Simultaneous Interrupt Priorities”, on page 255. Added information on ”CPU Watchdog Timer Register” on page 295and ”Machine-Check Miscellaneous-Error Information Register 0 (MC*i*_MISC0)” on page 302to Chapter 9. Added SSE4A support to Chapter 11, ”SSE, MMX, and x87 Programming” on page 335. Added Monitor and MWAIT intercept information to section 15.9, ”Instruction Intercepts” on page 498 and reorganized intercept information; clarified 15.16.1, ”TLB Flush” on page 513. Added Monitor and MWAIT intercepts to tables B-1, ”VMCB Layout, Control Area” on page 679 and C-1, ”SVM Intercept Codes” on page 693. Added Chapter 16, ”Advanced Programmable Interrupt Controller (APIC)” on page 601, Chapter 17, ”OS-Visible Workaround Information” on page 515, Chapter 17, ”Hardware Performance Monitoring and Control” on page 639. Added Table A-7, “Secure Virtual Machine MSR Cross-Reference”, on page 675. Added minor clarifications and corrected typographical and formatting errors.
September 2006	3.12	Added numerous minor clarifications.
December 2005	3.11	Added Chapter 15, Secure Virtual Machine. Incorporated numerous factual corrections and updates.
February 2005	3.10	Corrected Table 8-6, “General-Protection Exception Conditions”, on page 246. Added SSE3 information. Clarified and corrected information on the CPUID instruction and feature identification. Added information on the RDTSCP instruction. Clarified information about MTRRs and PATs in multiprocessing systems.

Date	Revision	Description
September 2003	3.09	Corrected numerous minor typographical errors.
April 2003	3.08	Clarified terms in section on FXSAVE/FXSTOR. Corrected several minor errors of omission. Documentation of CR0.NW bit has been corrected. Several register diagrams and figure labels have been corrected. Description of shared cache lines has been clarified in 7.3, ”Memory Coherency and Protocol” on page 189.
September 2002	3.07	Made numerous small grammatical changes and factual clarifications. Added Revision History.

Preface

About This Book

This book is part of a multivolume work entitled the *AMD64 Architecture Programmer's Manual*. This table lists each volume and its order number.

Title	Order No.
Volume 1: Application Programming	24592
Volume 2: System Programming	24593
Volume 3: General-Purpose and System Instructions	24594
Volume 4: 128-Bit and 256-Bit Media Instructions	26568
Volume 5: 64-Bit Media and x87 Floating-Point Instructions	26569

Audience

This volume (Volume 2) is intended for programmers writing operating systems, loaders, linkers, device drivers, or system utilities. It assumes an understanding of AMD64 architecture application-level programming as described in Volume 1.

This volume describes the AMD64 architecture's resources and functions that are managed by system software, including operating-mode control, memory management, interrupts and exceptions, task and state-change management, system-management mode (including power management), multi-processor support, debugging, and processor initialization.

Application-programming topics are described in Volume 1. Details about each instruction are described in Volumes 3, 4, and 5.

Organization

This volume begins with an overview of system programming and differences between the x86 and AMD64 architectures. This is followed by chapters that describe the following details of system programming:

- *System Resources*—The system registers and processor ID (CPUID) functions.
- *Segmented Virtual Memory*—The segmented-memory models supported by the architecture and their associated data structures and protection checks.
- *Page Translation and Protection*—The page-translation functions supported by the architecture and their associated data structures and protection checks.

- *System Instructions*—The instructions used to manage system functions.
- *Memory System*—The memory-system hierarchy and its resources and protocols, including memory-characterization, caching, and buffering functions.
- *Exceptions and Interrupts*—Details about the types and causes of exceptions and interrupts, and the methods of transferring control during these events.
- *Machine-Check Mechanism*—The resources and functions that support detection and handling of machine-check errors.
- *System-Management Mode*—The resources and functions that support system-management mode (SMM), including power-management functions.
- *SSE, MMX, and x87 Programming*—The resources and functions that support use (by application software) and state-saving (by the operation system) of the 256-bit media, 128-bit media, 64-bit media, and x87 floating-point instructions.
- *Multiple-Processor Management*—The features of the instruction set and the system resources and functions that support multiprocessing environments.
- *Debug and Performance Resources*—The system resources and functions that support software debugging and performance monitoring.
- *Legacy Task Management*—Support for the legacy hardware multitasking functions, including register resources and data structures.
- *Processor Initialization and Long-Mode Activation*—The methods by which system software initializes and changes operating modes.
- *Mixing Code Across Operating Modes*—Things to remember when running programs in different operating modes.
- *Secure Virtual Machine*—The system resources that support machine virtualization.
- *Advanced Programmable Interrupt Controller (APIC) operation.*

There are appendices describing details of model-specific registers (MSRs) and machine-check implementations. Definitions assumed throughout this volume are listed below. The index at the end of this volume cross-references topics within the volume. For other topics relating to the AMD64 architecture, see the tables of contents and indexes of the other volumes.

Conventions and Definitions

The section which follows, **Notational Conventions,** describes notational conventions used in this volume. The next section, **Definitions,** lists a number of terms used in this volume along with their technical definitions. Some of these definitions assume knowledge of the legacy x86 architecture. See “Related Documents” on page lvii for further information about the legacy x86 architecture. Finally, the **Registers** section lists the registers which are a part of the system programming model.

Notational Conventions

#GP(0)

An instruction exception—in this example, a general-protection exception with error code of 0.

1011b

A binary value—in this example, a 4-bit value.

F0EA_0B02h

A hexadecimal value. Underscore characters may be inserted to improve readability.

128

Numbers without an alpha suffix are decimal unless the context indicates otherwise.

7:4

A bit range, from bit 7 to 4, inclusive. The high-order bit is shown first. Commas may be inserted to indicate gaps.

CPUID Fn*XXXX_XXXX_RRR*[*FieldName*]

Support for optional features or the value of an implementation-specific parameter of a processor can be discovered by executing the CPUID instruction on that processor. To obtain this value, software must execute the CPUID instruction with the function code *XXXX_XXXX*h in EAX and then examine the field *FieldName* returned in register *RRR*. If the "*_RRR*" notation is followed by "_x*YYY*", register ECX must be set to the value *YYY*h before executing CPUID. When *FieldName* is not given, the entire contents of register *RRR* contains the desired value. When determining optional feature support, if the bit identified by *FieldName* is set to a one, the feature is supported on that processor.

CR0–CR4

A register range, from register CR0 through CR4, inclusive, with the low-order register first.

CR0[PE], CR0.PE

Notation for referring to a field within a register—in this case, the PE field of the CR0 register.

CR0[PE] = 1, CR0.PE = 1

The PE field of the CR0 register is set (contains the value 1).

EFER[LME] = 0, EFER.LME = 0

The LME field of the EFER register is cleared (contains a value of 0).

DS:SI

A far pointer or logical address. The real address or segment descriptor specified by the segment register (DS in this example) is combined with the offset contained in the second register (SI in this example) to form a real or virtual address.

RFLAGS[13:12]

A field within a register identified by its bit range. In this example, corresponding to the IOPL field.

Definitions

16-bit mode

Legacy mode or compatibility mode in which a 16-bit address size is active. See *legacy mode* and *compatibility mode*.

32-bit mode

Legacy mode or compatibility mode in which a 32-bit address size is active. See *legacy mode* and *compatibility mode*.

64-bit mode

A submode of *long mode*. In 64-bit mode, the default address size is 64 bits and new features, such as register extensions, are supported for system and application software.

absolute

Said of a displacement that references the base of a code segment rather than an instruction pointer. Contrast with *relative*.

ASID

Address space identifier.

byte

Eight bits.

clear

To write a bit value of 0. Compare *set*.

compatibility mode

A submode of *long mode*. In compatibility mode, the default address size is 32 bits, and legacy 16-bit and 32-bit applications run without modification.

commit

To irreversibly write, in program order, an instruction's result to software-visible storage, such as a register (including flags), the data cache, an internal write buffer, or memory.

CPL

Current privilege level.

direct

Referencing a memory location whose address is included in the instruction's syntax as an immediate operand. The address may be an absolute or relative address. Compare *indirect*.

dirty data

Data held in the processor's caches or internal buffers that is more recent than the copy held in main memory.

displacement

A signed value that is added to the base of a segment (absolute addressing) or an instruction pointer (relative addressing). Same as *offset*.

doubleword

Two words, or four bytes, or 32 bits.

double quadword

Eight words, or 16 bytes, or 128 bits. Also called *octword*.

effective address size

The address size for the current instruction after accounting for the default address size and any address-size override prefix.

effective operand size

The operand size for the current instruction after accounting for the default operand size and any operand-size override prefix.

exception

An abnormal condition that occurs as the result of executing an instruction. The processor's response to an exception depends on the type of the exception. For all exceptions except 128-bit media SIMD floating-point exceptions and x87 floating-point exceptions, control is transferred to the handler (or service routine) for that exception, as defined by the exception's vector. For floating-point exceptions defined by the IEEE 754 standard, there are both masked and unmasked responses. When unmasked, the exception handler is called, and when masked, a default response is provided instead of calling the handler.

flush

An often ambiguous term meaning (1) writeback, if modified, and invalidate, as in "flush the cache line," or (2) invalidate, as in "flush the pipeline," or (3) change a value, as in "flush to zero."

GDT

Global descriptor table.

GIF

Global interrupt flag.

GPA

Guest physical address. In a virtualized environment, the page tables maintained by the guest operating system provide the translation from the linear (virtual) address to the guest physical

address. Nested page tables define the translation of the GPA to the host physical address (HPA). See *SPA* and *HPA*.

HPA

Host physical address. The address space owned by the virtual machine monitor. In a virtualized environment, nested page translation tables controlled by the VMM provide the translation from the guest physical address to the host physical address. See *GPA*.

IDT

Interrupt descriptor table.

IGN

Ignored. Value written is ignored by hardware. Value returned on a read is indeterminate. See *reserved*.

indirect

Referencing a memory location whose address is in a register or other memory location. The address may be an absolute or relative address. Compare *direct*.

IRB

The virtual-8086 mode interrupt-redirection bitmap.

IST

The long-mode interrupt-stack table.

IVT

The real-address mode interrupt vector table.

LDT

Local descriptor table.

legacy x86

The legacy x86 architecture. See “Related Documents” on page lvii for descriptions of the legacy x86 architecture.

legacy mode

An operating mode of the AMD64 architecture in which existing 16-bit and 32-bit applications and operating systems run without modification. A processor implementation of the AMD64 architecture can run in either *long mode* or *legacy mode*. Legacy mode has three submodes, *real mode*, *protected mode*, and *virtual-8086 mode*.

LIP

Linear Instruction Pointer. LIP = (CS.base + rIP).

long mode

An operating mode unique to the AMD64 architecture. A processor implementation of the AMD64 architecture can run in either *long mode* or *legacy mode*. Long mode has two submodes, *64-bit mode* and *compatibility mode*.

lsb

Least-significant bit.

LSB

Least-significant byte.

main memory

Physical memory, such as RAM and ROM (but not cache memory) that is installed in a particular computer system.

mask

(1) A control bit that prevents the occurrence of a floating-point exception from invoking an exception-handling routine. (2) A field of bits used for a control purpose.

MBZ

Must be zero. If software attempts to set an MBZ bit to 1 in a system register, a general-protection exception (#GP) occurs; if in a translation table entry, a reserved-bit page fault exception (#PF) will occur if the hardware attempts to use the entry for address translation. See *reserved*.

memory

Unless otherwise specified, *main memory*.

ModRM

A byte following an instruction opcode that specifies address calculation based on mode (Mod), register (R), and memory (M) variables.

moffset

A 16, 32, or 64-bit offset that specifies a memory operand directly, without using a ModRM or SIB byte.

msb

Most-significant bit.

MSB

Most-significant byte.

octword

Same as *double quadword*.

offset

Same as *displacement*.

overflow

The condition in which a floating-point number is larger in magnitude than the largest, finite, positive or negative number that can be represented in the data-type format being used.

PAE

Physical-address extensions.

physical memory

Actual memory, consisting of *main memory* and cache.

probe

A check for an address in a processor's caches or internal buffers. *External probes* originate outside the processor, and *internal probes* originate within the processor.

procedure stack

A portion of a stack segment in memory that is used to link procedures. Also known as a *program stack*.

program stack

See *procedure stack*.

protected mode

A submode of *legacy mode*.

quadword

Four words, or eight bytes, or 64 bits.

RAZ

Value returned on a read is always zero (0) regardless of what was previously written. See *reserved*.

real-address mode

See *real mode*.

real mode

A short name for *real-address mode*, a submode of *legacy mode*.

relative

Referencing with a displacement (also called offset) from an instruction pointer rather than the base of a code segment. Contrast with *absolute*.

reserved

Fields marked as reserved may be used at some future time.

To preserve compatibility with future processors, reserved fields require special handling when read or written by software. Software must not depend on the state of a reserved field (unless qualified as RAZ), nor upon the ability of such fields to return a previously written state.

If a field is marked reserved without qualification, software must not change the state of that field; it must reload that field with the same value returned from a prior read.

Reserved fields may be qualified as IGN, MBZ, RAZ, or SBZ (see definitions).

REX

An instruction prefix that specifies a 64-bit operand size and provides access to additional registers.

RIP-relative addressing

Addressing relative to the 64-bit RIP instruction pointer.

SBZ

Should be zero. An attempt by software to set an SBZ bit to 1 results in undefined behavior. See *reserved*.

shadow stack

A shadow stack is a separate, protected stack that is conceptually parallel to the procedure stack and used only by the shadow stack feature.

set

To write a bit value of 1. Compare *clear*.

SIB

A byte following an instruction opcode that specifies address calculation based on scale (S), index (I), and base (B).

SPA

System physical address. The address directly used to address system memory. Under SVM, also known as the host physical address. See *HPA*.

sticky bit

A bit that is set or cleared by hardware and that remains in that state until explicitly changed by software.

SVM

Secure virtual machine. AMD's virtualization architecture. SVM is defined in Chapter 15 on page 483.

System software

Privileged software that owns and manages the hardware resources of a system after initialization by *system firmware* and controls access to these resources. In a non-virtualized environment,

system software is provided by the operating system. In a virtualized environment, system software is largely equivalent to the virtual machine monitor (VMM), also commonly known as the *hypervisor*.

TOP

The x87 top-of-stack pointer.

TSS

Task-state segment.

underflow

The condition in which a floating-point number is smaller in magnitude than the smallest nonzero, positive or negative number that can be represented in the data-type format being used.

vector

(1) A set of integer or floating-point values, called *elements*, that are packed into a single data object. Most of the SSE and 64-bit media instructions use vectors as operands.

(2) An index into an interrupt descriptor table (IDT), used to access exception handlers. Compare *exception*.

virtual-8086 mode

A submode of *legacy mode*.

VMCB

Virtual machine control block.

VMM

Virtual machine monitor.

word

Two bytes, or 16 bits.

x86

See *legacy x86*.

Registers

In the following list of registers, the names are used to refer either to a given register or to the contents of that register:

AH–DH

The high 8-bit AH, BH, CH, and DH registers. Compare *AL–DL*.

AL–DL

The low 8-bit AL, BL, CL, and DL registers. Compare *AH–DH*.

AL–r15B

The low 8-bit AL, BL, CL, DL, SIL, DIL, BPL, SPL, and R8B–R15B registers, available in 64-bit mode.

BP

Base pointer register.

CR*n*

Control register number *n*.

CS

Code segment register.

eAX–eSP

The 16-bit AX, BX, CX, DX, DI, SI, BP, and SP registers or the 32-bit EAX, EBX, ECX, EDX, EDI, ESI, EBP, and ESP registers. Compare *rAX–rSP*.

EFER

Extended features enable register.

eFLAGS

16-bit or 32-bit flags register. Compare *rFLAGS*.

EFLAGS

32-bit (extended) flags register.

eIP

16-bit or 32-bit instruction-pointer register. Compare *rIP*.

EIP

32-bit (extended) instruction-pointer register.

FLAGS

16-bit flags register.

GDTR

Global descriptor table register.

GPRs

General-purpose registers. For the 16-bit data size, these are AX, BX, CX, DX, DI, SI, BP, and SP. For the 32-bit data size, these are EAX, EBX, ECX, EDX, EDI, ESI, EBP, and ESP. For the 64-bit data size, these include RAX, RBX, RCX, RDX, RDI, RSI, RBP, RSP, and R8–R15.

IDTR

Interrupt descriptor table register.

IP

16-bit instruction-pointer register.

LDTR

Local descriptor table register.

MSR

Model-specific register.

r8–r15

The 8-bit R8B–R15B registers, or the 16-bit R8W–R15W registers, or the 32-bit R8D–R15D registers, or the 64-bit R8–R15 registers.

rAX–rSP

The 16-bit AX, BX, CX, DX, DI, SI, BP, and SP registers, or the 32-bit EAX, EBX, ECX, EDX, EDI, ESI, EBP, and ESP registers, or the 64-bit RAX, RBX, RCX, RDX, RDI, RSI, RBP, and RSP registers. Replace the placeholder *r* with nothing for 16-bit size, “E” for 32-bit size, or “R” for 64-bit size.

RAX

64-bit version of the EAX register.

RBP

64-bit version of the EBP register.

RBX

64-bit version of the EBX register.

RCX

64-bit version of the ECX register.

RDI

64-bit version of the EDI register.

RDX

64-bit version of the EDX register.

rFLAGS

16-bit, 32-bit, or 64-bit flags register. Compare *RFLAGS*.

RFLAGS

64-bit flags register. Compare *rFLAGS*.

rIP

16-bit, 32-bit, or 64-bit instruction-pointer register. Compare *RIP*.

RIP
: 64-bit instruction-pointer register.

RSI
: 64-bit version of the ESI register.

RSP
: 64-bit version of the ESP register.

SP
: Stack pointer register.

SS
: Stack segment register.

SSP
: Shadow-stack pointer register.

TPR
: Task priority register (CR8), a new register introduced in the AMD64 architecture to speed interrupt management.

TR
: Task register.

YMM/XMM
: Set of sixteen (eight accessible in legacy and compatibility modes) 256-bit wide registers that hold scala and vector operands used by the SSE instructions.

Endian Order

The x86 and AMD64 architectures address memory using little-endian byte-ordering. Multibyte values are stored with their least-significant byte at the lowest byte address, and they are illustrated with their least significant byte at the right side. Strings are illustrated in reverse order, because the addresses of their bytes increase from right to left.

1 System-Programming Overview

This entire volume is intended for system-software developers—programmers writing operating systems, loaders, linkers, device drivers, or utilities that require access to system resources. These system resources are generally available only to software running at the highest-privilege level (CPL=0), also referred to as *privileged software*. Privilege levels and their interactions are fully described in “Segment-Protection Overview” on page 104.

This chapter introduces the basic features and capabilities of the AMD64 architecture that are available to system-software developers. The concepts include:

- The supported address forms and how memory is organized.
- How memory-management hardware makes use of the various address forms to access memory.
- The processor operating modes, and how the memory-management hardware supports each of those modes.
- The system-control registers used to manage system resources.
- The interrupt and exception mechanism, and how it is used to interrupt program execution and to report errors.
- Additional, miscellaneous features available to system software, including support for hardware multitasking, reporting machine-check exceptions, debugging software problems, and optimizing software performance.

Many of the legacy features and capabilities are enhanced by the AMD64 architecture to support 64-bit operating systems and applications, while providing backward-compatibility with existing software.

1.1 Memory Model

The AMD64 architecture memory model is designed to allow system software to manage application software and associated data in a secure fashion. The memory model is backward-compatible with the legacy memory model. Hardware-translation mechanisms are provided to map addresses between virtual-memory space and physical-memory space. The translation mechanisms allow system software to relocate applications and data transparently, either anywhere in physical-memory space, or in areas on the system hard drive managed by the operating system.

In long mode, the AMD64 architecture implements a flat-memory model. In legacy mode, the architecture implements all legacy memory models.

1.1.1 Memory Addressing

The AMD64 architecture supports address relocation. To do this, several types of addresses are needed to completely describe memory organization. Specifically, four types of addresses are defined by the AMD64 architecture:

- Logical addresses
- Effective addresses, or segment offsets, which are a portion of the logical address.
- Linear (virtual) addresses
- Physical addresses

Logical Addresses. A *logical address* is a reference into a segmented-address space. It is comprised of the segment selector and the effective address. Notationally, a logical address is represented as

```
Logical Address = Segment Selector : Offset
```

The segment selector specifies an entry in either the global or local descriptor table. The specified descriptor-table entry describes the segment location in virtual-address space, its size, and other characteristics. The effective address is used as an offset into the segment specified by the selector.

Logical addresses are often referred to as *far pointers*. Far pointers are used in software addressing when the segment reference must be explicit (i.e., a reference to a segment outside the current segment).

Effective Addresses. The offset into a memory segment is referred to as an effective address (see “Segmentation” on page 5 for a description of segmented memory). Effective addresses are formed by adding together elements comprising a base value, a scaled-index value, and a displacement value. The effective-address computation is represented by the equation

```
Effective Address = Base + (Scale x Index) + Displacement
```

The elements of an effective-address computation are defined as follows:

- *Base*—A value stored in any general-purpose register.
- *Scale*—A positive value of 1, 2, 4, or 8.
- *Index*—A two’s-complement value stored in any general-purpose register.
- *Displacement*—An 8-bit, 16-bit, or 32-bit two’s-complement value encoded as part of the instruction.

Effective addresses are often referred to as *near pointers*. A near pointer is used when the segment selector is known implicitly or when the flat-memory model is used.

Long mode defines a 64-bit effective-address length. If a processor implementation does not support the full 64-bit virtual-address space, the effective address must be in *canonical form* (see “Canonical Address Form” on page 4).

Linear (Virtual) Addresses. The segment-selector portion of a logical address specifies a segment-descriptor entry in either the global or local descriptor table. The specified segment-descriptor entry contains the segment-base address, which is the starting location of the segment in linear-address space. A *linear address* is formed by adding the segment-base address to the effective address (segment offset), which creates a reference to any byte location within the supported linear-address space. Linear addresses are often referred to as *virtual addresses*, and both terms are used interchangeably throughout this document.

```
Linear Address = Segment Base Address + Effective Address
```

When the flat-memory model is used—as in 64-bit mode—a segment-base address is treated as 0. In this case, the linear address is identical to the effective address. In long mode, linear addresses must be in canonical address form, as described in “Canonical Address Form” on page 4.

Physical Addresses. A *physical address* is a reference into the physical-address space, typically main memory. Physical addresses are translated from virtual addresses using page-translation mechanisms. See “Paging” on page 7 for information on how the paging mechanism is used for virtual-address to physical-address translation. When the paging mechanism is not enabled, the virtual (linear) address is used as the physical address.

1.1.2 Memory Organization

The AMD64 architecture organizes memory into *virtual memory* and *physical memory*. Virtual-memory and physical-memory spaces can be (and usually are) different in size. Generally, the virtual-address space is much larger than physical-address memory. System software relocates applications and data between physical memory and the system hard disk to make it appear that much more memory is available than really exists. System software then uses the hardware memory-management mechanisms to map the larger virtual-address space into the smaller physical-address space.

Virtual Memory. Software uses virtual addresses to access locations within the virtual-memory space. System software is responsible for managing the relocation of applications and data in virtual-memory space using segment-memory management. System software is also responsible for mapping virtual memory to physical memory through the use of page translation. The AMD64 architecture supports different virtual-memory sizes using the following address-translation modes:

- *Protected Mode*—This mode supports 4 gigabytes of virtual-address space using 32-bit virtual addresses.
- *Long Mode*—This mode supports 16 exabytes of virtual-address space using 64-bit virtual addresses. A given implementation may however support less than this, as reported by the CPUID feature identification facility.

Physical Memory. Physical addresses are used to directly access main memory. For a particular computer system, the size of the *available* physical-address space is equal to the amount of main memory installed in the system. The maximum amount of physical memory accessible depends on the processor implementation and on the address-translation mode. The AMD64 architecture supports varying physical-memory sizes using the following address-translation modes:

- *Real-Address Mode*—This mode, also called *real mode*, supports 1 megabyte of physical-address space using 20-bit physical addresses. This address-translation mode is described in "Real Addressing" on page 10. Real mode is available only from legacy mode (see "Legacy Modes" on page 14).
- *Legacy Protected Mode*—This mode supports several different address-space sizes, depending on the translation mechanism used and whether extensions to those mechanisms are enabled.

  Legacy protected mode supports 4 gigabytes of physical-address space using 32-bit physical addresses. Both segment translation (see "Segmentation" on page 5) and page translation (see "Paging" on page 7) can be used to access the physical address space, when the processor is running in legacy protected mode.

  When the physical-address size extensions are enabled (see "Physical-Address Extensions (PAE) Bit" on page 132), the page-translation mechanism can be extended to support 52-bit physical addresses. 52-bit physical addresses allow up to 4 petabytes of physical-address space to be supported. (Currently, the AMD64 architecture supports 40-bit addresses in this mode, allowing up to 1 terabyte of physical-address space to be supported.
- *Long Mode*—This mode is unique to the AMD64 architecture. This mode supports up to 4 petabytes of physical-address space using 52-bit physical addresses. Long mode requires the use of page-translation and the physical-address size extensions (PAE).

1.1.3 Canonical Address Form

Long mode defines 64 bits of virtual-address space, but processor implementations can support less. Although some processor implementations do not use all 64 bits of the virtual address, they all check bits 63 through the most-significant implemented bit to see if those bits are all zeros or all ones. An address that complies with this property is in *canonical address form*. In most cases, a virtual-memory reference that is not in canonical form (in either the linear or effective form of the address) causes a general-protection exception (#GP) to occur. However, implied stack references where the stack address is not in canonical form causes a stack exception (#SS) to occur. Implied stack references include all push and pop instructions, and any instruction using RSP or RBP as a base register.

By checking canonical-address form, the AMD64 architecture prevents software from exploiting unused high bits of pointers for other purposes. Software complying with canonical-address form on a specific processor implementation can run unchanged on long-mode implementations supporting larger virtual-address spaces.

1.2 Memory Management

Memory management consists of the methods by which addresses generated by software are translated by segmentation and/or paging into addresses in physical memory. Memory management is not visible to application software. It is handled by the system software and processor hardware.

1.2.1 Segmentation

Segmentation was originally created as a method by which system software could isolate software processes (tasks), and the data used by those processes, from one another in an effort to increase the reliability of systems running multiple processes simultaneously.

The AMD64 architecture is designed to support all forms of legacy segmentation. However, most modern system software does not use the segmentation features available in the legacy x86 architecture. Instead, system software typically handles program and data isolation using page-level protection. For this reason, the AMD64 architecture dispenses with multiple segments in 64-bit mode and, instead, uses a flat-memory model. The elimination of segmentation allows new 64-bit system software to be coded more simply, and it supports more efficient management of multi-processing than is possible in the legacy x86 architecture.

Segmentation is, however, used in compatibility mode and legacy mode. Here, segmentation is a form of base memory-addressing that allows software and data to be relocated in virtual-address space off of an arbitrary base address. Software and data can be relocated in virtual-address space using one or more variable-sized *memory segments.* The legacy x86 architecture provides several methods of restricting access to segments from other segments so that software and data can be protected from interfering with each other.

In compatibility and legacy modes, up to 16,383 unique segments can be defined. The base-address value, segment size (called a *limit*), protection, and other attributes for each segment are contained in a data structure called a *segment descriptor*. Collections of segment descriptors are held in *descriptor tables*. Specific segment descriptors are referenced or selected from the descriptor table using a *segment selector register*. Six segment-selector registers are available, providing access to as many as six segments at a time.

Figure 1-1 on page 6 shows an example of segmented memory. Segmentation is described in Chapter 4, “Segmented Virtual Memory.”

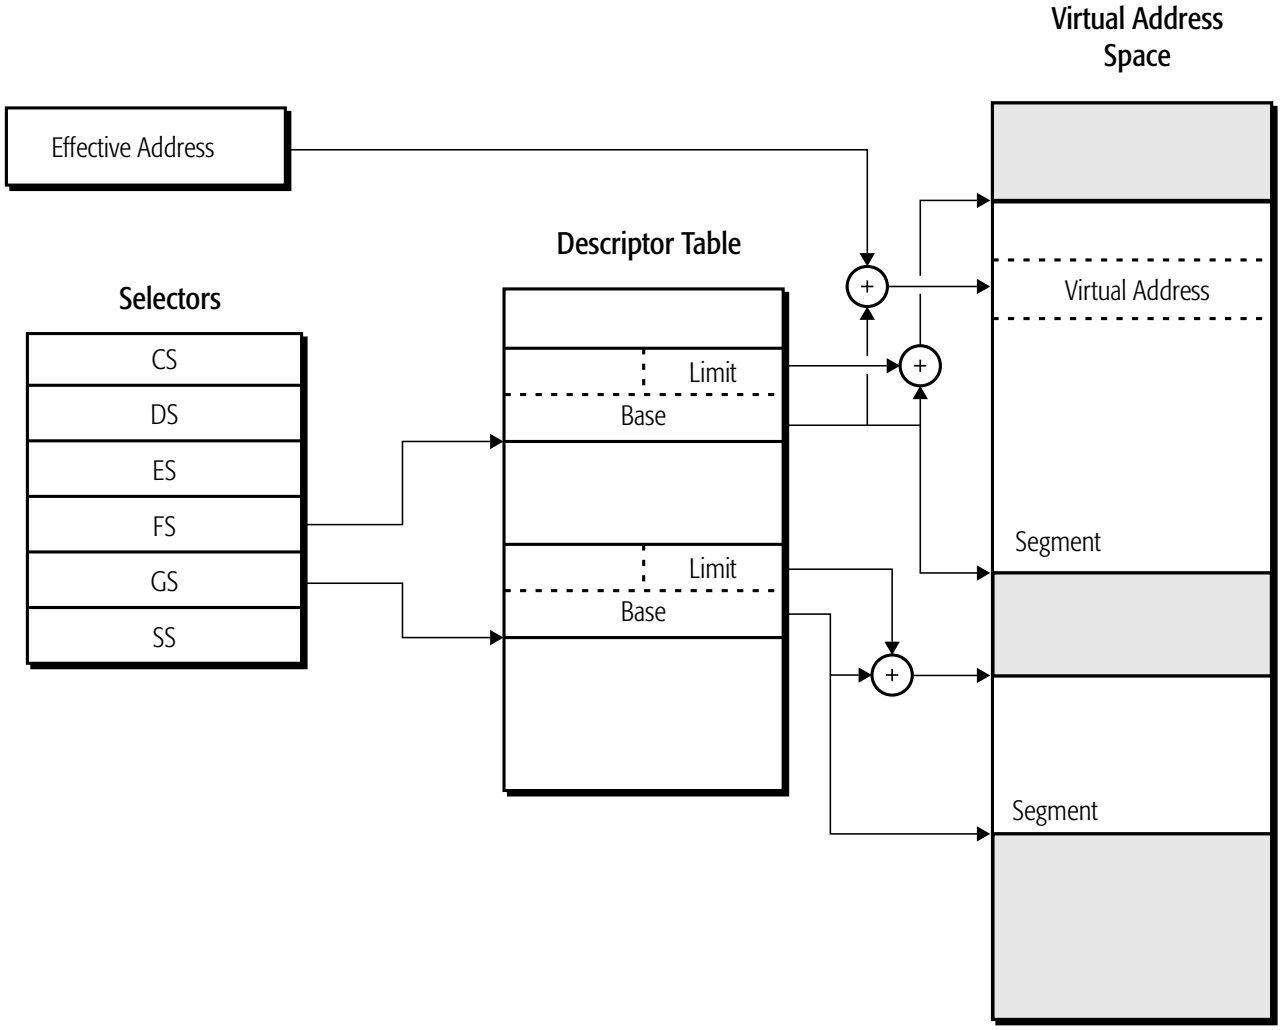

Figure 1-1. Segmented-Memory Model

Flat Segmentation. One special case of segmented memory is the flat-memory model. In the legacy flat-memory model, all segment-base addresses have a value of 0, and the segment limits are fixed at 4 Gbytes. Segmentation cannot be disabled but use of the flat-memory model effectively disables segment translation. The result is a virtual address that equals the effective address. Figure 1-2 on page 7 shows an example of the flat-memory model.

Software running in 64-bit mode automatically uses the flat-memory model. In 64-bit mode, the segment base is treated as if it were 0, and the segment limit is ignored. This allows an effective addresses to access the full virtual-address space supported by the processor.

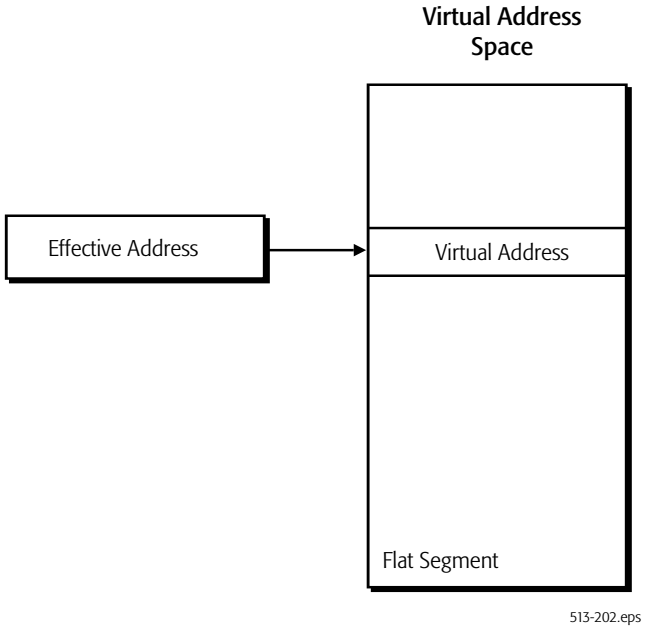

Figure 1-2. Flat Memory Model

1.2.2 Paging

Paging allows software and data to be relocated in physical-address space using fixed-size blocks called *physical pages*. The legacy x86 architecture supports three different physical-page sizes of 4 Kbytes, 2 Mbytes, and 4 Mbytes. As with segment translation, access to physical pages by lesser-privileged software can be restricted.

Page translation uses a hierarchical data structure called a page-translation table to translate virtual pages into physical-pages. The number of levels in the translation-table hierarchy can be as few as one or as many as four, depending on the physical-page size and processor operating mode. Translation tables are aligned on 4-Kbyte boundaries. Physical pages must be aligned on 4-Kbyte, 2-Mbyte, or 4-Mbyte boundaries, depending on the physical-page size.

Each table in the translation hierarchy is indexed by a portion of the virtual-address bits. The entry referenced by the table index contains a pointer to the base address of the next-lower-level table in the translation hierarchy. In the case of the lowest-level table, its entry points to the physical-page base address. The physical page is then indexed by the least-significant bits of the virtual address to yield the physical address.

Figure 1-3 on page 8 shows an example of paged memory with three levels in the translation-table hierarchy. Paging is described in Chapter 5, “Page Translation and Protection.”

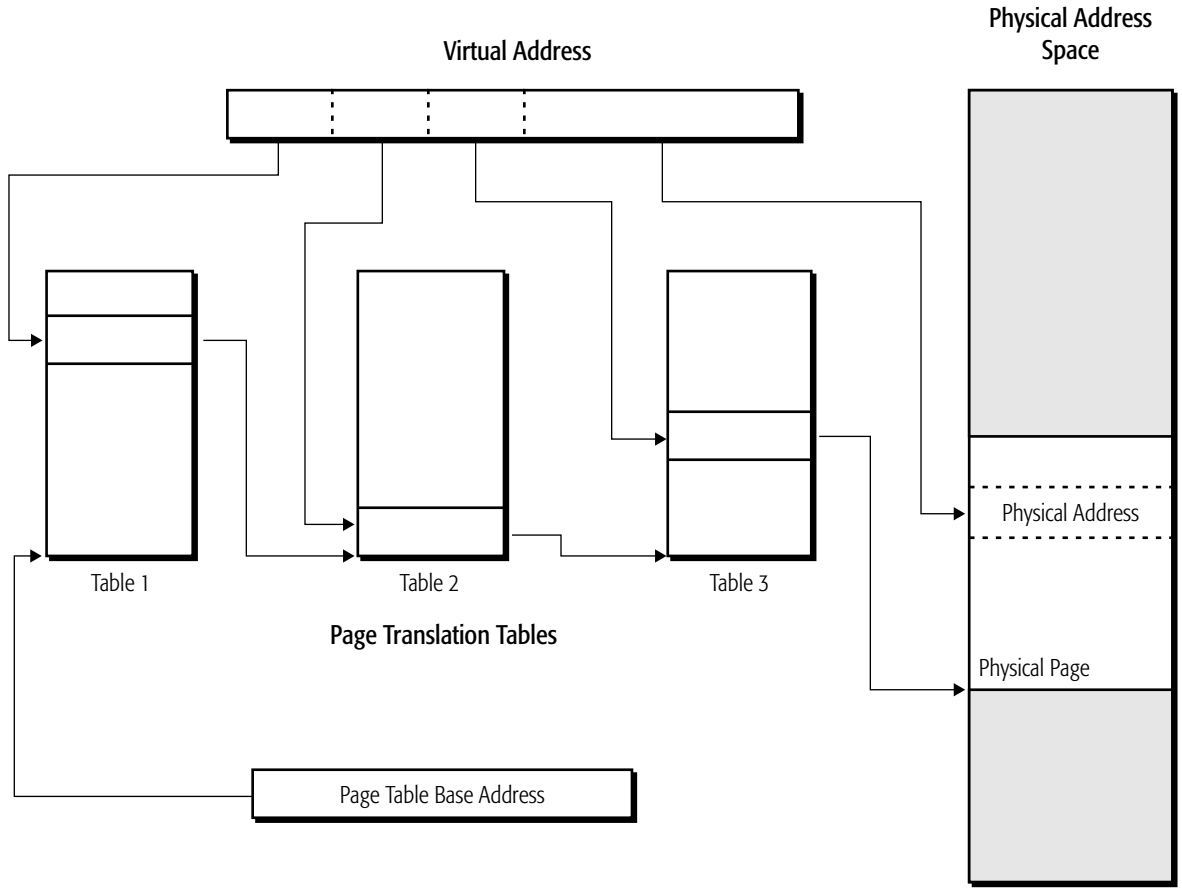

Figure 1-3. Paged Memory Model

Software running in long mode is required to have page translation enabled.

1.2.3 Mixing Segmentation and Paging

Memory-management software can combine the use of segmented memory and paged memory. Because segmentation cannot be disabled, paged-memory management requires some minimum initialization of the segmentation resources. Paging can be completely disabled, so segmented-memory management does not require initialization of the paging resources.

Segments can range in size from a single byte to 4 Gbytes in length. It is therefore possible to map multiple segments to a single physical page and to map multiple physical pages to a single segment. Alignment between segment and physical-page boundaries is not required, but memory-management software is simplified when segment and physical-page boundaries are aligned.

The simplest, most efficient method of memory management is the flat-memory model. In the flat-memory model, all segment base addresses have a value of 0 and the segment limits are fixed at 4 Gbytes. The segmentation mechanism is still used each time a memory reference is made, but because virtual addresses are identical to effective addresses in this model, the segmentation mechanism is effectively ignored. Translation of virtual (or effective) addresses to physical addresses takes place using the paging mechanism only.

Because 64-bit mode disables segmentation, it uses a flat, paged-memory model for memory management. The 4 Gbyte segment limit is ignored in 64-bit mode. Figure 1-4 shows an example of this model.

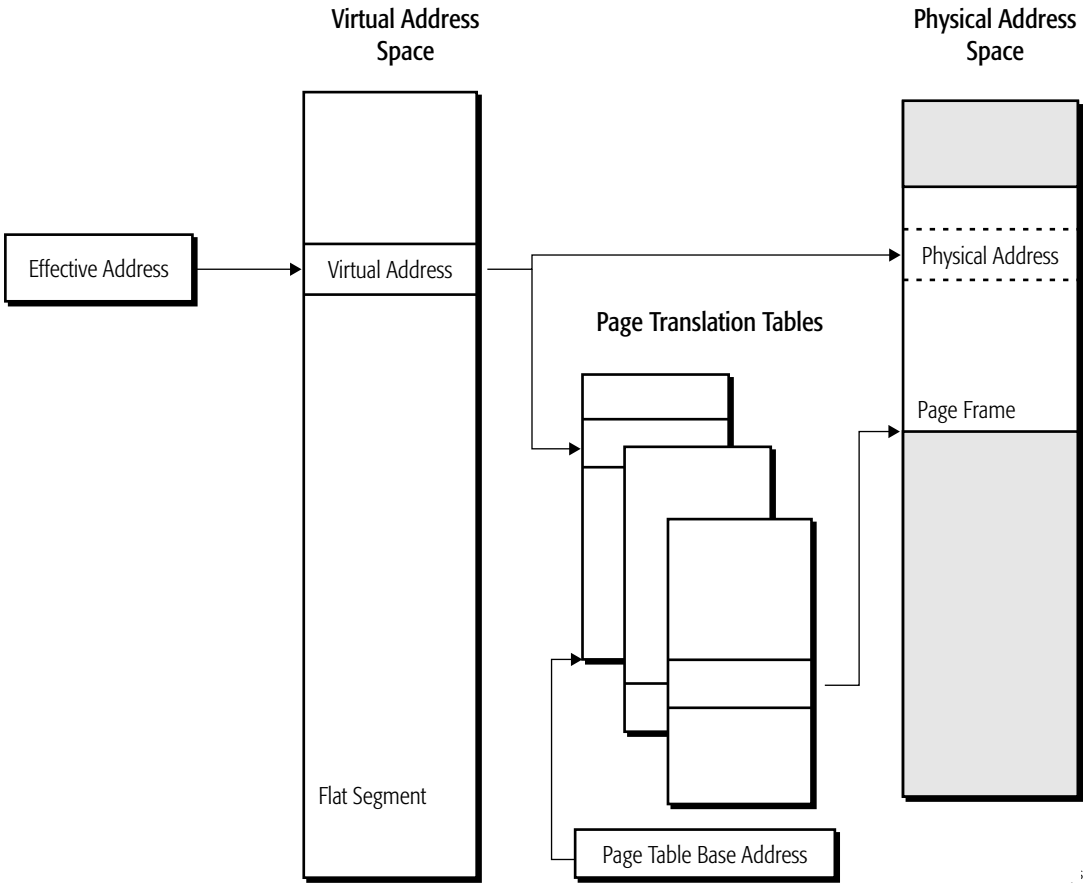

Figure 1-4. 64-Bit Flat, Paged-Memory Model

1.2.4 Real Addressing

Real addressing is a legacy-mode form of address translation used in real mode. This simplified form of address translation is backward compatible with 8086-processor effective-to-physical address translation. In this mode, 16-bit effective addresses are mapped to 20-bit physical addresses, providing a 1-Mbyte physical-address space.

Segment selectors are used in real-address translation, but not as an index into a descriptor table. Instead, the 16-bit segment-selector value is shifted left by 4 bits to form a 20-bit segment-base address. The 16-bit effective address is added to this 20-bit segment base address to yield a 20-bit physical address. If the sum of the segment base and effective address carries over into bit 20, that bit can be optionally truncated to mimic the 20-bit address wrapping of the 8086 processor by using the A20M# input signal to mask the A20 address bit.

A20 address bit masking should only be used in real mode (see next section for information on real mode). Use in other modes may result in address translation errors.

Real-address translation supports a 1-Mbyte physical-address space using up to 64K segments aligned on 16-byte boundaries. Each segment is exactly 64 Kbytes long. Figure 1-5 shows an example of real-address translation.

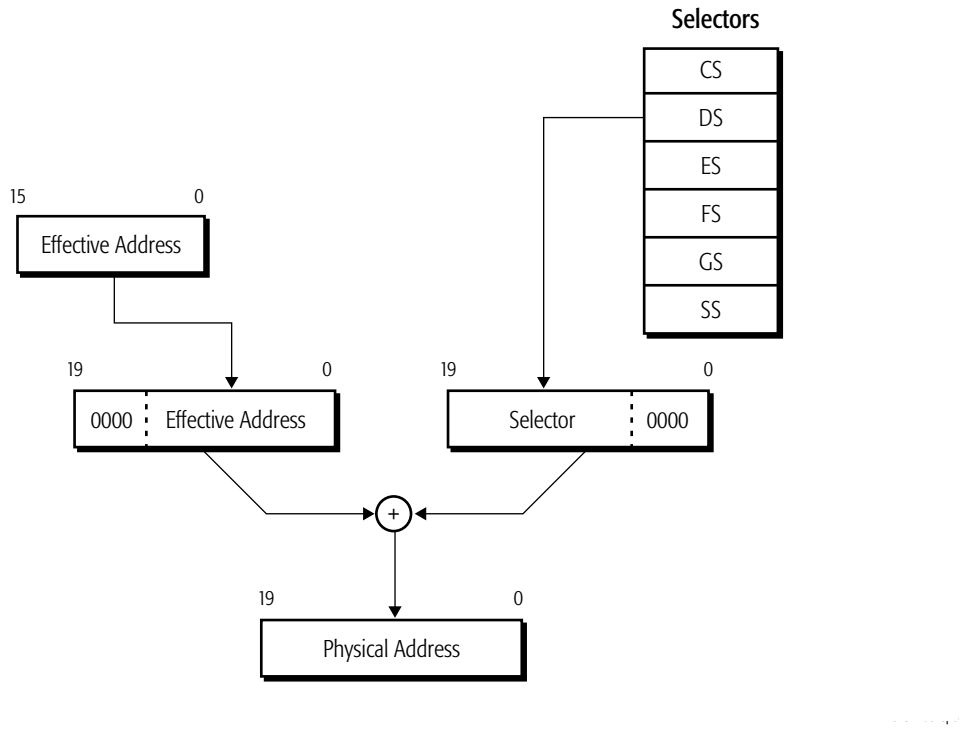

Figure 1-5. Real-Address Memory Model

1.3 Operating Modes

The legacy x86 architecture provides four operating modes or environments that support varying forms of memory management, virtual-memory and physical-memory sizes, and protection:

- Real Mode.
- Protected Mode.
- Virtual-8086 Mode.
- System Management Mode.

The AMD64 architecture supports all these legacy modes, and it adds a new operating mode called *long mode*. Table 1-1 shows the differences between long mode and legacy mode. Software can move between all supported operating modes as shown in Figure 1-6 on page 12. Each operating mode is described in the following sections.

Table 1-1. Operating Modes

Mode		System Software Required	Application Recompile Required	Defaults[1]		Register Extensions[2]	Maximum GPR Width (bits)
				Address Size (bits)	Operand Size (bits)		
Long Mode[3]	64-Bit Mode	New 64-bit OS	yes	64	32	yes	64
	Compatibility Mode		no	32		no	32
				16	16		
Legacy Mode	Protected Mode	Legacy 32-bit OS	no	32	32	no	32
				16	16		
	Virtual-8086 Mode			16	16		32
	Real Mode	Legacy 16-bit OS					

Note:

1. *Defaults can be overridden in most modes using an instruction prefix or system control bit.*
2. *Register extensions include access to the upper eight general-purpose and YMM/XMM registers, uniform access to lower 8 bits of all GPRs, and access to the upper 32 bits of the GPRs.*
3. *Long mode supports only x86 protected mode. It does not support x86 real mode or virtual-8086 mode.*

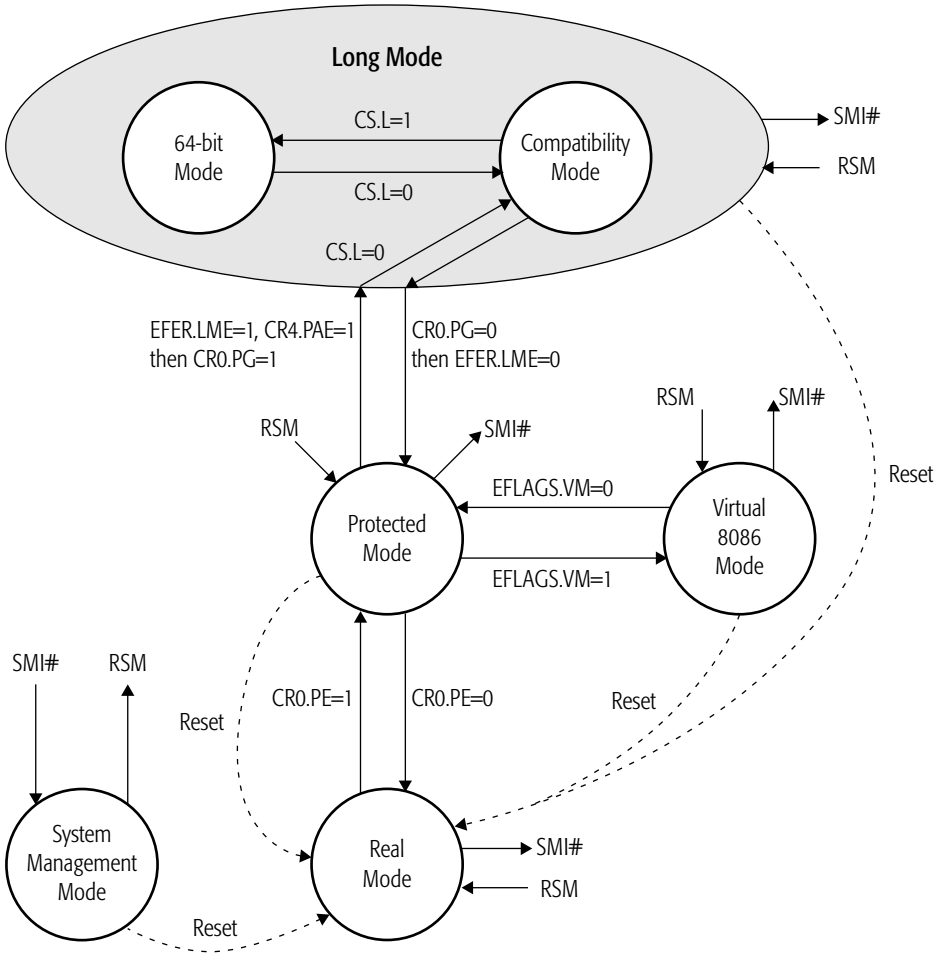

Figure 1-6. Operating Modes of the AMD64 Architecture

1.3.1 Long Mode

Long mode consists of two submodes: *64-bit mode* and *compatibility mode*. 64-bit mode supports several new features, including the ability to address 64-bit virtual-address space. Compatibility mode provides binary compatibility with existing 16-bit and 32-bit applications when running on 64-bit system software.

Throughout this document, references to *long mode* refer collectively to both *64-bit mode* and *compatibility mode*. If a function is specific to either 64-bit mode or compatibility mode, then those specific names are used instead of the name *long mode*.

Before enabling and activating long mode, system software must first enable protected mode. The process of enabling and activating long mode is described in Chapter 14, “Processor Initialization and

Long Mode Activation.” Long mode features are described throughout this document, where applicable.

1.3.2 64-Bit Mode

64-bit mode, a submode of long mode, provides support for 64-bit system software and applications by adding the following features:

- 64-bit virtual addresses (processor implementations can have fewer).
- Access to General Purpose Register bits 63:32
- Access to additional registers through the REX, VEX, and XOP instruction prefixes:
  - eight additional GPRs (R8–R15)
  - eight additional Streaming SIMD Extension (SSE) registers (YMM/XMM8–15)
- 64-bit instruction pointer (RIP).
- New RIP-relative data-addressing mode.
- Flat-segment address space with single code, data, and stack space.

The mode is enabled by the system software on an individual code-segment basis. Although code segments are used to enable and disable 64-bit mode, the legacy segmentation mechanism is largely disabled. Page translation is required for memory management purposes. Because 64-bit mode supports a 64-bit virtual-address space, it requires 64-bit system software and development tools.

In 64-bit mode, the default address size is 64 bits, and the default operand size is 32 bits. The defaults can be overridden on an instruction-by-instruction basis using instruction prefixes. A new REX prefix is introduced for specifying a 64-bit operand size and the new registers.

1.3.3 Compatibility Mode

Compatibility mode, a submode of long mode, allows system software to implement binary compatibility with existing 16-bit and 32-bit x86 applications. It allows these applications to run, without recompilation, under 64-bit system software in long mode, as shown in Table 1-1 on page 11.

In compatibility mode, applications can only access the first 4 Gbytes of virtual-address space. Standard x86 instruction prefixes toggle between 16-bit and 32-bit address and operand sizes.

Compatibility mode, like 64-bit mode, is enabled by system software on an individual code-segment basis. Unlike 64-bit mode, however, segmentation functions the same as in the legacy-x86 architecture, using 16-bit or 32-bit protected-mode semantics. From an application viewpoint, compatibility mode looks like a legacy protected-mode environment. From a system-software viewpoint, the long-mode mechanisms are used for address translation, interrupt and exception handling, and system data-structures.

1.3.4 Legacy Modes

L*egacy mode* consists of three submodes: real mode, protected mode, and virtual-8086 mode. Protected mode can be either paged or unpaged. L*egacy mode* preserves binary compatibility not only with existing x86 16-bit and 32-bit applications but also with existing x86 16-bit and 32-bit system software.

Real Mode. In this mode, also called real-address mode, the processor supports a physical-memory space of 1 Mbyte and operand sizes of 16 bits (default) or 32 bits (with instruction prefixes). Interrupt handling and address generation are nearly identical to the 80286 processor's real mode. Paging is not supported. All software runs at privilege level 0.

Real mode is entered after reset or processor power-up. The mode is not supported when the processor is operating in long mode because long mode requires that paged protected mode be enabled.

Protected Mode. In this mode, the processor supports virtual-memory and physical-memory spaces of 4 Gbytes and operand sizes of 16 or 32 bits. All segment translation, segment protection, and hardware multitasking functions are available. System software can use segmentation to relocate effective addresses in virtual-address space. If paging is not enabled, virtual addresses are equal to physical addresses. Paging can be optionally enabled to allow translation of virtual addresses to physical addresses and to use the page-based memory-protection mechanisms.

In protected mode, software runs at privilege levels 0, 1, 2, or 3. Typically, application software runs at privilege level 3, the system software runs at privilege levels 0 and 1, and privilege level 2 is available to system software for other uses. The 16-bit version of this mode was first introduced in the 80286 processor.

Virtual-8086 Mode. Virtual-8086 mode allows system software to run 16-bit real-mode software on a virtualized-8086 processor. In this mode, software written for the 8086, 8088, 80186, or 80188 processor can run as a privilege-level-3 task under protected mode. The processor supports a virtual-memory space of 1 Mbytes and operand sizes of 16 bits (default) or 32 bits (with instruction prefixes), and it uses real-mode address translation.

Virtual-8086 mode is enabled by setting the virtual-machine bit in the EFLAGS register (EFLAGS.VM). EFLAGS.VM can only be set or cleared when the EFLAGS register is loaded from the TSS as a result of a task switch, or by executing an IRET instruction from privileged software. The POPF instruction cannot be used to set or clear the EFLAGS.VM bit.

Virtual-8086 mode is not supported when the processor is operating in long mode. When long mode is enabled, any attempt to enable virtual-8086 mode is silently ignored.

1.3.5 System Management Mode (SMM)

System management mode (SMM) is an operating mode designed for system-control activities that are typically transparent to conventional system software. Power management is one popular use for system management mode. SMM is primarily targeted for use by platform firmware and specialized low-level device drivers. The code and data for SMM are stored in the SMM memory area, which is isolated from main memory by the SMM output signal.

SMM is entered by way of a system management interrupt (SMI). Upon recognizing an SMI, the processor enters SMM and switches to a separate address space where the SMM handler is located and executes. In SMM, the processor supports real-mode addressing with 4 Gbyte segment limits and default operand, address, and stack sizes of 16 bits (prefixes can be used to override these defaults).

1.4 System Registers

Figure 1-7 on page 16 shows the system registers defined for the AMD64 architecture. System software uses these registers to, among other things, manage the processor operating environment, define system resource characteristics, and to monitor software execution. With the exception of the RFLAGS register, system registers can be read and written only from privileged software.

Except for the descriptor-table registers and task register, the AMD64 architecture defines all system registers to be 64 bits wide. The descriptor table and task registers are defined by the AMD64 architecture to include 64-bit base-address fields, in addition to their other fields.

As shown in Figure 1-7 on page 16, the system registers include:

- *Control Registers*—These registers are used to control system operation and some system features. See “System-Control Registers” on page 41 for details.
- *System-Flags Register*—The RFLAGS register contains system-status flags and masks. It is also used to enable virtual-8086 mode and to control application access to I/O devices and interrupts. See “RFLAGS Register” on page 52 for details.
- *Descriptor-Table Registers*—These registers contain the location and size of descriptor tables stored in memory. Descriptor tables hold segmentation data structures used in protected mode. See “Descriptor Tables” on page 82 for details.
- *Task Register*—The task register contains the location and size in memory of the task-state segment. The hardware-multitasking mechanism uses the task-state segment to hold state information for a given task. The TSS also holds other data, such as the inner-level stack pointers used when changing to a higher privilege level. See “Task Register” on page 365 for details.
- *Debug Registers*—Debug registers are used to control the software-debug mechanism, and to report information back to a debug utility or application. See “Debug Registers” on page 386 for details.

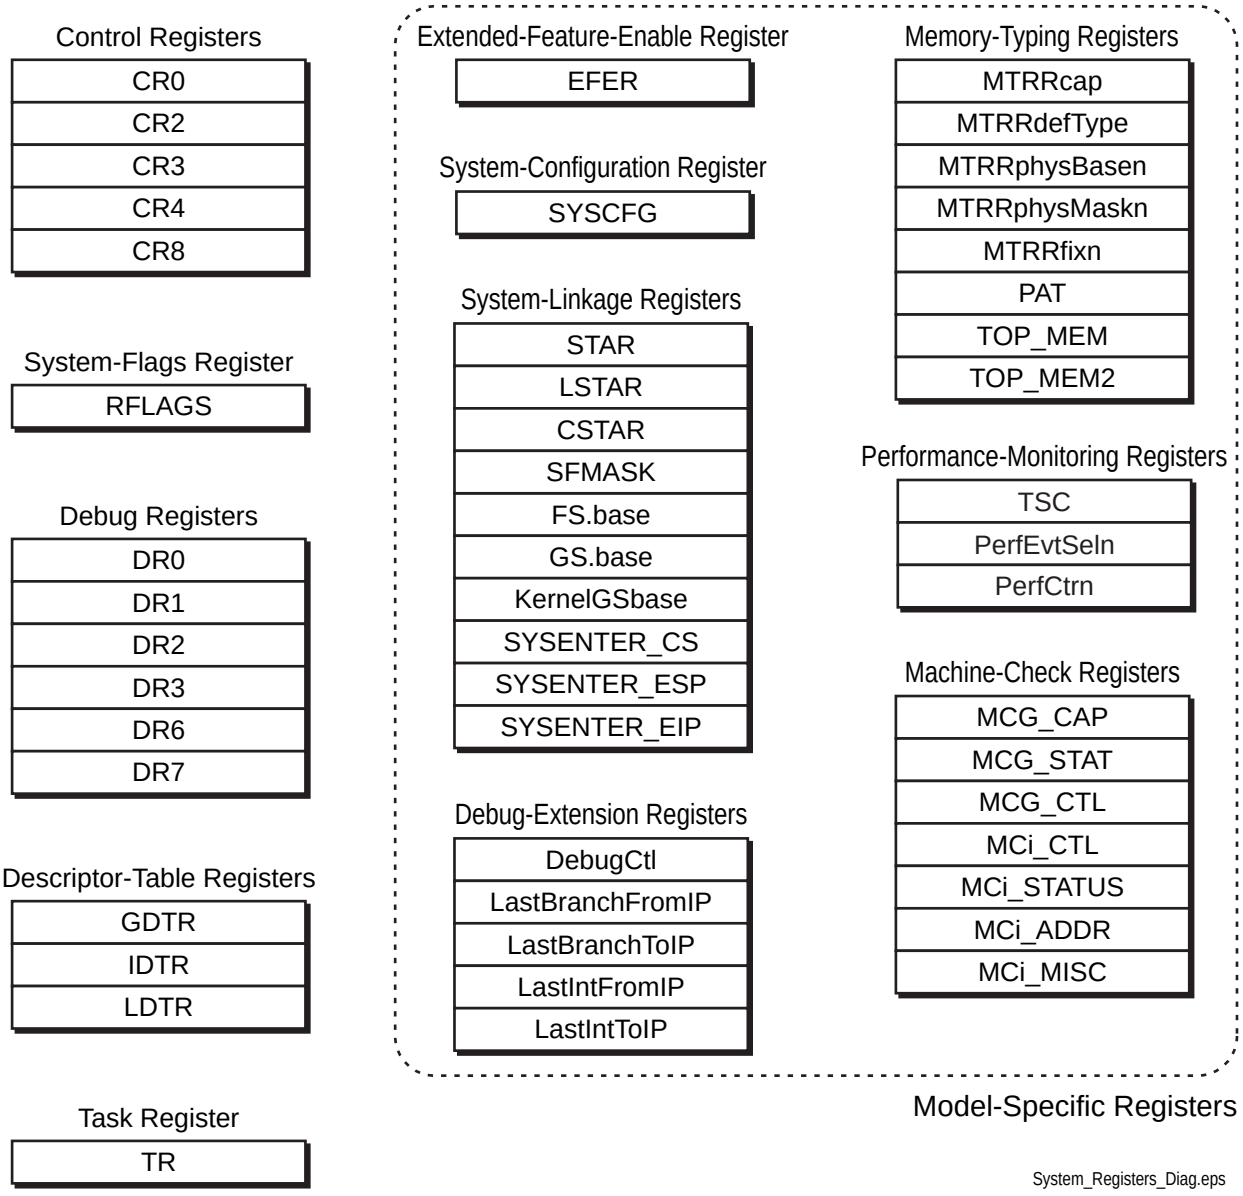

Figure 1-7. System Registers

Also defined as system registers are a number of *model-specific registers* included in the AMD64 architectural definition, and shown in Figure 1-7:

- *Extended-Feature-Enable Register*—The EFER register is used to enable and report status on special features not controlled by the CR*n* control registers. In particular, EFER is used to control activation of long mode. See “Extended Feature Enable Register (EFER)” on page 56 for more information.

- *System-Configuration Register*—The SYSCFG register is used to enable and configure system-bus features. See “System Configuration Register (SYSCFG)” on page 61 for more information.
- *System-Linkage Registers*—These registers are used by system-linkage instructions to specify operating-system entry points, stack locations, and pointers into system-data structures. See “Fast System Call and Return” on page 170 for details.
- *Memory-Typing Registers*—Memory-typing registers can be used to characterize (type) system memory. Typing memory gives system software control over how instructions and data are cached, and how memory reads and writes are ordered. See “MTRRs” on page 209 for details.
- *Debug-Extension Registers*—These registers control additional software-debug reporting features. See “Debug Registers” on page 386 for details.
- *Performance-Monitoring Registers*—Performance-monitoring registers are used to count processor and system events, or the duration of events. See “Performance Monitoring Counters” on page 400 for more information.
- *Machine-Check Registers*—The machine-check registers control the response of the processor to non-recoverable failures. They are also used to report information on such failures back to system utilities designed to respond to such failures. See “Machine Check Architecture MSRs” on page 291 for more information.

1.5 System-Data Structures

Figure 1-8 on page 18 shows the system-data structures defined for the AMD64 architecture. System-data structures are created and maintained by system software for use by the processor when running in protected mode. A processor running in protected mode uses these data structures to manage memory and protection, and to store program-state information when an interrupt or task switch occurs.

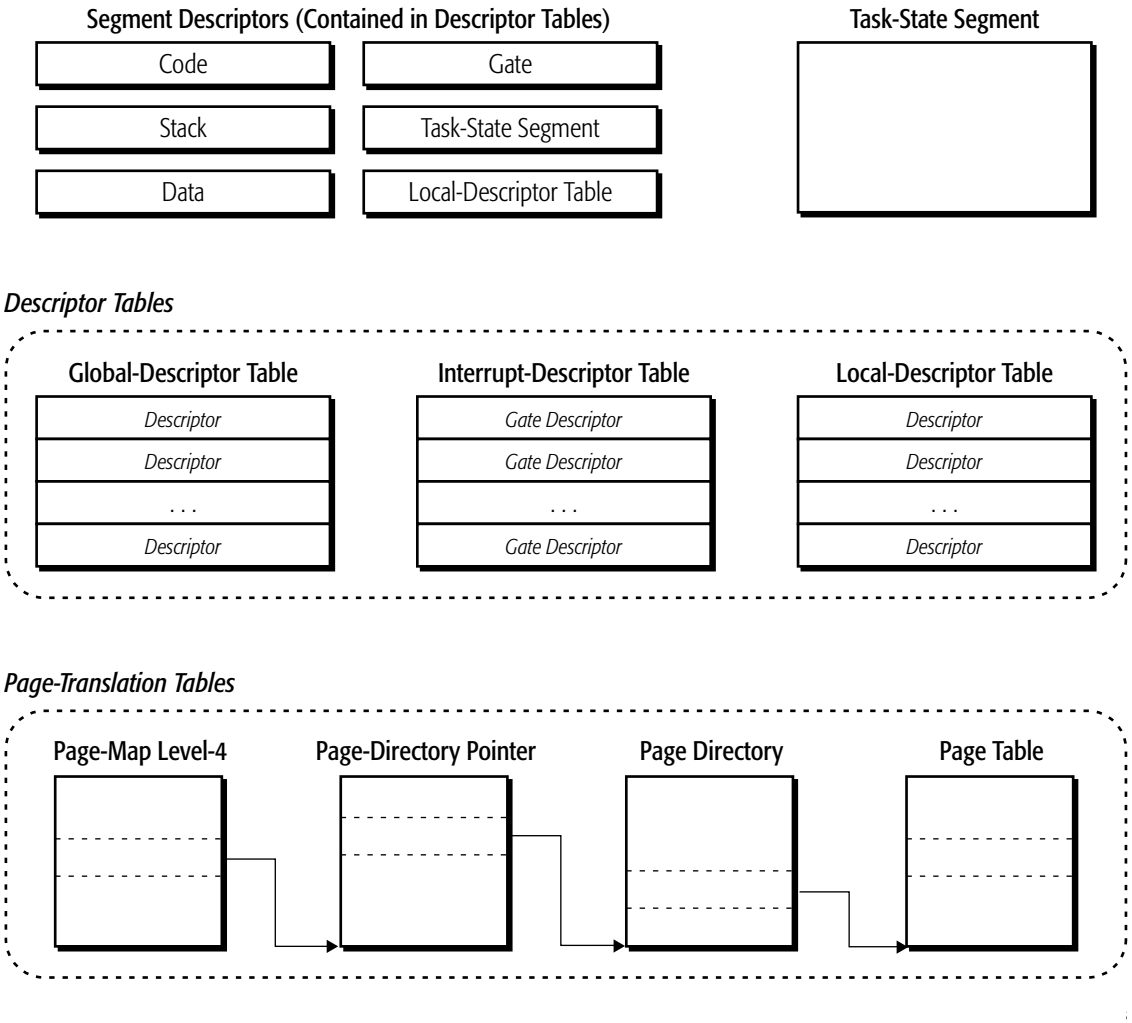

Figure 1-8. System-Data Structures

As shown in Figure 1-8, the system-data structures include:

- *Descriptors*—A descriptor provides information about a segment to the processor, such as its location, size and privilege level. A special type of descriptor, called a *gate*, is used to provide a code selector and entry point for a software routine. Any number of descriptors can be defined, but system software must at a minimum create a descriptor for the currently executing code segment and stack segment. See “Legacy Segment Descriptors” on page 88, and “Long-Mode Segment Descriptors” on page 97 for complete information on descriptors.
- *Descriptor Tables*—As the name implies, descriptor tables hold descriptors. The global-descriptor table holds descriptors available to all programs, while a local-descriptor table holds descriptors used by a single program. The interrupt-descriptor table holds only gate descriptors used by

interrupt handlers. System software must initialize the global-descriptor and interrupt-descriptor tables, while use of the local-descriptor table is optional. See “Descriptor Tables” on page 82 for more information.

- *Task-State Segment*—The task-state segment is a special segment for holding processor-state information for a specific program, or task. It also contains the stack pointers used when switching to more-privileged programs. The hardware multitasking mechanism uses the state information in the segment when suspending and resuming a task. Calls and interrupts that switch stacks cause the stack pointers to be read from the task-state segment. System software must create at least one task-state segment, even if hardware multitasking is not used. See “Legacy Task-State Segment” on page 367, and “64-Bit Task State Segment” on page 371 for details.
- *Page-Translation Tables*—Use of page translation is optional in protected mode, but it is required in long mode. A four-level page-translation data structure is provided to allow long-mode operating systems to translate a 64-bit virtual-address space into a 52-bit physical-address space. Legacy protected mode can use two- or three-level page-translation data structures. See “Page Translation Overview” on page 129 for more information on page translation.

1.6 Interrupts

The AMD64 architecture provides a mechanism for the processor to automatically suspend (interrupt) software execution and transfer control to an interrupt handler when an interrupt or exception occurs. An interrupt handler is privileged software designed to identify and respond to the cause of an interrupt or exception, and return control back to the interrupted software. *Interrupts* can be caused when system hardware signals an interrupt condition using one of the external-interrupt signals on the processor. Interrupts can also be caused by software that executes an interrupt instruction. *Exceptions* occur when the processor detects an abnormal condition as a result of executing an instruction. The term “interrupts” as used throughout this volume includes both interrupts and exceptions when the distinction is unnecessary.

System software not only sets up the interrupt handlers, but it must also create and initialize the data structures the processor uses to execute an interrupt handler when an interrupt occurs. The data structures include the code-segment descriptors for the interrupt-handler software and any data-segment descriptors for data and stack accesses. Interrupt-gate descriptors must also be supplied. Interrupt gates point to interrupt-handler code-segment descriptors, and the entry point in an interrupt handler. Interrupt gates are stored in the interrupt-descriptor table. The code-segment and data-segment descriptors are stored in the global-descriptor table and, optionally, the local-descriptor table.

When an interrupt occurs, the processor uses the interrupt vector to find the appropriate interrupt gate in the interrupt-descriptor table. The gate points to the interrupt-handler code segment and entry point, and the processor transfers control to that location. Before invoking the interrupt handler, the processor saves information required to return to the interrupted program. For details on how the processor transfers control to interrupt handlers, see “Legacy Protected-Mode Interrupt Control Transfers” on page 261, and “Long-Mode Interrupt Control Transfers” on page 272.

Table 1-2 shows the supported interrupts and exceptions, ordered by their vector number. Refer to “Vectors” on page 236 for a complete description of each interrupt, and a description of the interrupt mechanism.

Table 1-2. Interrupts and Exceptions

Vector	Description
0	Integer Divide-by-Zero Exception
1	Debug Exception
2	Non-Maskable-Interrupt
3	Breakpoint Exception (INT 3)
4	Overflow Exception (INTO instruction)
5	Bound-Range Exception (BOUND instruction)
6	Invalid-Opcode Exception
7	Device-Not-Available Exception
8	Double-Fault Exception
9	Coprocessor-Segment-Overrun Exception (reserved in AMD64)
10	Invalid-TSS Exception
11	Segment-Not-Present Exception
12	Stack Exception
13	General-Protection Exception
14	Page-Fault Exception
15	(Reserved)
16	x87 Floating-Point Exception
17	Alignment-Check Exception
18	Machine-Check Exception
19	SIMD Floating-Point Exception
21	Control-Protection Exception
0–255	Interrupt Instructions
0–255	Hardware Maskable Interrupts

1.7 Additional System-Programming Facilities

1.7.1 Hardware Multitasking

A task is any program that the processor can execute, suspend, and later resume executing at the point of suspension. During the time a task is suspended, other tasks are allowed to execute. Each task has its own execution space, consisting of a code segment, data segments, and a stack segment for each privilege level. Tasks can also have their own virtual-memory environment managed by the page-translation mechanism. The state information defining this execution space is stored in the task-state segment (TSS) maintained for each task.

Support for hardware multitasking is provided by implementations of the AMD64 architecture when software is running in legacy mode. Hardware multitasking provides automated mechanisms for switching tasks, saving the execution state of the suspended task, and restoring the execution state of the resumed task. When hardware multitasking is used to switch tasks, the processor takes the following actions:

- The processor automatically suspends execution of the task, allowing any executing instructions to complete and save their results.
- The execution state of a task is saved in the task TSS.
- The execution state of a new task is loaded into the processor from its TSS.
- The processor begins executing the new task at the location specified in the new task TSS.

Use of hardware-multitasking features is optional in legacy mode. Generally, modern operating systems do not use the hardware-multitasking features, and instead perform task management entirely in software. Long mode does not support hardware multitasking at all.

Whether hardware multitasking is used or not, system software must create and initialize at least one task-state segment data-structure. This requirement holds for both long-mode and legacy-mode software. The single task-state segment holds critical pieces of the task execution environment and is referenced during certain control transfers.

Detailed information on hardware multitasking is available in Chapter 12, “Task Management,” along with a full description of the requirements that must be met in initializing a task-state segment when hardware multitasking is not used.

1.7.2 Machine Check

Implementations of the AMD64 architecture support the machine-check exception. This exception is useful in system applications with stringent requirements for reliability, availability, and serviceability. The exception allows specialized system-software utilities to report hardware errors that are generally severe and non-recoverable. Providing the capability to report such errors can allow complex system problems to be pinpointed rapidly.

The machine-check exception is described in Chapter 9, “Machine Check Architecture.” Much of the error-reporting capabilities is implementation dependent. For more information, developers of machine-check error-reporting software should refer to the *BIOS and Kernel Developer’s Guide (BKDG)* or *Processor Programming Reference Manual (PPR)* or applicable to your product.

1.7.3 Software Debugging

A software-debugging mechanism is provided in hardware to help software developers quickly isolate programming errors. This capability can be used to debug system software and application software alike. Only privileged software can access the debugging facilities. Generally, software-debug support is provided by a privileged application program rather than by the operating system itself.

The facilities supported by the AMD64 architecture allow debugging software to perform the following:

- Set breakpoints on specific instructions within a program.
- Set breakpoints on an instruction-address match.
- Set breakpoints on a data-address match.
- Set breakpoints on specific I/O-port addresses.
- Set breakpoints to occur on task switches when hardware multitasking is used.
- Single step an application instruction-by-instruction.
- Single step only branches and interrupts.
- Record a history of branches and interrupts taken by a program.

The debugging facilities are fully described in “Software-Debug Resources” on page 386. Some processors provide additional, implementation-specific debug support. For more information, refer to the *BIOS and Kernel Developer’s Guide (BKDG)* or *Processor Programming Reference Manual (PPR)* applicable to your product.

1.7.4 Performance Monitoring

For many software developers, the ability to identify and eliminate performance bottlenecks from a program is nearly as important as quickly isolating programming errors. Implementations of the AMD64 architecture provide hardware performance-monitoring resources that can be used by special software applications to identify such bottlenecks. Non-privileged software can access the performance monitoring facilities, but only if privileged software grants that access.

The performance-monitoring facilities allow the counting of events, or the duration of events. Performance-analysis software can use the data to calculate the frequency of certain events, or the time spent performing specific activities. That information can be used to suggest areas for improvement and the types of optimizations that are helpful.

The performance-monitoring facilities are fully described in “Performance Monitoring Counters” on page 400. The specific events that can be monitored are generally implementation specific. For more information, refer to the *BIOS and Kernel Developer’s Guide (BKDG)* or *Processor Programming Reference Manual (PPR)* applicable to your product.

2 x86 and AMD64 Architecture Differences

The AMD64 architecture is designed to provide full binary compatibility with all previous AMD implementations of the x86 architecture. This chapter summarizes the new features and architectural enhancements introduced by the AMD64 architecture, and compares those features and enhancements with previous AMD x86 processors. Most of the new capabilities introduced by the AMD64 architecture are available only in long mode (64-bit mode, compatibility mode, or both). However, some of the new capabilities are also available in legacy mode, and are mentioned where appropriate.

The material throughout this chapter assumes the reader has a solid understanding of the x86 architecture. For those who are unfamiliar with the x86 architecture, please read the remainder of this volume before reading this chapter.

2.1 Operating Modes

See “Operating Modes” on page 11 for a complete description of the operating modes supported by the AMD64 architecture.

2.1.1 Long Mode

The AMD64 architecture introduces long mode and its two sub-modes: 64-bit mode and compatibility mode.

64-Bit Mode. 64-bit mode provides full support for 64-bit system software and applications. The new features introduced in support of 64-bit mode are summarized throughout this chapter. To use 64-bit mode, a 64-bit operating system and tool chain are required.

Compatibility Mode. Compatibility mode allows 64-bit operating systems to implement binary compatibility with existing 16-bit and 32-bit x86 applications. It allows these applications to run, without recompilation, under control of a 64-bit operating system in long mode. The architectural enhancements introduced by the AMD64 architecture that support compatibility mode are summarized throughout this chapter.

Unsupported Modes. Long mode does not support the following two operating modes:

- *Virtual-8086 Mode*—The virtual-8086 mode bit (EFLAGS.VM) is ignored when the processor is running in long mode. When long mode is enabled, any attempt to enable virtual-8086 mode is silently ignored. System software must leave long mode in order to use virtual-8086 mode.
- *Real Mode*—Real mode is not supported when the processor is operating in long mode because long mode requires that protected mode be enabled.

2.1.2 Legacy Mode

The AMD64 architecture supports a pure x86 legacy mode, which preserves binary compatibility not only with existing 16-bit and 32-bit applications but also with existing 16-bit and 32-bit operating

systems. L*egacy mode* supports real mode, protected mode, and virtual-8086 mode. A reset always places the processor in legacy mode (real mode), and the processor continues to run in legacy mode until system software activates long mode. New features added by the AMD64 architecture that are supported in legacy mode are summarized in this chapter.

2.1.3 System-Management Mode

The AMD64 architecture supports system-management mode (SMM). SMM can be entered from both long mode and legacy mode, and SMM can return directly to either mode. The following differences exist between the support of SMM in the AMD64 architecture and the SMM support found in previous processor generations:

- The SMRAM state-save area format is changed to hold the 64-bit processor state. This state-save area format is used regardless of whether SMM is entered from long mode or legacy mode.
- The auto-halt restart and I/O-instruction restart entries in the SMRAM state-save area are one byte instead of two bytes.
- The initial processor state upon entering SMM is expanded to reflect the 64-bit nature of the processor.
- New conditions exist that can cause a processor shutdown while exiting SMM.
- SMRAM caching considerations are modified because the legacy FLUSH# external signal (writeback, if modified, and invalidate) is not supported on implementations of the AMD64 architecture.

See Chapter 10, “System-Management Mode,” for more information on the SMM differences.

2.2 Memory Model

The AMD64 architecture provides enhancements to the legacy memory model to support very large physical-memory and virtual-memory spaces while in long mode. Some of this expanded support for physical memory is available in legacy mode.

2.2.1 Memory Addressing

Virtual-Memory Addressing. Virtual-memory support is expanded to 64 address bits in long mode. This allows up to 16 exabytes of virtual-address space to be accessed. The virtual-address space supported in legacy mode is unchanged.

Physical-Memory Addressing. Physical-memory support is expanded to 52 address bits in long mode and legacy mode. This allows up to 4 petabytes of physical memory to be accessed. The expanded physical-memory support is achieved by using paging and the page-size extensions.

Note that given processor may implement less than the architecturally-defined physical address size of 52 bits.

Effective Addressing. The effective-address length is expanded to 64 bits in long mode. An effective-address calculation uses 64-bit base and index registers, and sign-extends 8-bit and 32-bit displacements to 64 bits. In legacy mode, effective addresses remain 32 bits long.

2.2.2 Page Translation

The AMD64 architecture defines an expanded page-translation mechanism supporting translation of a 64-bit virtual address to a 52-bit physical address. See “Long-Mode Page Translation” on page 141 for detailed information on the enhancements to page translation in the AMD64 architecture. The enhancements are summarized below.

Physical-Address Extensions (PAE). The AMD64 architecture requires physical-address extensions to be enabled (CR4.PAE=1) before long mode is entered. When PAE is enabled, all paging data-structures are 64 bits, allowing references into the full 52-bit physical-address space supported by the architecture.

Page-Size Extensions (PSE). Page-size extensions (CR4.PSE) are ignored in long mode. Long mode does not support the 4-Mbyte page size enabled by page-size extensions. Long mode does, however, support 4-Kbyte and 2-Mbyte page sizes.

Paging Data Structures. The AMD64 architecture extends the page-translation data structures in support of long mode. The extensions are:

- *Page-map level-4 (PML4)*—Long mode defines a new page-translation data structure, the PML4 table. The PML4 table sits at the top of the page-translation hierarchy and references PDP tables.
- *Page-directory pointer (PDP)*—The PDP tables in long mode are expanded from 4 entries to 512 entries each.
- *Page-directory pointer entry (PDPE)*—Previously undefined fields within the legacy-mode PDPE are defined by the AMD64 architecture.

CR3 Register. The CR3 register is expanded to 64 bits for use in long-mode page translation. When long mode is active, the CR3 register references the base address of the PML4 table. In legacy mode, the upper 32 bits of CR3 are masked by the processor to support legacy page translation. CR3 references the PDP base-address when physical-address extensions are enabled, or the page-directory table base-address when physical-address extensions are disabled.

Legacy-Mode Enhancements. Legacy-mode software can take advantage of the enhancements made to the physical-address extension (PAE) support and page-size extension (PSE) support. The four-level page translation mechanism introduced by long mode is not available to legacy-mode software.

- *PAE*—When physical-address extensions are enabled (CR4.PAE=1), the AMD64 architecture allows legacy-mode software to load up to 52-bit (maximum size) physical addresses into the PDE and PTE. Note that addresses are expanded to the maximum physical address size supported by the implementation.

- *PSE*—The use of page-size extensions allows legacy mode software to define 4-Mbyte pages using the 32-bit page-translation tables. When page-size extensions are enabled (CR4.PSE=1), the AMD64 architecture enhances the 4-Mbyte PDE to support 40 physical-address bits.

See "Legacy-Mode Page Translation" on page 133 for more information on these enhancements.

2.2.3 Segmentation

In long mode, the effects of segmentation depend on whether the processor is running in compatibility mode or 64-bit mode:

- In compatibility mode, segmentation functions just as it does in legacy mode, using legacy 16-bit or 32-bit protected mode semantics.
- 64-bit mode requires a flat-memory model for creating a flat 64-bit virtual-address space. Much of the segmentation capability present in legacy mode and compatibility mode is disabled when the processor is running in 64-bit mode.

The differences in the segmentation model as defined by the AMD64 architecture are summarized in the following sections. See Chapter 4, "Segmented Virtual Memory," for a thorough description of these differences.

Descriptor-Table Registers. In long mode, the base-address portion of the descriptor-table registers (GDTR, IDTR, LDTR, and TR) are expanded to 64 bits. The full 64-bit base address can only be loaded by software when the processor is running in 64-bit mode (using the LGDT, LIDT, LLDT, and LTR instructions, respectively). However, the full 64-bit base address is *used* by a processor running in compatibility mode (in addition to 64-bit mode) when making a reference into a descriptor table.

A processor running in legacy mode can only load the low 32 bits of the base address, and the high 32 bits are ignored when references are made to the descriptor tables.

Code-Segment Descriptors. The AMD64 architecture defines a new code-segment descriptor attribute, L (long). In compatibility mode, the processor treats code-segment descriptors as it does in legacy mode, with the exception that the processor recognizes the L attribute. If a code descriptor with L=1 is loaded in compatibility mode, the processor leaves compatibility mode and enters 64-bit mode. In legacy mode, the L attribute is reserved.

The following differences exist for code-segment descriptors in 64-bit mode only:

- The CS base-address field is ignored by the processor.
- The CS limit field is ignored by the processor.
- Only the L (long), D (default size), and DPL (descriptor-privilege level) fields are used by the processor in 64-bit mode. All remaining attributes are ignored.

Data-Segment Descriptors. The following differences exist for data-segment descriptors in 64-bit mode only:

- The DS, ES, and SS descriptor base-address fields are ignored by the processor.

- The FS and GS descriptor base-address fields are expanded to 64 bits and used in effective-address calculations. The 64 bits of base address are mapped to model-specific registers (MSRs), and can only be loaded using the WRMSR instruction.
- The limit fields and attribute fields of all data-segment descriptors (DS, ES, FS, GS, and SS) are ignored by the processor.

In compatibility mode, the processor treats data-segment descriptors as it does in legacy mode. Compatibility mode ignores the high 32 bits of base address in the FS and GS segment descriptors when calculating an effective address.

System-Segment Descriptors. In 64-bit mode only, The LDT and TSS system-segment descriptor formats are expanded by 64 bits, allowing them to hold 64-bit base addresses. LLDT and LTR instructions can be used to load these descriptors into the LDTR and TR registers, respectively, from 64-bit mode.

In compatibility mode and legacy mode, the *formats* of the LDT and TSS system-segment descriptors are unchanged. Also, unlike code-segment and data-segment descriptors, system-segment descriptor limits *are checked* by the processor in long mode.

Some legacy mode LDT and TSS type-field encodings are illegal in long mode (both compatibility mode and 64-bit mode), and others are redefined to new types. See “System Descriptors” on page 99 for additional information.

Gate Descriptors. The following differences exist between gate descriptors in long mode (both compatibility mode and 64-bit mode) and in legacy mode:

- In long mode, all 32-bit gate descriptors are redefined as 64-bit gate descriptors, and are expanded to hold 64-bit offsets. The length of a gate descriptor in long mode is therefore 128 bits (16 bytes), versus the 64 bits (8 bytes) in legacy mode.
- Some type-field encodings are illegal in long mode, and others are redefined to new types. See “Gate Descriptors” on page 101 for additional information.
- The interrupt-gate and trap-gate descriptors define a new field, called the interrupt-stack table (IST) field.

2.3 Protection Checks

The AMD64 architecture makes the following changes to the protection mechanism in long mode:

- The page-protection-check mechanism is expanded in long mode to include the U/S and R/W protection bits stored in the PML4 entries and PDP entries.
- Several system-segment types and gate-descriptor types that are legal in legacy mode are illegal in long mode (compatibility mode and 64-bit mode) and fail type checks when used in long mode.
- Segment-limit checks are disabled in 64-bit mode for the CS, DS, ES, FS, GS, and SS segments. Segment-limit checks remain enabled for the LDT, GDT, IDT and TSS system segments.

  All segment-limit checks are performed in compatibility mode.

- Code and data segments used in 64-bit mode are treated as both readable and writable.

See “Page-Protection Checks” on page 158 and “Segment-Protection Overview” on page 104 for detailed information on the protection-check changes.

2.4 Registers

The AMD64 architecture adds additional registers to the architecture, and in many cases expands the size of existing registers to 64 bits. The 80-bit floating-point stack registers and their overlaid 64-bit MMX™ registers are not modified by the AMD64 architecture.

2.4.1 General-Purpose Registers

In 64-bit mode, the general-purpose registers (GPRs) are 64 bits wide, and eight additional GPRs are available. The GPRs are: RAX, RBX, RCX, RDX, RDI, RSI, RBP, RSP, and the new R8–R15 registers. To access the full 64-bit operand size, or the new R8–R15 registers, an instruction must include a new REX instruction-prefix byte (see “REX Prefixes” on page 29 for a summary of this prefix).

In compatibility and legacy modes, the GPRs consist only of the eight legacy 32-bit registers. All legacy rules apply for determining operand size.

2.4.2 YMM/XMM Registers

In 64-bit mode, eight additional YMM/XMM registers are available, YMM/XMM8–15. A REX instruction prefix is used to access these registers. In compatibility and legacy modes, only registers YMM/XMM0–7 are accessible.

2.4.3 Flags Register

The flags register is expanded to 64 bits, and is called RFLAGS. All 64 bits can be accessed in 64-bit mode, but the upper 32 bits are reserved and always read back as zeros. Compatibility mode and legacy mode can read and write only the lower-32 bits of RFLAGS (the legacy EFLAGS).

2.4.4 Instruction Pointer

In long mode, the instruction pointer is extended to 64 bits, to support 64-bit code offsets. This 64-bit instruction pointer is called RIP.

2.4.5 Stack Pointer

In 64-bit mode, the size of the stack pointer, RSP, is always 64 bits. The stack size is not controlled by a bit in the SS descriptor, as it is in compatibility or legacy mode, nor can it be overridden by an instruction prefix. Address-size overrides are ignored for implicit stack references.

2.4.6 Control Registers

The AMD64 architecture defines several enhancements to the control registers (CR*n*). In long mode, all control registers are expanded to 64 bits, although the entire 64 bits can be read and written only from 64-bit mode. A new control register, the task-priority register (CR8 or TPR) is added, and can be read and written from 64-bit mode. Last, the function of the page-enable bit (CR0.PG) is expanded. When long mode is enabled, the PG bit is used to activate and deactivate long mode.

2.4.7 Debug Registers

In long mode, all debug registers are expanded to 64 bits, although the entire 64 bits can be read and written only from 64-bit mode. Expanded register encodings for the decode registers allow up to eight new registers to be defined (DR8–DR15), although presently those registers are not supported by the AMD64 architecture.

2.4.8 Extended Feature Register (EFER)

The EFER is expanded by the AMD64 architecture to include a long-mode-enable bit (LME), and a long-mode-active bit (LMA). These new bits can be accessed from legacy mode and long mode.

2.4.9 Memory Type Range Registers (MTRRs)

The legacy MTRRs are architecturally defined as 64 bits, and can accommodate the maximum 52-bit physical address allowed by the AMD64 architecture. From both long mode and legacy mode, implementations of the AMD64 architecture reference the entire 52-bit physical-address value stored in the MTRRs. Long mode and legacy mode system software can update all 64 bits of the MTRRs to manage the expanded physical-address space.

2.4.10 Other Model-Specific Registers (MSRs)

Several other MSRs have fields holding physical addresses. Examples include the APIC-base register and top-of-memory register. Generally, any model-specific register that contains a physical address is defined architecturally to be 64 bits wide, and can accommodate the maximum physical-address size defined by the AMD64 architecture. When physical addresses are read from MSRs by the processor, the entire value is read regardless of the operating mode. In legacy implementations, the high-order MSR bits are reserved, and software must write those values with zeros. In legacy mode on AMD64 architecture implementations, software can read and write all supported high-order MSR bits.

2.5 Instruction Set

2.5.1 REX Prefixes

REX prefixes are used in 64-bit mode to:

- Specify the new GPRs and YMM/XMM registers.
- Specify a 64-bit operand size.

- Specify additional control registers. One additional control register, CR8, is defined in 64-bit mode.
- Specify additional debug registers (although none are currently defined).

Not all instructions require a REX prefix. The prefix is necessary only if an instruction references one of the extended registers or uses a 64-bit operand. If a REX prefix is used when it has no meaning, it is ignored.

Default 64-Bit Operand Size. In 64-bit mode, two groups of instructions have a default operand size of 64 bits and thus do not need a REX prefix for this operand size:

- Near branches.
- All instructions, except far branches, that implicitly reference the RSP. See “Instructions that Reference RSP” on page 31 for additional information.

2.5.2 Segment-Override Prefixes in 64-Bit Mode

In 64-bit mode, the DS, ES, SS, and CS segment-override prefixes have no effect. These four prefixes are no longer treated as segment-override prefixes in the context of multiple-prefix rules. Instead, they are treated as null prefixes.

The FS and GS segment-override prefixes are treated as segment-override prefixes in 64-bit mode. Use of the FS and GS prefixes cause their respective segment bases to be added to the effective address calculation. See “FS and GS Registers in 64-Bit Mode” on page 80 for additional information on using these segment registers.

2.5.3 Operands and Results

The AMD64 architecture provides support for using 64-bit operands and generating 64-bit results when operating in 64-bit mode.

Operand-Size Overrides. In 64-bit mode, the default operand size is 32 bits. A REX prefix can be used to specify a 64-bit operand size. Software uses a legacy operand-size (66h) prefix to toggle to 16-bit operand size. The REX prefix takes precedence over the legacy operand-size prefix.

Zero Extension of Results. In 64-bit mode, when performing 32-bit operations with a GPR destination, the processor zero-extends the 32-bit result into the full 64-bit destination. Both 8-bit and 16-bit operations on GPRs preserve all unwritten upper bits of the destination GPR. This is consistent with legacy 16-bit and 32-bit semantics for partial-width results.

2.5.4 Address Calculations

The AMD64 architecture modifies aspects of effective-address calculation to support 64-bit mode. These changes are summarized in the following sections. See “Memory Addressing” in Volume 1 for details.

Address-Size Overrides. In 64-bit mode, the default-address size is 64 bits. The address size can be overridden to 32 bits by using the address-size prefix (67h). 16-bit addresses are not supported in 64-bit mode. In compatibility mode and legacy mode, address-size overrides function the same as in x86 legacy architecture.

Displacements and Immediates. Generally, displacement and immediate values in 64-bit mode are not extended to 64 bits. They are still limited to 32 bits and are sign extended during effective-address calculations. In 64-bit mode, however, support is provided for some 64-bit displacement and immediate forms of the MOV instruction.

Zero Extending 16-Bit and 32-Bit Addresses. All 16-bit and 32-bit address calculations are zero-extended in long mode to form 64-bit addresses. Address calculations are first truncated to the effective-address size of the current mode (64-bit mode or compatibility mode), as overridden by any address-size prefix. The result is then zero-extended to the full 64-bit address width.

RIP-Relative Addressing. A new addressing form, RIP-relative (instruction-pointer relative) addressing, is implemented in 64-bit mode. The effective address is formed by adding the displacement to the 64-bit RIP of the next instruction.

2.5.5 Instructions that Reference RSP

With the exception of far branches, all instructions that implicitly reference the 64-bit stack pointer, RSP, default to a 64-bit operand size in 64-bit mode (see Table 2-1 for a listing). Pushes and pops of 32-bit stack values are not possible in 64-bit mode with these instructions, but they can be overridden to 16 bits.

Table 2-1. Instructions That Reference RSP

Mnemonic	Opcode (hex)	Description
ENTER	C8	Create Procedure Stack Frame
LEAVE	C9	Delete Procedure Stack Frame
POP reg/mem	8F/0	Pop Stack (register or memory)
POP reg	58-5F	Pop Stack (register)
POP FS	0F A1	Pop Stack into FS Segment Register
POP GS	0F A9	Pop Stack into GS Segment Register
POPF, POPFD, POPFQ	9D	Pop to rFLAGS Word, Doubleword, or Quadword
PUSH imm32	68	Push onto Stack (sign-extended doubleword)
PUSH imm8	6A	Push onto Stack (sign-extended byte)
PUSH reg/mem	FF/6	Push onto Stack (register or memory)
PUSH reg	50-57	Push onto Stack (register)
PUSH FS	0F A0	Push FS Segment Register onto Stack
PUSH GS	0F A8	Push GS Segment Register onto Stack
PUSHF, PUSHFD, PUSHFQ	9C	Push rFLAGS Word, Doubleword, or Quadword onto Stack

2.5.6 Branches

The AMD64 architecture expands two branching mechanisms to accommodate branches in the full 64-bit virtual-address space:

- In 64-bit mode, near-branch semantics are redefined.
- In both 64-bit and compatibility modes, a 64-bit call-gate descriptor is defined for far calls.

In addition, enhancements are made to the legacy SYSCALL and SYSRET instructions.

Near Branches. In 64-bit mode, the operand size for all near branches defaults to 64 bits (see Table 2-2 for a listing). Therefore, these instructions update the full 64-bit RIP without the need for a REX operand-size prefix. The following aspects of near branches default to 64 bits:

- Truncation of the instruction pointer.
- Size of a stack pop or stack push, resulting from a CALL or RET.
- Size of a stack-pointer increment or decrement, resulting from a CALL or RET.
- Size of operand fetched by indirect-branch operand size.

The operand size for near branches can be overridden to 16 bits in 64-bit mode.

Table 2-2. 64-Bit Mode Near Branches, Default 64-Bit Operand Size

Mnemonic	Opcode (hex)	Description
CALL	E8, FF/2	Call Procedure Near
Jcc	many	Jump Conditional Near
JMP	E9, EB, FF/4	Jump Near
LOOP	E2	Loop
LOOPcc	E0, E1	Loop Conditional
RET	C3, C2	Return From Call (near)

The address size of near branches is not forced in 64-bit mode. Such addresses are 64 bits by default, but they can be overridden to 32 bits by a prefix.

The size of the displacement field for relative branches is still limited to 32 bits.

Far Branches Through Long-Mode Call Gates. Long mode redefines the 32-bit call-gate descriptor type as a 64-bit call-gate descriptor and expands the call-gate descriptor size to hold a 64-bit offset. The long-mode call-gate descriptor allows far branches to reference any location in the supported virtual-address space. In long mode, the call-gate mechanism is changed as follows:

- In long mode, CALL and JMP instructions that reference call-gates must reference 64-bit call gates.
- A 64-bit call-gate descriptor must reference a 64-bit code-segment.

- When a control transfer is made through a 64-bit call gate, the 64-bit target address is read from the 64-bit call-gate descriptor. The base address in the target code-segment descriptor is ignored.

Stack Switching. Automatic stack switching is also modified when a control transfer occurs through a call gate in long mode:

- The target-stack pointer read from the TSS is a 64-bit RSP value.
- The SS register is loaded with a null selector. Setting the new SS selector to null allows nested control transfers in 64-bit mode to be handled properly. The SS.RPL value is updated to remain consistent with the newly loaded CPL value.
- The size of pushes onto the new stack is modified to accommodate the 64-bit RIP and RSP values.
- Automatic parameter copying is not supported in long mode.

Far Returns. In long mode, far returns can load a null SS selector from the stack under the following conditions:

- The target operating mode is 64-bit mode.
- The target CPL<3.

Allowing RET to load SS with a null selector under these conditions makes it possible for the processor to unnest far CALLs (and interrupts) in long mode.

Task Gates. Control transfers through task gates are not supported in long mode.

Branches to 64-Bit Offsets. Because immediate values are generally limited to 32 bits, the only way a full 64-bit absolute RIP can be specified in 64-bit mode is with an indirect branch. For this reason, direct forms of far branches are eliminated from the instruction set in 64-bit mode.

SYSCALL and SYSRET Instructions. The AMD64 architecture expands the function of the legacy SYSCALL and SYSRET instructions in long mode. In addition, two new STAR registers, LSTAR and CSTAR, are provided to hold the 64-bit target RIP for the instructions when they are executed in long mode. The legacy STAR register is not expanded in long mode. See “SYSCALL and SYSRET” on page 171 for additional information.

SWAPGS Instruction. The AMD64 architecture provides the SWAPGS instruction as a fast method for system software to load a pointer to system data-structures. SWAPGS is valid only in 64-bit mode. An undefined-opcode exception (#UD) occurs if software attempts to execute SWAPGS in legacy mode or compatibility mode. See “SWAPGS Instruction” on page 173 for additional information.

SYSENTER and SYSEXIT Instructions. The SYSENTER and SYSEXIT instructions are invalid in long mode, and result in an invalid opcode exception (#UD) if software attempts to use them. Software should use the SYSCALL and SYSRET instructions when running in long mode. See “SYSENTER and SYSEXIT (Legacy Mode Only)” on page 173 for additional information.

2.5.7 NOP Instruction

The legacy x86 architecture commonly uses opcode 90h as a one-byte NOP. In 64-bit mode, the processor treats opcode 90h specially in order to preserve this NOP definition. This is necessary because opcode 90h is actually the XCHG EAX, EAX instruction in the legacy architecture. Without special handling in 64-bit mode, the instruction would not be a true no-operation. Therefore, in 64-bit mode the processor treats opcode 90h (the legacy XCHG EAX, EAX instruction) as a true NOP, regardless of a REX operand-size prefix.

This special handling does not apply to the two-byte ModRM form of the XCHG instruction. Unless a 64-bit operand size is specified using a REX prefix byte, using the two-byte form of XCHG to exchange a register with itself does not result in a no-operation, because the default operation size is 32 bits in 64-bit mode.

2.5.8 Single-Byte INC and DEC Instructions

In 64-bit mode, the legacy encodings for the 16 single-byte INC and DEC instructions (one for each of the eight GPRs) are used to encode the REX prefix values. The functionality of these INC and DEC instructions is still available, however, using the ModRM forms of those instructions (opcodes FF /0 and FF /1). See “Single-Byte INC and DEC Instructions in 64-Bit Mode” in Volume 3 for additional information.

2.5.9 MOVSXD Instruction

MOVSXD is a new instruction in 64-bit mode (the legacy ARPL instruction opcode, 63h, is reassigned as the MOVSXD opcode). It reads a fixed-size 32-bit source operand from a register or memory and (if a REX prefix is used with the instruction) sign-extends the value to 64 bits. MOVSXD is analogous to the MOVSX instruction, which sign-extends a byte to a word or a word to a doubleword, depending on the effective operand size. See the instruction reference page for the MOVSXD instruction in Volume 3 for additional information.

2.5.10 Invalid Instructions

Table 2-3 lists instructions that are illegal in 64-bit mode. Table 2-4 on page 35 lists instructions that are invalid in long mode (both compatibility mode and 64-bit mode). Attempted use of these instructions causes an invalid-opcode exception (#UD) to occur.

Table 2-3. Invalid Instructions in 64-Bit Mode

Mnemonic	Opcode (hex)	Description
AAA	37	ASCII Adjust After Addition
AAD	D5	ASCII Adjust Before Division
AAM	D4	ASCII Adjust After Multiply
AAS	3F	ASCII Adjust After Subtraction
BOUND	62	Check Array Bounds
CALL (far)	9A	Procedure Call Far (absolute)

Table 2-3. Invalid Instructions in 64-Bit Mode (continued)

Mnemonic	Opcode (hex)	Description
DAA	27	Decimal Adjust after Addition
DAS	2F	Decimal Adjust after Subtraction
INTO	CE	Interrupt to Overflow Vector
JMP (far)	EA	Jump Far (absolute)
LDS	C5	Load DS Segment Register
LES	C4	Load ES Segment Register
POP DS	1F	Pop Stack into DS Segment
POP ES	07	Pop Stack into ES Segment
POP SS	17	Pop Stack into SS Segment
POPA, POPAD	61	Pop All to GPR Words or Doublewords
PUSH CS	0E	Push CS Segment Selector onto Stack
PUSH DS	1E	Push DS Segment Selector onto Stack
PUSH ES	06	Push ES Segment Selector onto Stack
PUSH SS	16	Push SS Segment Selector onto Stack
PUSHA, PUSHAD	60	Push All GPR Words or Doublewords onto Stack
Redundant Grp1 (undocumented)	82	Redundant encoding of group1 Eb,Ib opcodes
SALC (undocumented)	D6	Set AL According to CF

Table 2-4. Invalid Instructions in Long Mode

Mnemonic	Opcode (hex)	Description
SYSENTER	0F 34	System Call
SYSEXIT	0F 35	System Return

2.5.11 Reassigned Opcodes

Table 2-5 below lists opcodes that are assigned functions in 64-bit mode that differ from their legacy functions.

Table 2-5. Opcodes Reassigned in 64-Bit Mode

Opcode (hex)	Compatibility and Legacy Modes	64-Bit Mode
63	ARPL—Adjust Requestor Privilege Level	MOVSXD—Move Doubleword with Sign Extension
40–4F	DEC—Decrement by 1 INC—Increment by 1	REX Prefix
***Note**: Two-byte versions of DEC and INC are still available in 64-bit mode.*		

2.5.12 FXSAVE and FXRSTOR Instructions

The FXSAVE and FXRSTOR instructions are used to save and restore the entire 128-bit media (XMM), 64-bit media, and x87 instruction-set environment during a context switch. The AMD64 architecture modifies the memory format used by these instructions in order to save and restore the full 64-bit instruction and data pointers, as well as the XMM8–15 registers. Selection of the 32-bit legacy format or the expanded 64-bit format is accomplished by using the corresponding operand size with the FXSAVE and FXRSTOR instructions. When 64-bit software executes an FXSAVE and FXRSTOR with a 32-bit operand size (no operand-size override) the 32-bit legacy format is used. When 64-bit software executes an FXSAVE and FXRSTOR with a 64-bit operand size, the 64-bit format is used.

For more information on the save area formats, see Section 11.4.4, “Saving Media and x87 Execution Unit State,” on page 342

If the fast-FXSAVE/FXRSTOR (FFXSR) feature is enabled in EFER, FXSAVE and FXRSTOR do not save or restore the XMM0–15 registers when executed in 64-bit mode at CPL 0. The x87 environment and MXCSR are saved whether fast-FXSAVE/FXRSTOR is enabled or not. The fast-FXSAVE/FXRSTOR feature has no effect on FXSAVE/FXRSTOR in non 64-bit mode or when CPL > 0.

Software can use the CPUID instruction to determine whether the fast-FXSAVE/FXRSTOR feature is available (CPUID Fn8000_0001h_EDX[FFXSR]). For information on using the CPUID instruction to obtain processor feature information, see Section 3.3, “Processor Feature Identification,” on page 71.

2.6 Interrupts and Exceptions

When a processor is running in long mode, an interrupt or exception causes the processor to enter 64-bit mode. All long-mode interrupt handlers must be implemented as 64-bit code. The AMD64 architecture expands the legacy interrupt-processing and exception-processing mechanism to support

handling of interrupts by 64-bit operating systems and applications. The changes are summarized in the following sections. See “Long-Mode Interrupt Control Transfers” on page 272 for detailed information on these changes.

2.6.1 Interrupt Descriptor Table

The long-mode interrupt-descriptor table (IDT) must contain 64-bit mode interrupt-gate or trap-gate descriptors for all interrupts or exceptions that can occur while the processor is running in long mode. Task gates cannot be used in the long-mode IDT, because control transfers through task gates are not supported in long mode. In long mode, the IDT index is formed by scaling the interrupt vector by 16. In legacy protected mode, the IDT is indexed by scaling the interrupt vector by eight.

2.6.2 Stack Frame Pushes

In legacy mode, the size of an IDT entry (16 bits or 32 bits) determines the size of interrupt-stack-frame pushes, and SS:eSP is pushed only on a CPL change. In long mode, the size of interrupt stack-frame pushes is fixed at eight bytes, because interrupts are handled in 64-bit mode. Long mode interrupts also cause SS:RSP to be pushed unconditionally, rather than pushing only on a CPL change.

2.6.3 Stack Switching

Legacy mode provides a mechanism to automatically switch stack frames in response to an interrupt. In long mode, a slightly modified version of the legacy stack-switching mechanism is implemented, and an alternative stack-switching mechanism—called the interrupt stack table (IST)—is supported.

Long-Mode Stack Switches. When stacks are switched as part of a long-mode privilege-level change resulting from an interrupt, the following occurs:

- The target-stack pointer read from the TSS is a 64-bit RSP value.
- The SS register is loaded with a null selector. Setting the new SS selector to null allows nested control transfers in 64-bit mode to be handled properly. The SS.RPL value is cleared to 0.
- The old SS and RSP are saved on the new stack.

Interrupt Stack Table. In long mode, a new interrupt stack table (IST) mechanism is available as an alternative to the modified legacy stack-switching mechanism. The IST mechanism unconditionally switches stacks when it is enabled. It can be enabled for individual interrupt vectors using a field in the IDT entry. This allows mixing interrupt vectors that use the modified legacy mechanism with vectors that use the IST mechanism. The IST pointers are stored in the long-mode TSS. The IST mechanism is only available when long mode is enabled.

2.6.4 IRET Instruction

In compatibility mode, IRET pops SS:eSP off the stack only if there is a CPL change. This allows legacy applications to run properly in compatibility mode when using the IRET instruction.

In 64-bit mode, IRET unconditionally pops SS:eSP off of the interrupt stack frame, even if the CPL does not change. This is done because the original interrupt always pushes SS:RSP. Because interrupt

stack-frame pushes are always eight bytes in long mode, an IRET from a long-mode interrupt handler (64-bit code) must pop eight-byte items off the stack. This is accomplished by preceding the IRET with a 64-bit REX operand-size prefix.

In long mode, an IRET can load a null SS selector from the stack under the following conditions:

- The target operating mode is 64-bit mode.
- The target CPL<3.

Allowing IRET to load SS with a null selector under these conditions makes it possible for the processor to unnest interrupts (and far CALLs) in long mode.

2.6.5 Task-Priority Register (CR8)

The AMD64 architecture allows software to define up to 15 external interrupt-priority classes. Priority classes are numbered from 1 to 15, with priority-class 1 being the lowest and priority-class 15 the highest.

A new control register (CR8) is introduced by the AMD64 architecture for managing priority classes. This register, also called the *task-priority register* (TPR), uses the four low-order bits for specifying a task priority. How external interrupts are organized into these priority classes is implementation dependent. See “External Interrupt Priorities” on page 258 for information on this feature.

2.6.6 New Exception Conditions

The AMD64 architecture defines a number of new conditions that can cause an exception to occur when the processor is running in long mode. Many of the conditions occur when software attempts to use an address that is not in canonical form. See “Vectors” on page 236 for information on the new exception conditions that can occur in long mode.

2.7 Hardware Task Switching

The legacy hardware task-switch mechanism is disabled when the processor is running in long mode. However, long mode requires system software to create data structures for a single task—the long-mode task.

- *TSS Descriptors*—A new TSS-descriptor type, the 64-bit TSS type, is defined for use in long mode. It is the only valid TSS type that can be used in long mode, and it must be loaded into the TR by executing the LTR instruction in *64-bit mode*. See “TSS Descriptor” on page 364 for additional information.
- *Task Gates*—Because the legacy task-switch mechanism is not supported in long mode, *software cannot use task gates in long mode*. Any attempt to transfer control to another task through a task gate causes a general-protection exception (#GP) to occur.
- *Task-State Segment*—A 64-bit task state segment (TSS) is defined for use in long mode. This new TSS format contains 64-bit stack pointers (RSP) for privilege levels 0–2, interrupt-stack-table

(IST) pointers, and the I/O-map base address. See “64-Bit Task State Segment” on page 371 for additional information.

2.8 Long-Mode vs. Legacy-Mode Differences

Table 2-6 on page 39 summarizes several major system-programming differences between 64-bit mode and legacy protected mode. The third column indicates whether the difference also applies to compatibility mode. “Differences Between Long Mode and Legacy Mode” in Volume 3 summarizes the application-programming model differences.

Table 2-6. Differences Between Long Mode and Legacy Mode

Subject	64-Bit Mode Difference	Applies To Compatibility Mode?
x86 Modes	Real and virtual-8086 modes not supported	Yes
Task Switching	Task switching not supported	Yes
Addressing	64-bit virtual addresses	No
	4-level paging structures	Yes
	PAE must always be enabled	
Loaded Segment (Usage during memory reference)	CS, DS, ES, SS segment bases are ignored	No
	CS, DS, ES, FS, GS, SS segment limits are ignored	
	DS, ES, FS, GS attribute are ignored	
	CS, DS, ES, SS Segment prefixes are ignored	
Exception and Interrupt Handling	All pushes are 8 bytes	Yes
	IDT entries are expanded to 16 bytes	
	SS is not changed for stack switch	
	SS:RSP is pushed unconditionally	
Call Gates	All pushes are 8 bytes	Yes
	16-bit call gates are illegal	
	32-bit call gate type is redefined as 64-bit call gate and is expanded to 16 bytes	
	SS is not changed for stack switch	
System-Descriptor Registers	GDT, IDT, LDT, TR base registers expanded to 64 bits	Yes
System-Descriptor Table Entries and Pseudo-Descriptors	LGDT and LIDT use expanded 10-byte pseudo-descriptors	No
	LLDT and LTR use expanded 16-byte table entries	

3 System Resources

The operating system manages the software-execution environment and general system operation through the use of system resources. These resources consist of system registers (control registers and model-specific registers) and system-data structures (memory-management and protection tables). The system-control registers are described in detail in this chapter; many of the features they control are described elsewhere in this volume. The model-specific registers supported by the AMD64 architecture are introduced in this chapter.

Because of their complexity, system-data structures are described in separate chapters. Refer to the following chapters for detailed information on these data structures:

- Descriptors and descriptor tables are described in Section 4.4 “Segmentation Data Structures and Registers,” on page 75.
- Page-translation tables are described in Section 5.2 “Legacy-Mode Page Translation,” on page 133 and Section 5.3 “Long-Mode Page Translation,” on page 141.
- The task-state segment is described in Section 12.2.4 “Legacy Task-State Segment,” on page 367 and Section 12.2.5 “64-Bit Task State Segment,” on page 371.

Not all processor implementations are required to support all possible features. The last section in this chapter addresses processor-feature identification. System software uses the capabilities described in that section to determine which features are supported so that the appropriate service routines are loaded.

3.1 System-Control Registers

The registers that control the AMD64 architecture operating environment include:

- *CR0*—Provides operating-mode controls and some processor-feature controls.
- *CR2*—This register is used by the page-translation mechanism. It is loaded by the processor with the page-fault virtual address when a page-fault exception occurs.
- *CR3*—This register is also used by the page-translation mechanism. It contains the base address of the highest-level page-translation table, and also contains cache controls for the specified table.
- *CR4*—This register contains additional controls for various operating-mode features.
- *CR8*—This new register, accessible in 64-bit mode using the REX prefix, is introduced by the AMD64 architecture. CR8 is used to prioritize external interrupts and is referred to as the *task-priority register* (TPR).
- *RFLAGS*—This register contains processor-status and processor-control fields. The status and control fields are used primarily in the management of virtual-8086 mode, hardware multitasking, and interrupts.

- *EFER*—This model-specific register contains status and controls for additional features not managed by the CR0 and CR4 registers. Included in this register are the long-mode enable and activation controls introduced by the AMD64 architecture.

Control registers CR1, CR5–CR7, and CR9–CR15 are reserved.

In legacy mode, all control registers and RFLAGS are 32 bits. The EFER register is 64 bits in all modes. The AMD64 architecture expands all 32-bit system-control registers to 64 bits. In 64-bit mode, the MOV CR*n* instructions read or write all 64 bits of these registers (operand-size prefixes are ignored). In compatibility and legacy modes, control-register writes fill the low 32 bits with data and the high 32 bits with zeros, and control-register reads return only the low 32 bits.

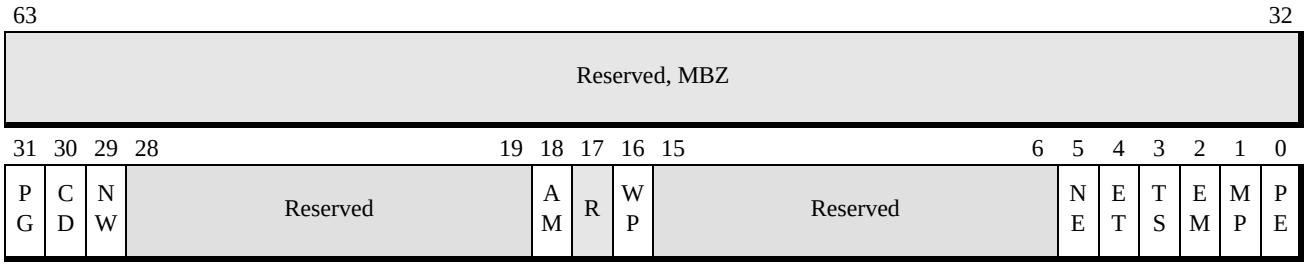
In 64-bit mode, the high 32 bits of CR0 and CR4 are reserved and must be written with zeros. Writing a 1 to any of the high 32 bits results in a general-protection exception, #GP(0). All 64 bits of CR2 are writable. However, the MOV CR*n* instructions *do not* check that addresses written to CR2 are within the virtual-address limitations of the processor implementation.

All CR3 bits are writable, except for unimplemented physical address bits, which must be cleared to 0.

The upper 32 bits of RFLAGS are always read as zero by the processor. Attempts to load the upper 32 bits of RFLAGS with anything other than zero are ignored by the processor.

3.1.1 CR0 Register

The CR0 register is shown in Figure 3-1 on page 43. The legacy CR0 register is identical to the low 32 bits of this register (CR0 bits 31:0).



Bits	Mnemonic	Description	Access type
63:32	—	Reserved	MBZ
31	PG	Paging	R/W
30	CD	Cache Disable	R/W
29	NW	Not Writethrough	R/W
28:19	—	Reserved - do not change	
18	AM	Alignment Mask	R/W
17	—	Reserved - do not change	
16	WP	Write Protect	R/W[1]
15:6	—	Reserved - do not change	
5	NE	Numeric Error	R/W
4	ET	Extension Type	R
3	TS	Task Switched	R/W
2	EM	Emulation	R/W
1	MP	Monitor Coprocessor	R/W
0	PE	Protection Enabled	R/W

1. Conditionally -- see description below.

Figure 3-1. Control Register 0 (CR0)

The functions of the CR0 control bits are (unless otherwise noted, all bits are read/write):

Protected-Mode Enable (PE) Bit. Bit 0. Software enables protected mode by setting PE to 1, and disables protected mode by clearing PE to 0. When the processor is running in protected mode, segment-protection mechanisms are enabled.

See Section 4.9 “Segment-Protection Overview,” on page 104 for information on the segment-protection mechanisms.

Monitor Coprocessor (MP) Bit. Bit 1. Software uses the MP bit with the task-switched control bit (CR0.TS) to control whether execution of the WAIT/FWAIT instruction causes a device-not-available exception (#NM) to occur, as follows:

- If both the monitor-coprocessor and task-switched bits are set (CR0.MP=1 *and* CR0.TS=1), then executing the WAIT/FWAIT instruction causes a device-not-available exception (#NM).
- If either the monitor-coprocessor or task-switched bits are clear (CR0.MP=0 *or* CR0.TS=0), then executing the WAIT/FWAIT instruction proceeds normally.

Software typically should set MP to 1 if the processor implementation supports x87 instructions. This allows the CR0.TS bit to completely control when the x87-instruction context is saved as a result of a task switch.

Emulate Coprocessor (EM) Bit. Bit 2. Software forces all x87 instructions to cause a device-not-available exception (#NM) by setting EM to 1. Likewise, setting EM to 1 forces an invalid-opcode exception (#UD) when an attempt is made to execute any of the 64-bit or 128-bit media instructions except the FXSAVE and FXRSTOR instructions. Attempting to execute these instructions when EM is set results in an #NM exception instead.The exception handlers can emulate these instruction types if desired. Setting the EM bit to 1 does not cause an #NM exception when the WAIT/FWAIT instruction is executed.

Task Switched (TS) Bit. Bit 3. When an attempt is made to execute an x87 or media instruction while TS=1, a device-not-available exception (#NM) occurs. Software can use this mechanism—sometimes referred to as “lazy context-switching”—to save the unit contexts before executing the next instruction of those types. As a result, the x87 and media instruction-unit contexts are saved only when necessary as a result of a task switch.

When a hardware task switch occurs, TS is automatically set to 1. System software that implements software task-switching rather than using the hardware task-switch mechanism can still use the TS bit to control x87 and media instruction-unit context saves. In this case, the task-management software uses a MOV CR0 instruction to explicitly set the TS bit to 1 during a task switch. Software can clear the TS bit by either executing the CLTS instruction or by writing to the CR0 register directly. Long-mode system software can use this approach even though the hardware task-switch mechanism is not supported in long mode.

The CR0.MP bit controls whether the WAIT/FWAIT instruction causes an #NM exception when TS=1.

Extension Type (ET) Bit. Bit 4, read-only. In some early x86 processors, software set ET to 1 to indicate support of the 387DX math-coprocessor instruction set. This bit is now reserved and forced to 1 by the processor. Software cannot clear this bit to 0.

Numeric Error (NE) Bit. Bit 5. Clearing the NE bit to 0 disables internal control of x87 floating-point exceptions and enables external control. When NE is cleared to 0, the IGNNE# input signal controls whether x87 floating-point exceptions are ignored:

- When IGNNE# is 1, x87 floating-point exceptions are ignored.
- When IGNNE# is 0, x87 floating-point exceptions are reported by setting the FERR# input signal to 1. External logic can use the FERR# signal as an external interrupt.

When NE is set to 1, internal control over x87 floating-point exception reporting is enabled and the external reporting mechanism is disabled. It is recommended that software set NE to 1. This enables optimal performance in handling x87 floating-point exceptions.

Write Protect (WP) Bit. Bit 16. Read-only pages are protected from supervisor-level writes when the WP bit is set to 1. When WP is cleared to 0, supervisor software can write into read-only pages.

See Section 5.6 “Page-Protection Checks,” on page 158 for information on the page-protection mechanism. If the shadow stack feature has been enabled (CR4.CET=1), attempting to clear WP to 0 causes a general-protection exception (#GP).

Alignment Mask (AM) Bit. Bit 18. Software enables automatic alignment checking by setting the AM bit to 1 when RFLAGS.AC=1. Alignment checking can be disabled by clearing either AM or RFLAGS.AC to 0. When automatic alignment checking is enabled and CPL=3, a memory reference to an unaligned operand causes an alignment-check exception (#AC).

Not Writethrough (NW) Bit. Bit 29. Ignored. This bit can be set to 1 or cleared to 0, but its value is ignored. The NW bit exists only for legacy purposes.

Cache Disable (CD) Bit. Bit 30. When CD is cleared to 0, the internal caches are enabled. When CD is set to 1, no new data or instructions are brought into the internal caches. However, the processor still accesses the internal caches when CD = 1 under the following situations:

- Reads that hit in an internal cache cause the data to be read from the internal cache that reported the hit.
- Writes that hit in an internal cache cause the cache line that reported the hit to be written back to memory and invalidated in the cache.

Cache misses do not affect the internal caches when CD = 1. Software can prevent cache access by setting CD to 1 and invalidating the caches.

Setting CD to 1 also causes the processor to ignore the page-level cache-control bits (PWT and PCD) when paging is enabled. These bits are located in the page-translation tables and CR3 register. See Section “Page-Level Writethrough (PWT) Bit,” on page 151 and Section “Page-Level Cache Disable (PCD) Bit,” on page 151 for information on page-level cache control.

See Section 7.6 “Memory Caches,” on page 199 for information on the internal caches.

Paging Enable (PG) Bit. Bit 31. Software enables page translation by setting PG to 1, and disables page translation by clearing PG to 0. Page translation cannot be enabled unless the processor is in protected mode (CR0.PE=1). If software attempts to set PG to 1 when PE is cleared to 0, the processor causes a general-protection exception (#GP).

See Section 5.1 “Page Translation Overview,” on page 129 for information on the page-translation mechanism.

Reserved Bits. Bits 28:19, 17, 15:6, and 63:32. When writing the CR0 register, software should set the values of reserved bits to the values found during the previous CR0 read. No attempt should be made to change reserved bits, and software should never rely on the values of reserved bits. In long mode, bits 63:32 are reserved and must be written with zero, otherwise a #GP occurs.

3.1.2 CR2 and CR3 Registers

The CR2 (page-fault linear address) register, shown in Figure 3-2 on page 46 and Figure 3-3 on page 46, and the CR3 (page-translation-table base address) register, shown in Figure 3-4 and Figure 3-5 on page 46, and Figure 3-6 on page 47, are used only by the page-translation mechanism.

Figure 3-2. Control Register 2 (CR2)—Legacy-Mode

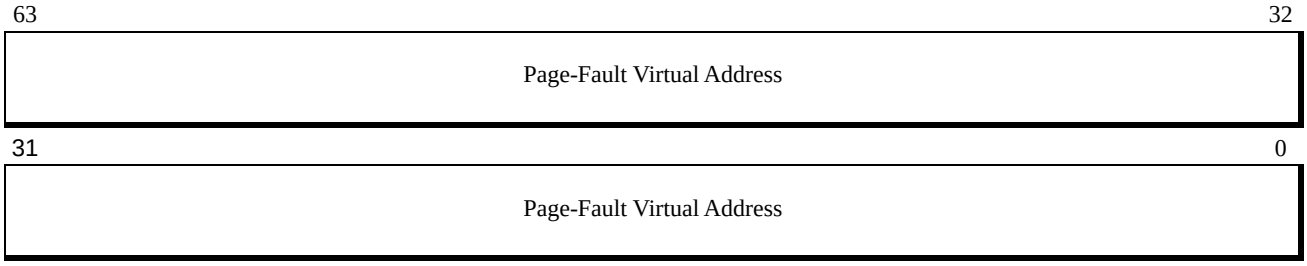


Figure 3-3. Control Register 2 (CR2)—Long Mode

See Section “CR2 Register,” on page 247 for a description of the CR2 register.

The CR3 register is used to point to the base address of the highest-level page-translation table.

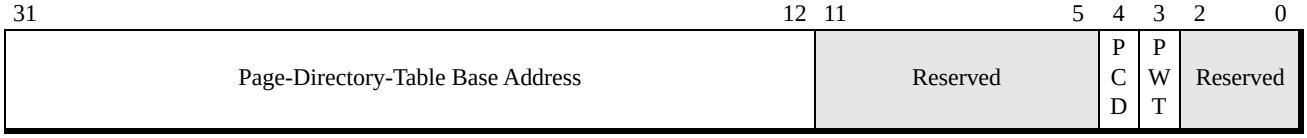

Figure 3-4. Control Register 3 (CR3)—Legacy-Mode Non-PAE Paging

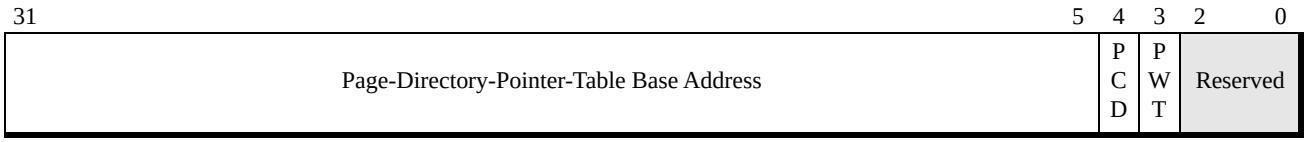

Figure 3-5. Control Register 3 (CR3)—Legacy-Mode PAE Paging

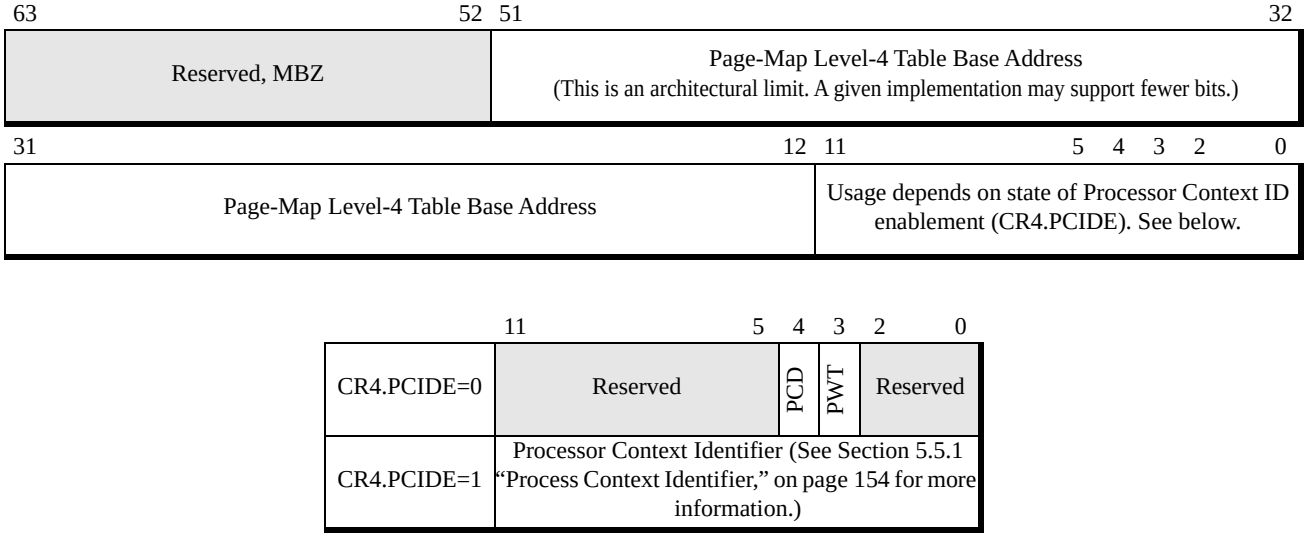

Figure 3-6. Control Register 3 (CR3)—Long Mode

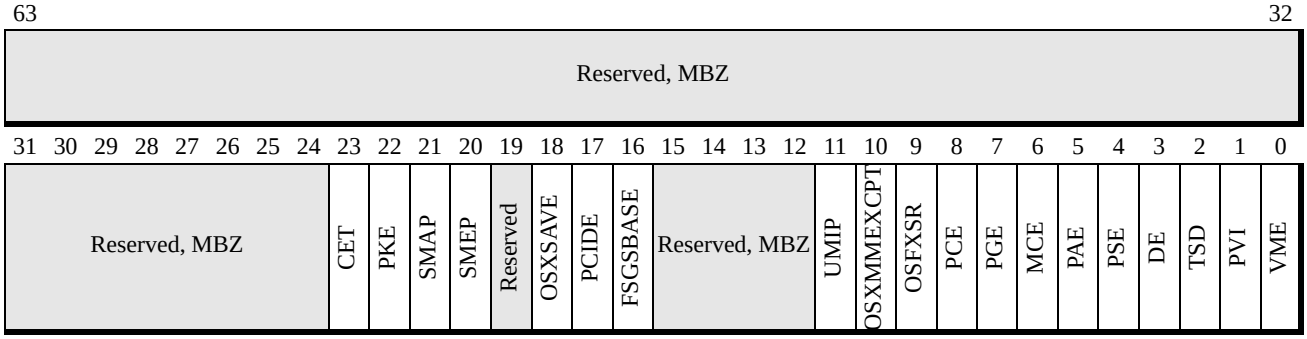
The legacy CR3 register is described in Section 5.2.1 “CR3 Register,” on page 134, and the long-mode CR3 register is described in Section 5.3.2 “CR3,” on page 141.

3.1.3 CR4 Register

The CR4 register is shown in Figure 3-7. In legacy mode, the CR4 register is identical to the low 32 bits of the register (CR4 bits 31:0). The features controlled by the bits in the CR4 register are model-specific extensions. Except for the performance-counter extensions (PCE) feature, software can use the CPUID instruction to verify that each feature is supported before using that feature. See Section 3.3 “Processor Feature Identification,” on page 71 for information on using the CPUID instruction.



Bits	Mnemonic	Description	Access Type
63:24	—	Reserved	MBZ
23	CET	Control-flow Enforcement Technology	R/W
22	PKE	Protection Key Enable	R/W
21	SMAP	Supervisor Mode Access Protection	R/W
20	SMEP	Supervisor Mode Execution Prevention	R/W
19	—	Reserved	MBZ
18	OSXSAVE	XSAVE and Processor Extended States Enable Bit	R/W
17	PCIDE	Process Context Identifier Enable	R/W
16	FSGSBASE	Enable RDFSBASE, RDGSBASE, WRFSBASE, and WRGSBASE instructions	R/W
15:12	—	Reserved	MBZ
11	UMIP	User Mode Instruction Prevention	R/W
10	OSXMMEXCPT	Operating System Unmasked Exception Support	R/W
9	OSFXSR	Operating System FXSAVE/FXRSTOR Support	R/W
8	PCE	Performance-Monitoring Counter Enable	R/W
7	PGE	Page-Global Enable	R/W
6	MCE	Machine Check Enable	R/W
5	PAE	Physical-Address Extension	R/W
4	PSE	Page Size Extensions	R/W
3	DE	Debugging Extensions	R/W
2	TSD	Time Stamp Disable	R/W
1	PVI	Protected-Mode Virtual Interrupts	R/W
0	VME	Virtual-8086 Mode Extensions	R/W

The function of the CR4 control bits are (all bits are read/write):

Virtual-8086 Mode Extensions (VME). Bit 0. Setting VME to 1 enables hardware-supported performance enhancements for software running in virtual-8086 mode. Clearing VME to 0 disables this support. The enhancements enabled when VME=1 include:

- Virtualized, maskable, external-interrupt control and notification using the VIF and VIP bits in the RFLAGS register. Virtualizing affects the operation of several instructions that manipulate the RFLAGS.IF bit.
- Selective intercept of software interrupts (INT*n* instructions) using the interrupt-redirection bitmap in the TSS.

Protected-Mode Virtual Interrupts (PVI). Bit 1. Setting PVI to 1 enables support for protected-mode virtual interrupts. Clearing PVI to 0 disables this support. When PVI=1, hardware support of two bits in the RFLAGS register, VIF and VIP, is enabled.

Only the STI and CLI instructions are affected by enabling PVI. Unlike the case when CR0.VME=1, the interrupt-redirection bitmap in the TSS cannot be used for selective INT*n* interception.

PVI enhancements are also supported in long mode. See Section 8.10 “Virtual Interrupts,” on page 279 for more information on using PVI.

Time-Stamp Disable (TSD). Bit 2. The TSD bit allows software to control the privilege level at which the time-stamp counter can be read. When TSD is cleared to 0, software running at any privilege level can read the time-stamp counter using the RDTSC or RDTSCP instructions. When TSD is set to 1, only software running at privilege-level 0 can execute the RDTSC or RDTSCP instructions.

Debugging Extensions (DE). Bit 3. Setting the DE bit to 1 enables the I/O breakpoint capability and enforces treatment of the DR4 and DR5 registers as reserved. Software that accesses DR4 or DR5 when DE=1 causes a invalid opcode exception (#UD).

When the DE bit is cleared to 0, I/O breakpoint capabilities are disabled. Software references to the DR4 and DR5 registers are aliased to the DR6 and DR7 registers, respectively.

Page-Size Extensions (PSE). Bit 4. Setting PSE to 1 enables the use of 4-Mbyte physical pages. With PSE=1, the physical-page size is selected between 4 Kbytes and 4 Mbytes using the page-directory entry page-size field (PS). Clearing PSE to 0 disables the use of 4-Mbyte physical pages and restricts all physical pages to 4 Kbytes.

The PSE bit has no effect when physical-address extensions are enabled (CR4.PAE=1). Because long mode requires CR4.PAE=1, the PSE bit is ignored when the processor is running in long mode.

See Section “4-Mbyte Page Translation,” on page 136 for more information on 4-Mbyte page translation.

Physical-Address Extension (PAE). Bit 5. Setting PAE to 1 enables the use of physical-address extensions and 2-Mbyte physical pages. Clearing PAE to 0 disables these features.

With PAE=1, the page-translation data structures are expanded from 32 bits to 64 bits, allowing the translation of up to 52-bit physical addresses. Also, the physical-page size is selectable between 4 Kbytes and 2 Mbytes using the page-directory-entry page-size field (PS). Long mode requires PAE to be enabled in order to use the 64-bit page-translation data structures to translate 64-bit virtual addresses to 52-bit physical addresses.

See Section 5.2.3 “PAE Paging,” on page 137 for more information on physical-address extensions.

Machine-Check Enable (MCE). Bit 6. Setting MCE to 1 enables the machine-check exception mechanism. Clearing this bit to 0 disables the mechanism. When enabled, a machine-check exception (#MC) occurs when an uncorrectable machine-check error is encountered.

Regardless of whether machine-check exceptions are enabled, the processor records enabled-errors when they occur. Error-reporting is performed by the machine-check error-reporting register banks. Each bank includes a control register for enabling error reporting and a status register for capturing errors. Correctable machine-check errors are also reported, but they do not cause a machine-check exception.

See Chapter 9, “Machine Check Architecture,” for a description of the machine-check mechanism, the registers used, and the types of errors captured by the mechanism.

Page-Global Enable (PGE). Bit 7. When page translation is enabled, system-software performance can often be improved by making some page translations *global* to all tasks and procedures. Setting PGE to 1 enables the global-page mechanism. Clearing this bit to 0 disables the mechanism.

When PGE is enabled, system software can set the global-page (G) bit in the lowest level of the page-translation hierarchy to 1, indicating that the page translation is global. Page translations marked as global are not invalidated in the TLB when the page-translation-table base address (CR3) is updated. When the G bit is cleared, the page translation is not global. All supported physical-page sizes also support the global-page mechanism. See Section 5.5.2 “Global Pages,” on page 155 for information on using the global-page mechanism.

Performance-Monitoring Counter Enable (PCE). Bit 8. Setting PCE to 1 allows software running at any privilege level to use the RDPMC instruction. Software uses the RDPMC instruction to read the performance-monitoring counter MSRs, *PerfCtr*n*. Clearing PCE to 0 allows only the most-privileged software (CPL=0) to use the RDPMC instruction.

FXSAVE/FXRSTOR Support (OSFXSR). Bit 9. System software must set the OSFXSR bit to 1 to enable use of the legacy SSE instructions. When this bit is set to 1, it also indicates that system software uses the FXSAVE and FXRSTOR instructions to save and restore the processor state for the x87, 64-bit media, and 128-bit media instructions.

Clearing the OSFXSR bit to 0 indicates that legacy SSE instructions cannot be used. Attempts to use those instructions while this bit is clear result in an invalid-opcode exception (#UD). Software can continue to use the FXSAVE/FXRSTOR instructions for saving and restoring the processor state for the x87 and 64-bit media instructions.

Unmasked Exception Support (OSXMMEXCPT). Bit 10. System software must set the OSXMMEXCPT bit to 1 when it supports the SIMD floating-point exception (#XF) for handling of unmasked 256-bit and 128-bit media floating-point errors. Clearing the OSXMMEXCPT bit to 0 indicates the #XF handler is not supported. When OSXMMEXCPT=0, unmasked 128-bit media floating-point exceptions cause an invalid-opcode exception (#UD). See “SIMD Floating-Point Exception Causes” in Volume 1 for more information on unmasked SSE floating-point exceptions.

User Mode Instruction Prevention (UMIP). Bit 11. Setting UMIP to 1 enables a security mode to restrict certain instructions executing at CPL>0 so that they do not reveal information about structures that are controlled by the processor when it is at CPL=0. When UMIP is enabled, execution of SGDT, SIDT, SLDT, SMSW and STR instructions become available only at CPL=0 and any attempt to execute them with CPL>0 results in a #GP fault with error code 0. See Section 6 “System Instructions,” on page 167 for more information about UMIP.

FSGSBASE. Bit 16. System software must set this bit to 1 to enable the execution of the RDFSBASE, RDGSBASE, WRFSBASE, and WRGSBASE instructions when supported. When enabled, these instructions allow software running in 64-bit mode at any privilege level to read and write the FS.base and GS.base hidden segment register state. See the discussion of segment registers in 64-bit mode in Section 4.5.3 “Segment Registers in 64-Bit Mode,” on page 80. Also see descriptions of the RDFSBASE, RDGSBASE, WRFSBASE, and WRGSBASE instructions in Volume 3.

Processor Context Identifier Enable (PCIDE). Bit 17. Enable support for Process Context Identifiers (PCIDs). System software must set this bit to 1 to enable execution of the INVPCID instruction when supported. Can only be set in long mode (EFER.LMA = 1). See Chapter 5.5.1, “Process Context Identifier,” for more information on Process Context Identifiers.

XSAVE and Extended States (OSXSAVE). Bit 18. After verifying hardware support for the extended processor state management instructions, operating system software sets this bit to indicate support for the XGETBV, XSAVE and XRSTOR instructions.

Setting this bit also:

- allows the execution of the XGETBV and XSETBV instructions, and
- enables the XSAVE and XRSTOR instructions to save and restore the x87 FPU state (including MMX registers), along with other processor extended states enabled in XCR0.

After initializing the XSAVE/XRSTOR save area, XSAVEOPT (if supported) may be used to save x87 FPU and other enabled extended processor state. For more information on XSAVEOPT, see individual instruction listing in Chapter 2 of Volume 4.

Note that legacy SSE instruction execution must be enabled prior to enabling extended processor state management.

Supervisor Mode Execution Prevention (SMEP). Bit 20. Setting this bit enables the supervisor mode execution prevention feature, if supported. This feature prevents the execution of instructions that reside in pages accessible by user-mode software when the processor is in supervisor-mode. See Section 5.6 “Page-Protection Checks,” on page 158 for more information.

Supervisor Mode Access Prevention (SMAP). Bit 21. Setting this bit enables the supervisor mode access prevention feature, if supported. This feature prevents certain data accesses to pages accessible by user-mode software when the processor is in supervisor mode. See Section 5.6.6 “Supervisor-Mode Access Prevention(CR4.SMAP) Bit,” on page 160 for more information.

Protection Key Enable (PKE). Bit 22. Enable support for memory Protection Keys. Also enables support for the RDPKRU and WRPKRU instructions. A MOV to CR4 that changes CR4.PKE from 0 to 1 causes all cached entries in the TLB for the logical processor to be invalidated. (See Section 5.6.7 “Memory Protection Keys (MPK) Bit,” on page 161 for more information on memory protection keys.)

Control-flow Enforcement Technology (CET). Bit 23. Setting this bit enables the shadow stack feature. This feature ensures that return addresses read from the stack by RET and IRET instructions originated from a CALL instruction or similar control transfer.

See Section 18 “Shadow Stacks,” on page 647 for more information. Before setting this bit, CR0.WP must be set to 1, otherwise a #GP fault is generated.

CR1 and CR5–CR7 Registers. Control registers CR1, CR5–CR7, and CR9–CR15 are reserved. Attempts by software to use these registers result in an undefined-opcode exception (#UD).

3.1.4 Additional Control Registers in 64-Bit-Mode

In 64-bit mode, additional encodings are available to address up to eight additional control registers. The REX.R bit, in a REX prefix, is used to modify the ModRM *reg* field when that field encodes a control register, as shown in "REX Prefixes" in Volume 3. These additional encodings enable the processor to address CR8–CR15.

One additional control register, CR8, is defined in 64-bit mode for all hardware implementations, as described in "CR8 (Task Priority Register, TPR)," below. Access to the CR9–CR15 registers is implementation-dependent. Any attempt to access an unimplemented register results in an invalid-opcode exception (#UD).

3.1.5 CR8 (Task Priority Register, TPR)

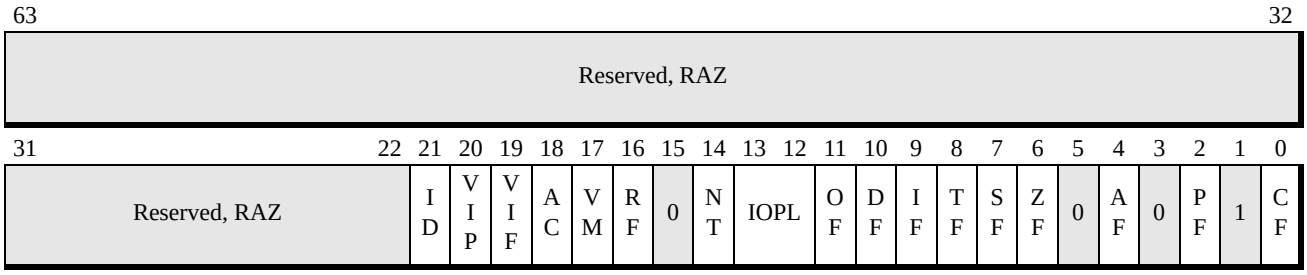
The AMD64 architecture introduces a new control register, CR8, defined as the task priority register (TPR). The register is accessible in 64-bit mode using the REX prefix. See Section 8.5.2 "External Interrupt Priorities," on page 258 for a description of the TPR and how system software can use the TPR for controlling external interrupts.

3.1.6 RFLAGS Register

The RFLAGS register contains two different types of information:

- *Control bits* provide system-software controls and directional information for string operations. Some of these bits can have privilege-level restrictions.
- *Status bits* provide information resulting from logical and arithmetic operations. These are written by the processor and can be read by software running at any privilege level.

Figure 3-7 on page 53 shows the format of the RFLAGS register. The legacy EFLAGS register is identical to the low 32 bits of the register shown in Figure 3-7 (RFLAGS bits 31:0). The term *rFLAGS* is used to refer to the 16-bit, 32-bit, or 64-bit flags register, depending on context.



Bits	Mnemonic	Description	Access type
63:22	—	Reserved	RAZ
21	ID	ID Flag	R/W
20	VIP	Virtual Interrupt Pending	R/W
19	VIF	Virtual Interrupt Flag	R/W
18	AC	Alignment Check	R/W
17	VM	Virtual-8086 Mode	R/W
16	RF	Resume Flag	R/W
15	—	Reserved	RAZ
14	NT	Nested Task	R/W
13:12	IOPL	I/O Privilege Level	R/W
11	OF	Overflow Flag	R/W
10	DF	Direction Flag	R/W
9	IF	Interrupt Flag	R/W
8	TF	Trap Flag	R/W
7	SF	Sign Flag	R/W
6	ZF	Zero Flag	R/W
5	—	Reserved	RAZ
4	AF	Auxiliary Flag	R/W
3	—	Reserved	RAZ
2	PF	Parity Flag	R/W
1	—	Reserved	RA1
0	CF	Carry Flag	R/W

Figure 3-7. RFLAGS Register

The functions of the RFLAGS control and status bits used by application software are described in “Flags Register” in Volume 1. The functions of RFLAGS system bits are (unless otherwise noted, all bits are read/write):

Trap Flag (TF) Bit. Bit 8. Software sets the TF bit to 1 to enable single-step mode during software debug. Clearing this bit to 0 disables single-step mode.

When single-step mode is enabled at the start of an instruction's execution, a debug exception (#DB) occurs immediately after the instruction completes execution. Single stepping is automatically disabled (TF is set to 0) when the #DB exception occurs or when any exception or interrupt occurs.

See Section 13.1.4 “Single Stepping,” on page 398 for information on using the single-step mode during debugging.

Interrupt Flag (IF) Bit. Bit 9. Software sets the IF bit to 1 to enable maskable interrupts. Clearing this bit to 0 causes the processor to ignore maskable interrupts. The state of the IF bit does not affect the response of a processor to non-maskable interrupts, software-interrupt instructions, or exceptions.

The ability to modify the IF bit depends on several factors:

- The current privilege-level (CPL)
- The I/O privilege level (RFLAGS.IOPL)
- Whether or not virtual-8086 mode extensions are enabled (CR4.VME=1)
- Whether or not protected-mode virtual interrupts are enabled (CR4.PVI=1)

See Section 8.1.4 “Masking External Interrupts,” on page 235 for information on interrupt masking. See Section 6.2.3 “Accessing the RFLAGS Register,” on page 175 for information on the specific instructions used to modify the IF bit.

I/O Privilege Level Field (IOPL) Field. Bits 13:12. The IOPL field specifies the privilege level required to execute I/O address-space instructions (i.e., instructions that address the I/O space rather than memory-mapped I/O, such as IN, OUT, INS, OUTS, etc.). For software to execute these instructions, the current privilege-level (CPL) must be equal to or higher than (lower numerical value than) the privilege specified by IOPL (CPL <= IOPL). If the CPL is lower than (higher numerical value than) that specified by the IOPL (CPL > IOPL), the processor causes a general-protection exception (#GP) when software attempts to execute an I/O instruction. See “Protected-Mode I/O” in Volume 1 for information on how IOPL controls access to address-space I/O.

Virtual-8086 mode uses IOPL to control virtual interrupts and the IF bit when virtual-8086 mode extensions are enabled (CR4.VME=1). The protected-mode virtual-interrupt mechanism (PVI) also uses IOPL to control virtual interrupts and the IF bit when PVI is enabled (CR4.PVI=1). See Section 8.10 “Virtual Interrupts,” on page 279 for information on how IOPL is used by the virtual interrupt mechanism.

Nested Task (NT) Bit. Bit 14, IRET reads the NT bit to determine whether the current task is nested within another task. When NT is set to 1, the current task is nested within another task. When NT is cleared to 0, the current task is at the top level (not nested).

The processor sets the NT bit during a task switch resulting from a CALL, interrupt, or exception through a task gate. When an IRET is executed from legacy mode while the NT bit is set, a task switch occurs. See Section 12.3.3 “Task Switches Using Task Gates,” on page 380 for information on switching tasks using task gates, and Section 12.3.4 “Nesting Tasks,” on page 382 for information on task nesting.

Resume Flag (RF) Bit. Bit 16. The RF bit, when set to 1, temporarily disables instruction breakpoint reporting to prevent repeated debug exceptions (#DB) from occurring. This allows an instruction

which had been inhibited by an instruction-breakpoint debug exception to be restarted by the debug exception handler.

The processor clears the RF bit after every instruction is successfully executed, except when the

instruction is:

- An IRET that sets the RF bit.
- JMP, CALL, or INT*n* through a task gate.

In both of the above cases, RF is not cleared to 0 until the *next* instruction successfully executes.

When an exception occurs (or when a string instruction is interrupted), the processor normally sets RF=1 in the RFLAGS image saved on the interrupt stack. However, when a #DB exception occurs as a result of an instruction breakpoint, the processor clears the RF bit to 0 in the interrupt-stack RFLAGS image.

For instruction restart to work properly following an instruction breakpoint, the #DB exception handler must set RF to 1 in the interrupt-stack RFLAGS image. When an IRET is later executed to return to the instruction that caused the instruction-breakpoint #DB exception, the set RF bit (RF=1) is loaded from the interrupt-stack RFLAGS image. RF is not cleared by the processor until the instruction causing the #DB exception successfully executes.

Virtual-8086 Mode (VM) Bit. Bit 17. Software sets the VM bit to 1 to enable virtual-8086 mode. Software clears the VM bit to 0 to disable virtual-8086 mode. System software can only change this bit using a task switch or an IRET. It cannot modify the bit using the POPFD instruction.

Alignment Check (AC) Bit. Bit 18. Software enables automatic alignment checking by setting the AC bit to 1 when CR0.AM=1. Alignment checking can be disabled by clearing either AC or CR0.AM to 0. When automatic alignment checking is enabled and the current privilege-level (CPL) is 3 (least privileged), a memory reference to an unaligned operand causes an alignment-check exception (#AC).

When the supervisor mode access prevention feature is enabled (CR4.SMAP=1), certain supervisor-mode data accesses to pages accessible by user mode are allowed only if RFLAGS.AC=1. See Section 5.6.6 “Supervisor-Mode Access Prevention(CR4.SMAP) Bit,” on page 160 for more information.

Virtual Interrupt (VIF) Bit. Bit 19. The VIF bit is a virtual image of the RFLAGS.IF bit. It is enabled when either virtual-8086 mode extensions are enabled (CR4.VME=1) or protected-mode virtual interrupts are enabled (CR4.PVI=1), and the RFLAGS.IOPL field is less than 3. When enabled, instructions that ordinarily would modify the IF bit actually modify the VIF bit with no effect on the RFLAGS.IF bit.

System software that supports virtual-8086 mode should enable the VIF bit using CR4.VME. This allows 8086 software to execute instructions that can set and clear the RFLAGS.IF bit without causing an exception. With VIF enabled in virtual-8086 mode, those instructions set and clear the VIF bit instead, giving the appearance to the 8086 software that it is modifying the RFLAGS.IF bit. System

software reads the VIF bit to determine whether or not to take the action desired by the 8086 software (enabling or disabling interrupts by setting or clearing the RFLAGS.IF bit).

In long mode, the use of the VIF bit is supported when CR4.PVI=1. See Section 8.10 “Virtual Interrupts,” on page 279 for more information on virtual interrupts.

Virtual Interrupt Pending (VIP) Bit. Bit 20. The VIP bit is provided as an extension to both virtual-8086 mode and protected mode. It is used by system software to indicate that an external, maskable interrupt is pending (awaiting) execution by either a virtual-8086 mode or protected-mode interrupt-service routine. Software must enable virtual-8086 mode extensions (CR4.VME=1) or protected-mode virtual interrupts (CR4.PVI=1) before using VIP.

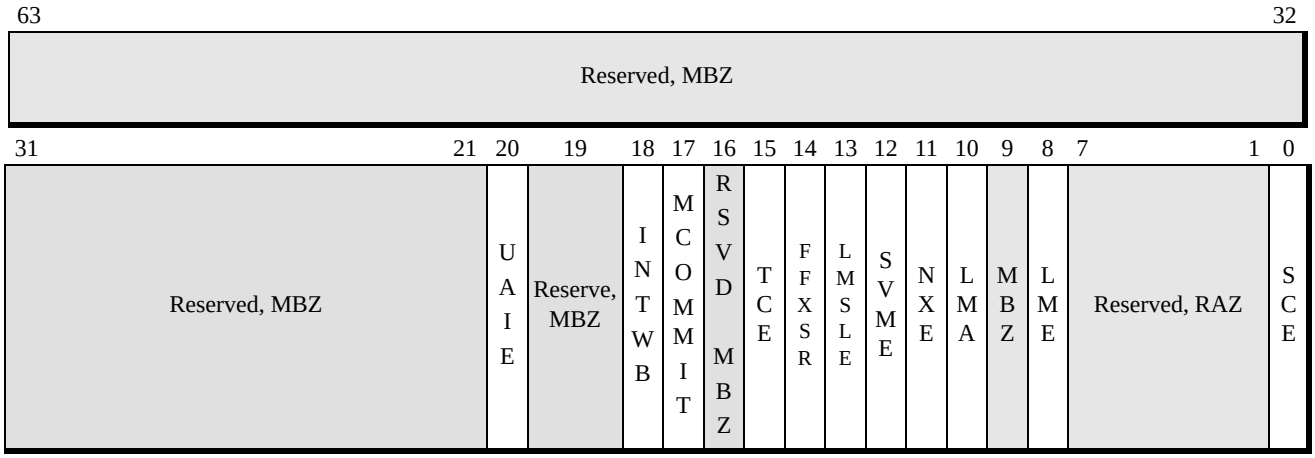
VIP is normally set to 1 by a protected-mode interrupt-service routine that was entered from virtual-8086 mode as a result of an external, maskable interrupt. Before returning to the virtual-8086 mode application, the service routine sets VIP to 1 if EFLAGS.VIF=1. When the virtual-8086 mode application attempts to enable interrupts by clearing EFLAGS.VIF to 0 while VIP=1, a general-protection exception (#GP) occurs. The #GP service routine can then decide whether to allow the virtual-8086 mode service routine to handle the pending external, maskable interrupt. (EFLAGS is specifically referred to in this case because virtual-8086 mode is supported only from legacy mode.)

In long mode, the use of the VIP bit is supported when CR4.PVI=1. See Section 8.10 “Virtual Interrupts,” on page 279 for more information on virtual-8086 mode interrupts and the VIP bit.

Processor Feature Identification (ID) Bit. Bit 21. The ability of software to modify this bit indicates that the processor implementation supports the CPUID instruction. See Section 3.3 “Processor Feature Identification,” on page 71 for more information on the CPUID instruction.

3.1.7 Extended Feature Enable Register (EFER)

The extended-feature-enable register (EFER) contains control bits that enable additional processor features not controlled by the legacy control registers. The EFER is a model-specific register (MSR) with an address of C000_0080h (see Section 3.2 “Model-Specific Registers (MSRs),” on page 59 for more information on MSRs). It can be read and written only by privileged software. Figure 3-8 on page 57 shows the format of the EFER register.



Bits	Mnemonic	Description	Access type
63:21	—	Reserved	MBZ
20	UAIE	Upper Address Ignore Enable	R/W
19	—	Reserved	MBZ
18	INTWB	Interruptible WBINVD/WBNOINVD enable	R/W
17	MCOMMIT	Enable MCOMMIT instruction	R/W
16	—	Reserved	MBZ
15	TCE	Translation Cache Extension	R/W
14	FFXSR	Fast FXSAVE/FXRSTOR	R/W
13	LMSLE	Long Mode Segment Limit Enable	R/W
12	SVME	Secure Virtual Machine Enable	R/W
11	NXE	No-Execute Enable	R/W
10	LMA	Long Mode Active	R/W
9	—	Reserved	MBZ
8	LME	Long Mode Enable	R/W
7:1	—	Reserved	RAZ
0	SCE	System Call Extensions	R/W

Figure 3-8. Extended Feature Enable Register (EFER)

The defined EFER bits shown in Figure 3-8 above are described below:

System-Call Extension (SCE) Bit. Bit 0, read/write. Setting this bit to 1 enables the SYSCALL and SYSRET instructions. Application software can use these instructions for low-latency system calls and returns in a non-segmented (flat) address space. See Section 6.1 “Fast System Call and Return,” on page 170 for additional information.

Long Mode Enable (LME) Bit. Bit 8, read/write. Setting this bit to 1 enables the processor to activate long mode. Long mode is not activated until software enables paging some time later. When paging is enabled after LME is set to 1, the processor sets the EFER.LMA bit to 1, indicating that long mode is not only enabled but also active. See Chapter 14, “Processor Initialization and Long Mode Activation,” for more information on activating long mode.

Long Mode Active (LMA) Bit. Bit 10, read/write. This bit indicates that long mode is active. The processor sets LMA to 1 when both long mode and paging have been enabled by system software. See Chapter 14, “Processor Initialization and Long Mode Activation,” for more information on activating long mode.

When LMA=1, the processor is running either in compatibility mode or 64-bit mode, depending on the value of the L bit in a code-segment descriptor, as shown in Figure 1-6 on page 12.

When LMA=0, the processor is running in legacy mode. In this mode, the processor behaves like a standard 32-bit x86 processor, with none of the new 64-bit features enabled. When writing the EFER register the value of this bit must be preserved. Software must read the EFER register to determine the value of LMA, change any other bits as required and then write the EFER register. An attempt to write a value that differs from the state determined by hardware results in a #GP fault.

No-Execute Enable (NXE) Bit. Bit 11, read/write. Setting this bit to 1 enables the no-execute page-protection feature. The feature is disabled when this bit is cleared to 0. See Section “No Execute (NX) Bit,” on page 152 for more information.

Before setting NXE, system software should verify the processor supports the feature by examining the feature flag CPUID Fn8000_0001_EDX[NX]. See Section 3.3 “Processor Feature Identification,” on page 71 for information on using the CPUID instruction.

Secure Virtual Machine Enable (SVME) Bit. Bit 12, read/write. Enables the SVM extensions. When this bit is zero, the SVM instructions cause #UD exceptions. EFER.SVME defaults to a reset value of zero. The effect of turning off EFER.SVME while a guest is running is undefined; therefore, the VMM should always prevent guests from writing EFER. SVM extensions can be disabled by setting VM_CR.SVME_DISABLE. For more information, see descriptions of LOCK and SMVE_DISABLE bits in Section 15.30.1 “VM_CR MSR (C001_0114h),” on page 566.

Long Mode Segment Limit Enable (LMSLE) bit. Bit 13, read/write. Setting this bit to 1 enables certain limit checks in 64-bit mode. This feature has been deprecated and is not supported by all processor implementations. If CPUID Fn8000_0008_EBX[EferLmlseUnsupported](bit 20)=1, 64-bit mode segment limit checking is not supported and attempting to set EFER.LMSLE =1 causes a #GP exception. See Section 4.12.2 “Data Limit Checks in 64-bit Mode,” on page 123, for more information on these limit checks.

Fast FXSAVE/FXRSTOR (FFXSR) Bit. Bit 14, read/write. Setting this bit to 1 enables the FXSAVE and FXRSTOR instructions to execute faster in 64-bit mode at CPL 0. This is accomplished by not saving or restoring the XMM registers (XMM0-XMM15). The FFXSR bit has no effect when the FXSAVE/FXRSTOR instructions are executed in non 64-bit mode, or when CPL > 0. The FFXSR bit does not affect the save/restore of the legacy x87 floating-point state, or the save/restore of MXCSR.

Before setting FFXSR, system software should verify whether this feature is supported by examining the feature flag CPUID Fn8000_0001_EDX[FFXSR]. See Section 3.3 “Processor Feature Identification,” on page 71 for information on using the CPUID instruction.

Translation Cache Extension (TCE) Bit. Bit 15, read/write. Setting this bit to 1 changes how the INVLPG, INVLPGB, and INVPCID instructions operate on TLB entries. When this bit is 0, these instructions remove the target PTE from the TLB as well as *all* upper-level table entries that are cached in the TLB, whether or not they are associated with the target PTE. When this bit is set, these instructions will remove the target PTE and only those upper-level entries that lead to the target PTE in the page table hierarchy, leaving unrelated upper-level entries intact. This may provide a performance benefit.

Page table management software must be written in a way that takes this behavior into account. Software that was written for a processor that does not cache upper-level table entries may result in stale entries being incorrectly used for translations when TCE is enabled. Software that is compatible with TCE mode will operate in either mode.

For software using INVLPGB to broadcast TLB invalidations, the invalidations are controlled by the EFER.TCE value on the processor executing the INVLPGB instruction.

Before setting TCE, system software should verify that this feature is supported by examining the feature flag CPUID Fn8000_0001_ECX[TCE]. See Section 3.3 “Processor Feature Identification,” on page 71 for information on using the CPUID instruction.

MCOMMIT ENABLE (MCOMMIT) Bit. Bit 17, read/write. Setting this bit to 1 enables the MCOMMIT instruction. When clear, attempting to execute MCOMMIT causes a #UD exception.

INTERRUPTIBLE WBINVD (INTWB) Bit. Bit 18. Setting this bit to 1 allows the WBINVD and WBNOINVD instructions to be interruptible. See WBINVD and WBNOINVD in Volume 3.

UPPER ADDRESS IGNORE ENABLE (UAIE) Bit. Bit 20. Setting this bit to 1 excludes bits [63:57] of an address from the canonical check for some memory references. Section 5.10 “Upper Address Ignore,” on page 164.

Extended control registers (XCR*n*) form a new register space that is available for managing processor architectural features and capabilities. Currently only XCR0 is defined. All other XCR registers are reserved. For more details on the Extended Control Registers, see “Extended Control Registers” in Volume 4, Chapter 1.

3.2 Model-Specific Registers (MSRs)

Processor implementations provide model-specific registers (MSRs) for software control over the unique features supported by that implementation. Software reads and writes MSRs using the privileged RDMSR and WRMSR instructions. Implementations of the AMD64 architecture can contain a mixture of two basic MSR types:

- *Legacy MSRs*. The AMD family of processors often share model-specific features with other x86 processor implementations. Where possible, AMD implementations use the same MSRs for the same functions. For example, the memory-typing and debug-extension MSRs are implemented on many AMD and non-AMD processors.

- *AMD model-specific MSRs*. There are many MSRs common to the AMD family of processors but not to legacy x86 processors. Where possible, AMD implementations use the same AMD-specific MSRs for the same functions.

Every model-specific register, as the name implies, is not necessarily implemented by all members of the AMD family of processors. Appendix A, “MSR Cross-Reference,” lists MSR-address ranges currently used by various AMD and other x86 processors.

The AMD64 architecture includes a number of features that are controlled using MSRs. Those MSRs are shown in Figure 3-9. The EFER register—described in Section 3.1.7 “Extended Feature Enable Register (EFER),” on page 56—is also an MSR.

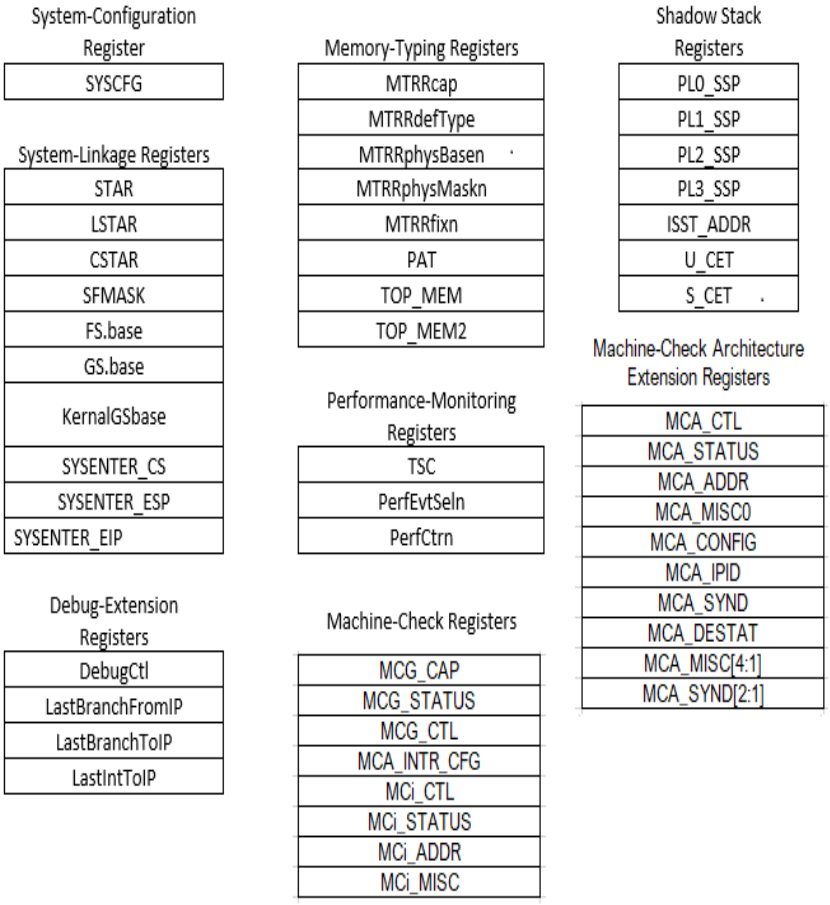


Figure 3-9. AMD64 Architecture Model-Specific Registers

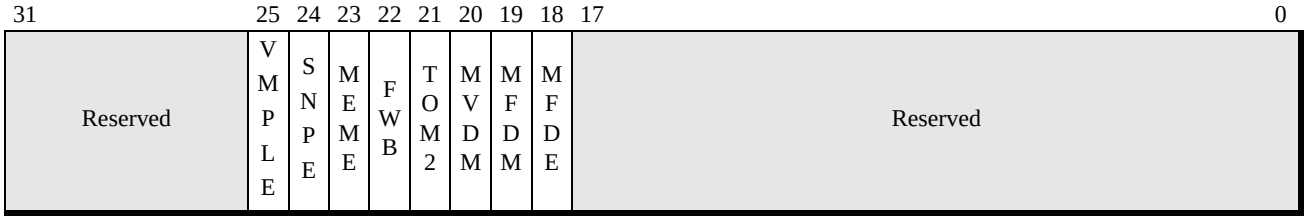
The following sections briefly describe the MSRs in the AMD64 architecture.

3.2.1 System Configuration Register (SYSCFG)

The system-configuration register (SYSCFG) contains control bits for enabling and configuring system bus features. SYSCFG is a model-specific register (MSR) with an address of C001_0010h. Figure 3-10 on page 61 shows the format of the SYSCFG register. Some features are implementation specific, and are described in the *BIOS and Kernel Developer's Guide (BKDG)* or *Processor Programming Reference Manual* applicable to your product. Implementation-specific features are not shown in Figure 3-10.



Bits	Mnemonic	Description	Access type
31:26	—	Reserved	MBZ
25	VMPLE	VMPLEn	R/W
24	SNPE	SecureNestedPagingEn	R/W
23	MEME	MemEncryptionModeEn	R/W
22	FWB	Tom2ForceMemTypeWB	R/W
21	TOM2	MtrrTom2En	R/W
20	MVDM	MtrrVarDramEn	R/W
19	MFDM	MtrrFixDramModEn	R/W
18	MFDE	MtrrFixDramEn	R/W
17:0	—	Reserved	MBZ

Figure 3-10. System-Configuration Register (SYSCFG)

The function of the SYSCFG bits are (all bits are read/write unless otherwise noted):

MtrrFixDramEn Bit. Bit 18. Setting this bit to 1 enables use of the RdMem and WrMem attributes in the fixed-range MTRR registers. When cleared, these attributes are disabled. The RdMem and WrMem attributes allow system software to define fixed-range IORRs using the fixed-range MTRRs. See Section 7.9.1 "Extended Fixed-Range MTRR Type-Field Encodings," on page 223 for information on using this feature.

MtrrFixDramModEn Bit. Bit 19. Setting this bit to 1 allows software to read and write the RdMem and WrMem bits. When cleared, writes do not modify the RdMem and WrMem bits, and reads return 0. See Section 7.9.1 "Extended Fixed-Range MTRR Type-Field Encodings," on page 223 for information on using this feature.

MtrrVarDramEn Bit. Bit 20. Setting this bit to 1 enables the TOP_MEM register and the variable-range IORRs. These registers are disabled when the bit is cleared to 0. See Section 7.9.2 “IORRs,” on page 224 and Section 7.9.4 “Top of Memory,” on page 226 for information on using these features.

MtrrTom2En Bit. Bit 21. Setting this bit to 1 enables the TOP_MEM2 register. The register is disabled when this bit is cleared to 0. See Section 7.9.4 “Top of Memory,” on page 226 for information on using this feature.

Tom2ForceMemTypeWB. Bit 22. Setting this bit to 1 forces the default memory type for memory between 4GB and the address specified by TOP_MEM2 to be write back instead of the memory type defined by MTRRdefType[Type]. For this bit to have any effect, MTRRdefType[E] must be 1. MTRR variable-range settings and PAT can be used to override this memory type.

MemEncryptionModeEn. Bit 23. Setting this bit to 1 enables the SME (Section 7.10 “Secure Memory Encryption,” on page 228) and SEV (Section 15.34 “Secure Encrypted Virtualization,” on page 571) memory encryption features. When cleared, these features are disabled. If MSR C001_0015[SmmLock] is set, the MemEncryptionModeEn bit is sticky and cannot be changed from a 1 to a 0.

SecureNestedPagingEn. Bit 24. Setting this bit to 1 enables SEV-SNP (Section 15.36 “Secure Nested Paging (SEV-SNP),” on page 585). When cleared, this feature is disabled. Once this bit is set to 1, it cannot be changed. This bit can only be set if MemEncryptionModeEn is already set or is simultaneously also set to 1. After SecureNestedPagingEn is set to 1, certain MSRs may no longer be written. See Section 15.36.2 “Enabling SEV-SNP,” on page 586 for details.

VMPLEn. Bit 25. Setting this bit to 1 enables the VMPL feature (Section 15.36.7 “Virtual Machine Privilege Levels,” on page 590). Software should set this bit to 1 when SecureNestedPagingEn is being set to 1. Once SecureNestedPagingEn is set to 1, VMPLEn cannot be changed.

3.2.2 System-Linkage Registers

System-linkage MSRs are used by system software to allow fast control transfers between applications and the operating system. The functions of these registers are:

STAR, LSTAR, CSTAR, and SFMASK Registers. These registers are used to provide mode-dependent linkage information for the SYSCALL and SYSRET instructions. STAR is used in legacy modes, LSTAR in 64-bit mode, and CSTAR in compatibility mode. SFMASK is used by the SYSCALL instruction for RFLAGS in long mode.

FS.base and GS.base Registers. These registers allow 64-bit base-address values to be specified for the FS and GS segments, for use in 64-bit mode. See Section “FS and GS Registers in 64-Bit Mode,” on page 80 for a description of the special treatment the FS and GS segments receive.

KernelGSbase Register. This register is used by the SWAPGS instruction. This instruction exchanges the value located in KernelGSbase with the value located in GS.base.

SYSENTER*x* Registers. The SYSENTER_CS, SYSENTER_ESP, and SYSENTER_EIP registers are used to provide linkage information for the SYSENTER and SYSEXIT instructions. These instructions are only used in legacy mode.

The system-linkage instructions and their use of MSRs are described in Section 6.1 “Fast System Call and Return,” on page 170.

3.2.3 Memory-Typing Registers

Memory-typing MSRs are used to characterize, or type, memory. Memory typing allows software to control the cacheability of memory, and determine how accesses to memory are ordered. The memory-typing registers perform the following functions:

MTRRcap Register. This register contains information describing the level of MTRR support provided by the processor.

MTRRdefType Register. This register establishes the default memory type to be used for physical memory that is not specifically characterized using the fixed-range and variable-range MTRRs.

MTRRphysBasen and MTRRphysMaskn Registers. These registers form a register pair that can be used to characterize any address range within the physical-memory space, including all of physical memory. Up to eight address ranges of varying sizes can be characterized using these registers.

MTRRfixn Registers. These registers are used to characterize fixed-size memory ranges in the first 1 Mbytes of physical-memory space.

PAT Register. This register allows memory-type characterization based on the virtual (linear) address. It is an extension to the PCD and PWT memory types supported by the legacy paging mechanism. The PAT mechanism provides the same memory-typing capabilities as the MTRRs, but with the added flexibility provided by the paging mechanism.

TOP_MEM and TOP_MEM2 Registers. These top-of-memory registers allow system software to specify physical addresses ranges as memory-mapped I/O locations.

Refer to Section 7.7 “Memory-Type Range Registers,” on page 208 for more information on using these registers.

3.2.4 Debug-Extension Registers

The debug-extension MSRs provide software-debug capability not available in the legacy debug registers (DR0–DR7). These MSRs allow single stepping and recording of control transfers to take place. The debug-extension registers perform the following functions:

DebugCtl Register. This MSR register provides control over control-transfer recording and single stepping, and external-breakpoint reporting and trace messages.

LastBranch*x* and LastInt*x* Registers. The four registers, LastBranchToIP, LastBranchFromIP, LastIntToIP, and LastIntFromIP, are all used to record the source and target of control transfers when branch recording is enabled.

Refer to Section 13.1.6 “Control-Transfer Breakpoint Features,” on page 398 for more information on using these debug registers.

3.2.5 Performance-Monitoring Registers

The time-stamp counter and performance-monitoring registers are useful in identifying performance bottlenecks. The number of performance counters can vary based on the implementation. These registers perform the following functions:

TSC Register. This register is used to count processor-clock cycles. It can be read using the RDMSR instruction, or it can be read using the either of the *read time-stamp counter* instructions, RDTSC or RDTSCP. System software can make RDTSC or RDTSCP available for use by non-privileged software by clearing the time-stamp disable bit (CR4.TSD) to 0.

***PerfEvtSel*n* Registers.** These registers are used to specify the events counted by the corresponding performance counter, and to control other aspects of its operation.

***PerfCtr*n* Registers.** These registers are performance counters that hold a count of processor, northbridge, or L2 cache events or the duration of events, under the control of the corresponding *PerfEvtSel*n* register. Each *PerfCtr*n* register can be read using the RDMSR instruction, or they can be read using the *read performance-monitor counter* instruction, RDPMC. System software can make RDPMC available for use by non-privileged software by setting the performance-monitor counter enable bit (CR4.PCE) to 1.

Refer to Section 13.2.3 “Using Performance Counters,” on page 407 for more information on using these registers.

3.2.6 Machine-Check Registers

The machine-check registers control the detection and reporting of hardware machine-check errors. The types of errors that can be reported include cache-access errors, load-data and store-data errors, bus-parity errors, and ECC errors. Three types of machine-check MSRs are shown in Figure 3-9 on page 60.

The first type is global machine-check registers, which perform the following functions:

MCG_CAP Register. This register identifies the machine-check capabilities supported by the processor.

MCG_CTL Register. This register provides global control over machine-check-error reporting.

MCG_STATUS Register. This register reports global status on detected machine-check errors.

The second type is error-reporting register banks, which report on machine-check errors associated with a specific processor unit (or group of processor units). There can be different numbers of register banks for each processor implementation, and each bank is numbered from 0 to *i*. The registers in each bank perform the following functions:

MC*i*_CTL Registers. These registers control error-reporting.

MC*i*_STATUS Registers. These registers report machine-check errors.

MC*i*_ADDR Registers. These registers report the machine-check error address.

MC*i*_MISC Registers. These registers report miscellaneous-error information.

The third type is MCA Extension (MCAX) register banks, which report on machine-check errors associated with a specific processor unit (or group of processor units). There can be different numbers of register banks for each processor implementation, and each bank is numbered from 0 to i. Legacy MCA supports up to 32 banks. MCAX bank 0 will alias to Legacy bank 0 registers. Similarly, MCAX bank n will alias to Legacy bank n registers. The registers in each bank perform the following functions:

MCA_CTL Register. This register is an alias to MCi_CTL for banks 0 to 31. For banks 32 and above, this register controls error-reporting.

MCA_STATUS Register. This register is an alias to MCi_Status.

MCA_ADDR Register. This register is an alias to MCi_ADDR.

MCA_MISC0 Register. This register is an alias to MCi_MISC0.

MCA_CONFIG Register. This register holds configuration information for the MCA bank.

MCA_IPID Register. This register holds information which identifies the specific MCA bank.

MCA_SYND Register. This register stores information associated with the error in MCA_STATUS or MCA_DESTAT.

MCA_DESTAT Register. This register reports deferred machine check errors.

MCA_DEADDR Register. This register provides the address associated with the deferred machine check error.

MCA_MISC[4:1] Registers. Extended miscellaneous error-information registers.

MCA_SYND[2:1] Registers. This register contains information associated with the error in MCA_STATUS or MCA_DESTAT.

Refer to Section 9.5 “Using MCA Features,” on page 312 for more information on using these registers.

3.2.7 Shadow Stack Registers

These registers are defined if the shadow stack feature is supported as indicated by CPUID Fn 0000_0007_0 ECX[CET_SS] (bit 7) = 1.

PL0_SSP, PL1_SSP, PL2_SSP Registers. These registers specify the linear address to be loaded into SSP on the next transition to CPLn, where n=0, 1, 2. The linear address must be in canonical format and aligned to 4 bytes.

PL3_SSP Register. The user mode SSP is saved to and restored from this register. The linear address must be in canonical format and aligned to 4 bytes.

ISST_ADDR Register. This register specifies the linear address of the Interrupt SSP Table (ISST). The linear address must be in canonical format.

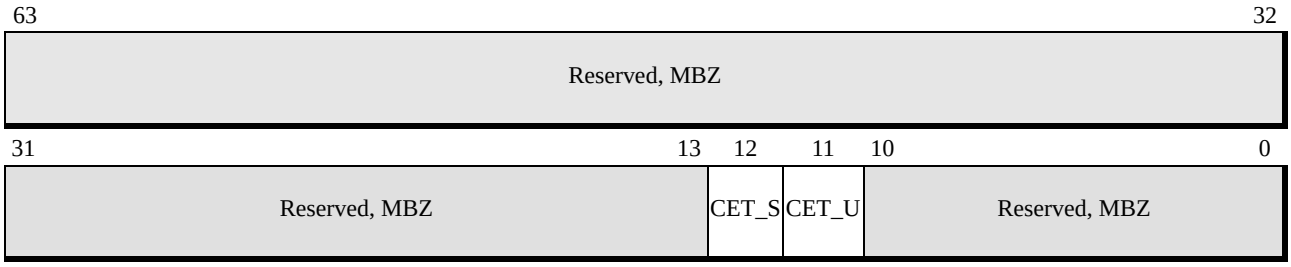
U_CET Register. This register specifies the user mode shadow stack controls.

S_CET Register. This register specifies the supervisor mode shadow stack controls.

3.2.8 Extended State Save MSRs

XSS Register. This register contains a bitmap of supervisor-level state components. System software sets bits in the XSS register bitmap to enable management of corresponding state component by the XSAVES/XRSTORS instructions. XSS register support is indicated by CPUID Fn0000_000D_EAX[XSAVES]_x1 = 1.

The XSS bitmap is defined as follows:



Bits	Mnemonic	Description
63:13	—	Reserved, Must be Zero
12	CET_S	Enables the CET_U state component.
11	CET_U	Enables the CET_S state component.
10:0	—	Reserved, Must be Zero

Figure 3-11. XSS Register

3.2.9 Speculation Control MSRs

Modern processors implement hardware techniques such as branch prediction, speculative execution and out-of-order processing to significantly improve performance. If the processor incorrectly predicts or speculates on an outcome, this is detected and any speculative results are discarded. The processor then supplies the architecturally correct, in-order response to the program's instructions. Even though the speculative results are discarded, microarchitectural side effects may remain which can be detected by software, and which in some cases may lead to side-channel vulnerabilities.

The two speculation control MSRs, SPEC_CTRL (MSR 048h) and PRED_CMD (MSR 049h), enable hardware features that are designed to limit certain types of speculation. Support for these features is indicated by CPUID Fn8000_0008_EBX as described in Table 3-1 below. The presence of a given speculation control feature also implies support for its associated MSR.

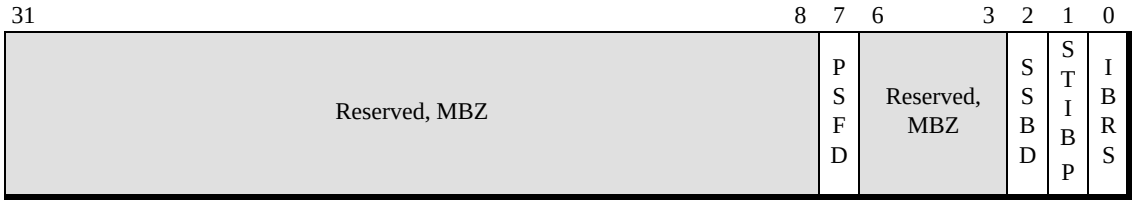
Table 3-1. Speculation Control MSRs

Feature	Indicated by CPUID Function	MSR
IBRS	Fn8000_0008 EBX[14]=1	SPEC_CTRL (MSR 048h)
STIBP	Fn8000_0008 EBX[15]=1	SPEC_CTRL (MSR 048h)
SSBD	Fn8000_0008 EBX[24]=1	SPEC_CTRL (MSR 048h)
PSFD	Fn8000_0008 EBX[28]=1	SPEC_CTRL (MSR 048h)
IBPB	Fn8000_0008 EBX[12]=1	PRED_CMD (MSR 049h)

See ‘Additional CPUID Functions’ at the end of this subsection and APM volume 3 Appendix E.4 ‘CPUID Fn8000_0008_EBX’ for more information on CPUID functions related to speculation control.

SPEC_CTRL (MSR 048h)

SPEC_CTRL (MSR 48h) is a read-write register. Attempts to write a 1 into any reserved bit cause a #GP(0) fault. Unlike most MSRs, a WRMSR to SPEC_CTRL does not serialize memory operations. However, a write to this register is dispatch serializing and prevents execution of younger instructions until the WRMSR has completed. The format of SPEC_CTRL is shown in Figure 3-12.



Bits	Mnemonic	Description	Access type
31:8	—	Reserved	Must be Zero
7	PSFD	Predicted Store Forward Disable.	R/W
6:3	—	Reserved	Must be Zero
2	SSBD	Speculative Store Bypass Disable.	R/W
1	STIBP	Single-Thread Indirect Branch Prediction Mode.	R/W
0	IBRS	Indirect Branch Restricted Speculation.	R/W

Figure 3-12. SPEC_CTRL Register (MSR 048h)

The SPEC_CTRL bits defined in Figure 3-1 are described below:

Indirect Branch Restricted Speculation (IBRS). Bit 0. Setting this bit to 1 prevents indirect branches that occurred in a less privileged prediction mode before this bit was set from influencing the predictions of future indirect branches in a more privileged prediction mode that occur after this bit is set. A lesser privileged prediction mode is defined as CPL 3 or Guest mode, and a more privileged prediction mode is defined as CPL 0-2 or Host mode.

After setting IBRS to 1, if software subsequently

- clears IBRS to 0: The processor may allow older indirect branches that occurred when IBRS was previously 0 to influence future indirect branch predictions.
- writes another 1 to IBRS: The processor starts a new window where older indirect branches do not influence future indirect branch predictions.

Only indirect branches that occurred prior to setting IBRS are prevented from influencing future indirect branches. Therefore, if IBRS were already set on a transition to a more privileged mode from a lesser privileged mode, software at the more privileged mode must write a 1 to IBRS if it requires indirect branch predictions in the new mode to not be influenced by those from the previous mode.

On processors with a shared indirect branch predictor, setting IBRS also prevents indirect branch predictions of one thread from influencing the predictions of its sibling threads, as if SPEC_CTRL[STIBP] was also set. For more information on STIBP, see Single Thread Indirect Branch Predictor below.

Some processors, identified by CPUID Fn8000_0008_EBX[IbrsSameMode] (bit 19) = 1, provide additional speculation limits. For these processors, when IBRS is set, indirect branch predictions are not influenced by any prior indirect branches, regardless of mode (CPL and guest/host) and regardless of whether the prior indirect branches occurred before or after the setting of IBRS.

Although return instructions can be considered a type of indirect branch, IBRS does not affect them. Software requiring IBRS-style indirect branch speculation limits for RET instructions should clear out any return address predictions by executing 32 CALL instructions having a non-zero displacement. Processors implementing more than 32 return predictions include hardware to clear the additional entries when software writes a 1 to IBRS. If the kernel and user virtual address spaces are disjoint with at least one unmapped 4K page separating them, and SMEP is enabled, then there is no need to clear out the return address predictions.

Single Thread Indirect Branch Prediction mode (STIBP). Bit 1. Setting this bit to 1 prevents indirect branch predictions of one thread from influencing the predictions of any sibling threads, on processors where branch prediction resources are shared. RET (return) instructions are not influenced by sibling threads. Therefore, setting STIBP is not required to prevent one thread's RET predictions from influencing the predictions of a sibling thread.

Note that STIBP mode is automatically enabled when SPEC_CTRL[IBRS] is set, regardless of value of SPEC_CTRL[STIBP].

Speculative Store Bypass Disable (SSBD). Bit 2. Setting this bit to 1 prevents load-type instructions from speculatively bypassing older store instructions whose final address have not yet been resolved.

As specified in Section 7.1.1 "Read Ordering," on page 184, loads from memory marked with the proper memory type can read memory out-of-order, speculatively and before older stores have completed. This means it is possible for a load to read and pass forward, in a speculative manner, previous values of the memory location. The processor has logic to correct this occurrence and provide the proper in-order load response to the program. However, this mis-speculation may have resulted in microarchitectural side effects. When SSBD is set to 1, the processor can return speculative load data only if there are no older stores with unknown addresses.

Some legacy processors implement SSBD in a different MSR. On these processors, indicated by CPUID function 8000_0008, EBX[25]=1, SSBD is enabled by setting VIRT_SPEC_CTRL (MSR C001_011F) bit 2. On processors that support both SPEC_CTRL and VIRT_SPEC_CTRL, if SSBD is enabled in either MSR, the processor prevents loads from speculating around older stores. However, it is preferred that software uses SPEC_CTRL[SSBD] in this scenario.

On some processor models, setting SSBD is not needed to prevent speculative loads from bypassing older stores. This is indicated by CPUID Fn8000_0008_EBX[SsbdNotRequired] (bit 26) = 1.

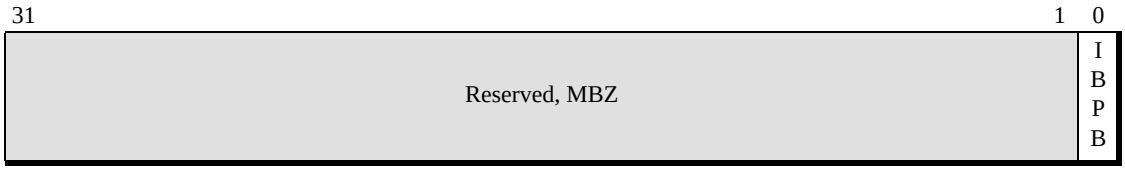
Predicted Store Forward Disable (PSFD). Bit 7. Setting this bit disables Predictive Store Forwarding (PSF).

As specified in Section 7.1.1 "Read Ordering," on page 184, write data for cacheable memory types can be forwarded to read instructions before that data is actually written to memory, via a mechanism called store-to-load forwarding. PSF expands on store-to-load forwarding via a mechanism that predicts the relationship between loads and stores based on past behavior, without waiting for their address calculations to complete. Like other forms of speculative store bypass, an incorrect prediction may result in microarchitectural side effects. PSF speculation can be disabled by setting PFSD.

The PSF feature is also disabled when SPEC_CTRL[SSBD] is set. However, SSBD disables both PSF and speculative store bypass, while PSFD only disables PSF. PSFD may be desirable for software which is concerned with the speculative behavior of PSF but desires a smaller performance impact than setting SSBD.

PRED_CMD (MSR 049h)

PRED_CMD is a write-only register. Attempts to read this register or to write a 1 into any reserved bit cause a #GP(0) fault. Unlike most MSRs, a WRMSR to PRED_CMD does not serialize memory operations. However, a write to this register is dispatch serializing and prevents execution of younger instructions until the WRMSR has completed. The format of the PRED_CMD register is shown in Figure 3-13 below.



Bits	Mnemonic	Description	Access type
31:1	—	Reserved	MBZ
0	IBPB	Indirect Branch Prediction Barrier.	W

Figure 3-13. PRED_CMD Register (MSR 049h)

Indirect Branch Prediction Barrier (IBPB). Bit 0, write only. Setting this bit to 1 prevents the processor from using older indirect branch predictions to influence future indirect branches. This applies to JMP indirect, CALL indirect and to RET (return) instructions. In some implementations, setting IBPB causes the processor to flush all previous indirect branch predictions. As this restricts the processor from using any previous indirect branch information, IBPB is intended to be used by software when switching between contexts that do not trust each other. Examples of such contexts include switching from one user context to another, or from one guest to another. In some implementations, IBPB will only flush the indirect predictions that are accessible to the current thread.

Additional CPUID Functions

The following CPUID functions provide more information on the speculation control features to aid system software in optimizing processor performance:

- CPUID Function 8000_0008_EBX[16] (IBRS always on). When set, indicates that the processor prefers that IBRS is only set once during boot and not changed. If IBRS is set on a processor supporting IBRS always on mode, indirect branches executed in a less privileged prediction mode will not influence branch predictions for indirect branches in a more privileged prediction mode. This eliminates the need for WRMSR instructions to manage speculation effects at elevated-privilege entry and exit points.

- CPUID Function 8000_0008_EBX[17] (STIBP always on). When set, indicates that the processor prefers that STIBP is only set once during boot and not changed. This eliminates the need for a WRMSR at the necessary transition points.
- CPUID Function 8000_0008_EBX[18] (IBRS preferred). When set, indicates that the processor prefers using the IBRS feature instead of other software mitigations such as retpoline. This allows software to remove the software mitigation and utilize the more performant IBRS mechanism.

3.2.10 Hardware Configuration Register (HWCR)

The HWCR register contains control bits that affect the functionality of other features. Some HWCR bits are implementation specific, and are described in the BIOS and Kernel Developer's Guide (BKDG) or Processor Programming Reference Manual applicable to your product. Implementation specific HWCR bits are not listed below.

SmmLock. Bit 0. Enables SMM code lock. When set to 1, SMM code in the ASeg and TSeg memory ranges, and the SMM registers, become read-only and SMI interrupts are not intercepted in SVM. See Section 15.32 "SMM-Lock," on page 570 for information on using this feature.

CpbDis. Bit 25. Core performance boost disable. When set to 1, core performance boost is disabled. See Section 17.2 "Core Performance Boost," on page 641 for further details on this feature.

IRPerfEn. Bit 30. Setting this bit to 1 enables the instructions retired counter. See Section 13.2.1 "Performance Counter MSRs," on page 401 for information on using this feature.

SmmPgCfgLock. Bit 33. Setting this bit to 1 locks the paging configuration while in SMM. See Section 10.3.9 "SMM Page Configuration Lock," on page 332 for information on using this feature.

3.3 Processor Feature Identification

The CPUID instruction provides information about the processor implementation and its capabilities. Software operating at any privilege level can execute the CPUID instruction to collect this information. Software can utilize this information to optimize performance.

The CPUID instruction supports multiple functions, each providing specific information about the processor implementation, including the vendor, model number, revision (stepping), features, cache organization, and name. The multifunction approach allows the CPUID instruction to return a detailed picture of the processor implementation and its capabilities—more detailed information than could be returned by a single function. This flexibility also allows for the addition of new CPUID functions in future processor generations.

The desired function number is loaded into the EAX register before executing the CPUID instruction. CPUID functions are divided into two types:

- *Standard functions* return information about features common to all x86 implementations, including the earliest features offered in the x86 architecture, as well as information about the

presence of features such as support for the AVX and FMA instruction subsets. Standard function numbers are in the range 0000_0000h–0000_FFFFh.

- *Extended functions* return information about AMD-specific features such as long mode and the presence of features such as support for the FMA4 and XOP instruction subsets. Extended function numbers are in the range 8000_0000h–8000_FFFFh.

Feature information is returned in the EAX, EBX, ECX, and EDX registers. Some functions accept a second input parameter passed to the instruction in the ECX register.

In this and the other three volumes of this *Programmer's Manual*, the notation *CPUID FnXXXX_XXXX_RRR[FieldName]_xYY* is used to represent the input parameters and return value that corresponds to a particular processor capability or feature.

In this notation, *XXXX_XXXX* represents the 32-bit value to be placed in the EAX register prior to executing the CPUID instruction. This value is the function number. *RRR* is either EAX, EBX, ECX, or EDX and represents the register to be examined after the execution of the instruction. If the contents of the entire 32-bit register provides the capability information, the notation *[FieldName]* is omitted, otherwise this provides the name of the field within the return value that represents the capability or feature.

When the field is a single bit, this is called a feature flag. Normally, if a feature flag bit is set, the corresponding processor feature is supported and if it is cleared, the feature is not supported. The optional input parameter passed to the CPUID instruction in the ECX register is represented by the notation _x*YY* appended after the return value notation. If a CPUID function does not accept this optional input parameter, this notation is omitted.

For more specific information on the CPUID instruction, see the instruction reference page in Volume 3. For a description of all feature flags related to instruction subset support, see Volume 3, Appendix D, "Instruction Subsets and CPUID Feature Flags." For a comprehensive list of all processor capabilities and feature flags, see Volume 3, Appendix E, "Obtaining Processor Information Via the CPUID Instruction."

4 Segmented Virtual Memory

The legacy x86 architecture supports a segment-translation mechanism that allows system software to relocate and isolate instructions and data anywhere in the virtual-memory space. A segment is a contiguous block of memory within the linear address space. The size and location of a segment within the linear address space is arbitrary. Instructions and data can be assigned to one or more memory segments, each with its own protection characteristics. The processor hardware enforces the rules dictating whether one segment can access another segment.

The segmentation mechanism provides ten segment registers, each of which defines a single segment. Six of these registers (CS, DS, ES, FS, GS, and SS) define user segments. User segments hold software, data, and the stack and can be used by both application software and system software. The remaining four segment registers (GDT, LDT, IDT, and TR) define system segments. System segments contain data structures initialized and used only by system software. Segment registers contain a *base address* pointing to the starting location of a segment, a *limit* defining the segment size, and *attributes* defining the segment-protection characteristics.

Although segmentation provides a great deal of flexibility in relocating and protecting software and data, it is often more efficient to handle memory isolation and relocation with a combination of software and hardware paging support. For this reason, most modern system software bypasses the segmentation features. However, segmentation cannot be completely disabled, and an understanding of the segmentation mechanism is important to implementing long-mode system software.

In long mode, the effects of segmentation depend on whether the processor is running in compatibility mode or 64-bit mode:

- In compatibility mode, segmentation functions just as it does in legacy mode, using legacy 16-bit or 32-bit protected mode semantics.
- 64-bit mode, segmentation is disabled, creating a flat 64-bit virtual-address space. As will be seen, certain functions of some segment registers, particularly the system-segment registers, continue to be used in 64-bit mode.

4.1 Real Mode Segmentation

After reset or power-up, the processor always initially enters real mode. Protected modes are entered from real mode.

As noted in “Real Addressing” on page 10, real mode (real-address mode), provides a physical-memory space of 1 Mbyte. In this mode, a 20-bit physical address is determined by shifting a 16-bit segment selector to the left four bits and adding the 16-bit effective address.

Each 64K segment (CS, DS, ES, FS, GS, SS) is aligned on 16-byte boundaries. The *segment base* is the lowest address in a given segment, and is equal to the segment selector * 16. The POP and MOV instructions can be used to load a (possibly) new segment selector into one of the segment registers.

When this occurs, the selector is updated and the segment base is set to selector * 16. The segment limit and segment attributes are unchanged, but are normally 64K (the maximum allowable limit) and read/write data, respectively.

On FAR transfers, CS (code segment) selector is updated to the new value, and the CS segment base is set to selector * 16. The CS segment limit and attributes are unchanged, but are usually 64K and read/write, respectively.

If the interrupt descriptor table (IDT) is used to find the real mode IDT see “Real-Mode Interrupt Control Transfers” on page 259.

The GDT, LDT, and TSS (see below) are not used in real mode.

4.2 Virtual-8086 Mode Segmentation

Virtual-8086 mode supports 16-bit real mode programs running under protected mode (see below). It uses a simple form of memory segmentation, optional paging, and limited protection checking. Programs running in virtual-8086 mode can access up to 1MB of memory space.

As with real mode segmentation, each 64K segment (CS, DS, ES, FS, GS, SS) is aligned on 16-byte boundaries. The *segment base* is the lowest address in a given segment, and is equal to the segment selector * 16. The POP and MOV instructions work exactly as in real mode and can be used to load a (possibly) new segment selector into one of the segment registers. When this occurs, the selector is updated and the segment base is set to selector * 16. The segment limit and segment attributes are unchanged, but are normally 64K (the maximum allowable limit) and read/write data, respectively.

FAR transfers, with the exception of interrupts and exceptions, operate as in real mode. On FAR transfers, the CS (code segment) selector is updated to the new value, and the CS segment base is set to selector * 16. The CS segment limit and attributes are unchanged, but are usually 64K and read/write, respectively. Interrupts and exceptions switch the processor to protected mode. (See Chapter 8, “Exceptions and Interrupts” for more information.)

4.3 Protected Mode Segmented-Memory Models

System software can use the segmentation mechanism to support one of two basic segmented-memory models: a flat-memory model or a multi-segmented model. These segmentation models are supported in legacy mode and in compatibility mode. Each type of model is described in the following sections.

4.3.1 Multi-Segmented Model

In the multi-segmented memory model, each segment register can reference a unique base address with a unique segment size. Segments can be as small as a single byte or as large as 4 Gbytes. When page translation is used, multiple segments can be mapped to a single page and multiple pages can be mapped to a single segment. Figure 1-1 on page 6 shows an example of the multi-segmented model.

The multi-segmented memory model provides the greatest level of flexibility for system software using the segmentation mechanism.

Compatibility mode allows the multi-segmented model to be used in support of legacy software. However, in compatibility mode, the multi-segmented memory model is restricted to the first 4 Gbytes of virtual-memory space. Access to virtual memory above 4 Gbytes requires the use of 64-bit mode, which does not support segmentation.

4.3.2 Flat-Memory Model

The flat-memory model is the simplest form of segmentation to implement. Although segmentation cannot be disabled, the flat-memory model allows system software to bypass most of the segmentation mechanism. In the flat-memory model, all segment-base addresses have a value of 0 and the segment limits are fixed at 4 Gbytes. Clearing the segment-base value to 0 effectively disables segment translation, resulting in a single segment spanning the entire virtual-address space. All segment descriptors reference this single, flat segment. Figure 1-2 on page 7 shows an example of the flat-memory model.

4.3.3 Segmentation in 64-Bit Mode

In 64-bit mode, segmentation is disabled. The segment-base value is ignored and treated as 0 by the segmentation hardware. Likewise, segment limits and most attributes are ignored. There are a few exceptions. The CS-segment DPL, D, and L attributes are used (respectively) to establish the privilege level for a program, the default operand size, and whether the program is running in 64-bit mode or compatibility mode. The FS and GS segments can be used as additional base registers in address calculations, and those segments can have non-zero base-address values. This facilitates addressing thread-local data and certain system-software data structures. See “FS and GS Registers in 64-Bit Mode” on page 80 for details about the FS and GS segments in 64-bit mode. The system-segment registers are always used in 64-bit mode.

4.4 Segmentation Data Structures and Registers

Figure 4-1 on page 76 shows the following data structures used by the segmentation mechanism:

- *Segment Descriptors*—As the name implies, a segment descriptor *describes* a segment, including its location in virtual-address space, its size, protection characteristics, and other attributes.
- *Descriptor Tables*—Segment descriptors are stored in memory in one of three tables. The global-descriptor table (GDT) holds segment descriptors that can be shared among all tasks. Multiple local-descriptor tables (LDT) can be defined to hold descriptors that are used by specific tasks and are not shared globally. The interrupt-descriptor table (IDT) holds gate descriptors that are used to access the segments where interrupt handlers are located.
- *Task-State Segment*—A task-state segment (TSS) is a special type of system segment that contains task-state information and data structures for each task. For example, a TSS holds a copy of the GPRs and EFLAGS register when a task is suspended. A TSS also holds the pointers to privileged-

software stacks. The TSS and task-switch mechanism are described in Chapter 12, “Task Management.”

- *Segment Selectors*—Descriptors are selected for use from the descriptor tables using a segment selector. A segment selector contains an index into either the GDT or LDT. The IDT is indexed using an interrupt vector, as described in “Legacy Protected-Mode Interrupt Control Transfers” on page 261, and in “Long-Mode Interrupt Control Transfers” on page 272.

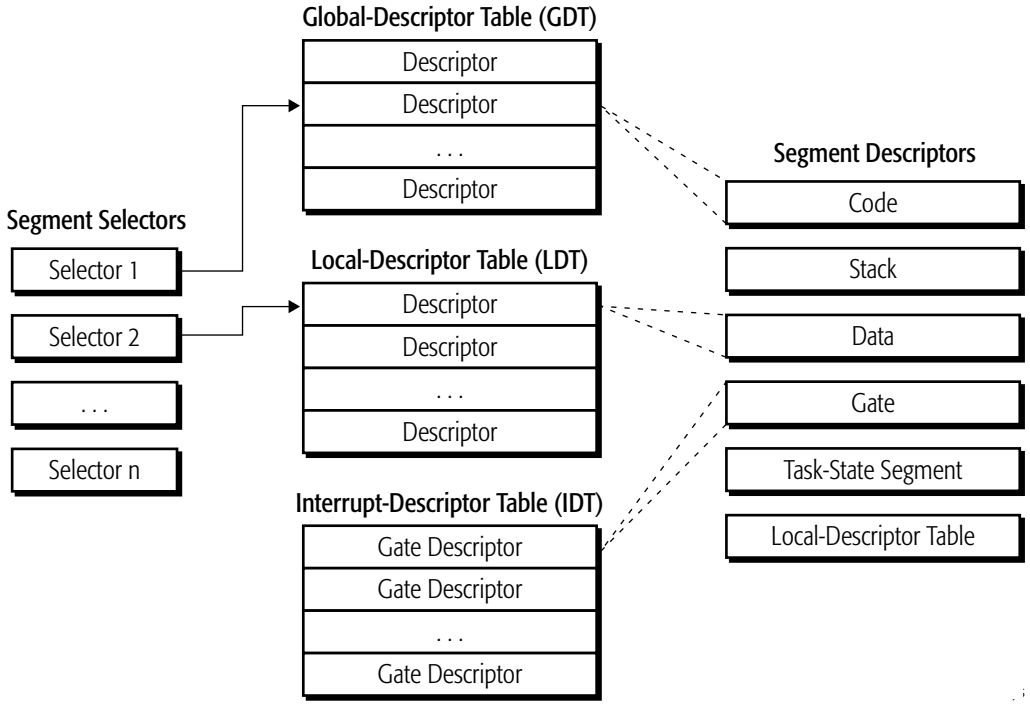


Figure 4-1. Segmentation Data Structures

Figure 4-2 on page 77 shows the registers used by the segmentation mechanism. The registers have the following relationship to the data structures:

- *Segment Registers*—The six segment registers (CS, DS, ES, FS, GS, and SS) are used to point to the user segments. A segment selector selects a descriptor when it is loaded into one of the segment registers. This causes the processor to automatically load the selected descriptor into a software-invisible portion of the segment register.
- *Descriptor-Table Registers*—The three descriptor-table registers (GDTR, LDTR, and IDTR) are used to point to the system segments. The descriptor-table registers identify the virtual-memory location and size of the descriptor tables.
- *Task Register (TR)*—Describes the location and limit of the current task state segment (TSS).

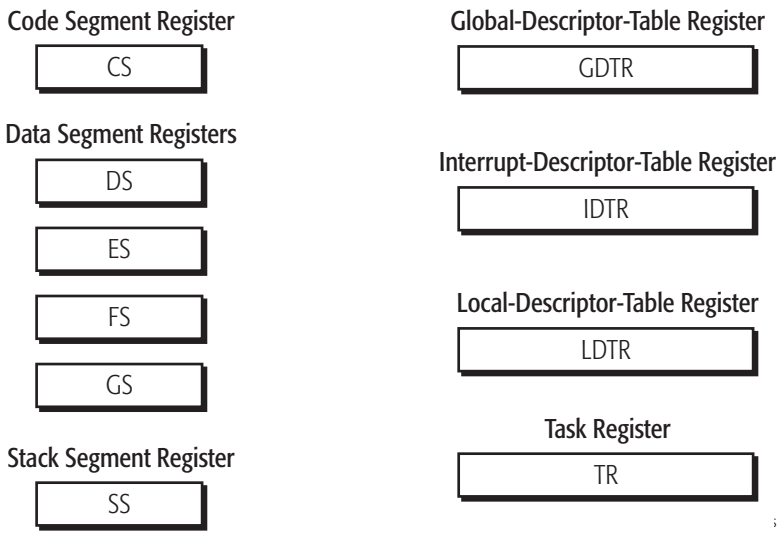

Figure 4-2. Segment and Descriptor-Table Registers

A fourth system-segment register, the TR, points to the TSS. The data structures and registers associated with task-state segments are described in “Task-Management Resources” on page 362.

4.5 Segment Selectors and Registers

4.5.1 Segment Selectors

Segment selectors are pointers to specific entries in the global and local descriptor tables. Figure 4-3 shows the segment selector format.

Bits	Mnemonic	Description	R/W
15:3	SI	Selector Index	R/W
2	TI	Table Indicator	R/W
1:0	RPL	Requestor Privilege Level	R/W

Figure 4-3. Segment Selector

The selector format consists of the following fields:

Selector Index Field. Bits 15:3. The selector-index field specifies an entry in the descriptor table. Descriptor-table entries are eight bytes long, so the selector index is scaled by 8 to form a byte offset into the descriptor table. The offset is then added to either the global or local descriptor-table base address (as indicated by the table-index bit) to form the descriptor-entry address in virtual-address space.

Some descriptor entries in long mode are 16 bytes long rather than 8 bytes (see “Legacy Segment Descriptors” on page 88 for more information on long-mode descriptor-table entries). These expanded descriptors consume two entries in the descriptor table. Long mode, however, continues to scale the selector index by eight to form the descriptor-table offset. It is the responsibility of system software to assign selectors such that they correctly point to the start of an expanded entry.

Table Indicator (TI) Bit. Bit 2. The TI bit indicates which table holds the descriptor referenced by the selector index. When TI=0 the GDT is used and when TI=1 the LDT is used. The descriptor-table base address is read from the appropriate descriptor-table register and added to the scaled selector index as described above.

Requestor Privilege-Level (RPL) Field. Bits 1:0. The RPL represents the privilege level (CPL) the processor is operating under at the time the selector is created.

RPL is used in segment privilege-checks to prevent software running at lesser privilege levels from accessing privileged data. See “Data-Access Privilege Checks” on page 106 and “Control-Transfer Privilege Checks” on page 109 for more information on segment privilege-checks.

Null Selector. Null selectors have a selector index of 0 and TI=0, corresponding to the first entry in the GDT. However, null selectors do not reference the first GDT entry but are instead used to invalidate unused segment registers. A general-protection exception (#GP) occurs if a reference is made to use a segment register containing a null selector in non-64-bit mode. By initializing unused segment registers with null selectors software can trap references to unused segments.

Null selectors can only be loaded into the DS, ES, FS and GS data-segment registers, and into the LDTR descriptor-table register. A #GP occurs if software attempts to load the CS register with a null selector or if software attempts to load the SS register with a null selector in non 64-bit mode or at CPL 3.

If CPUID Fn8000_0021_EAX[NullSelectorClearsBase] (bit 6) = 1, loading a segment register with a null selector clears the base address and limit of the segment register in all cases except a load of DS, ES, FS, or GS by an IRET, IRETD, IRETQ, or RETF instruction that changes the current privilege level, in which case these fields are left untouched. If CPUID Fn8000_0021_EAX[NullSelectorClearsBase] (bit 6) = 0, loading a segment register with a null selector makes the base address and limit of the segment register undefined. Because references to segment registers containing a null selector cause a #GP exception, the segment base and limit values have no effect. However, OS management of segment state may be simplified for processors supporting this clearing functionality.

4.5.2 Segment Registers

Six 16-bit segment registers are provided for referencing up to six segments at one time. All software tasks require segment selectors to be loaded in the CS and SS registers. Use of the DS, ES, FS, and GS segments is optional, but nearly all software accesses data and therefore requires a selector in the DS register. Table 4-1 on page 79 lists the supported segment registers and their functions.

Table 4-1. Segment Registers

Segment Register	Encoding	Segment Register Function
ES	/0	References optional data-segment descriptor entry
CS	/1	References code-segment descriptor entry
SS	/2	References stack segment descriptor entry
DS	/3	References default data-segment descriptor entry
FS	/4	References optional data-segment descriptor entry
GS	/5	References optional data-segment descriptor entry

The processor maintains a *hidden portion* of the segment register in addition to the selector value loaded by software. This hidden portion contains the values found in the descriptor-table entry referenced by the segment selector. The processor loads the descriptor-table entry into the hidden portion when the segment register is loaded. By keeping the corresponding descriptor-table entry in hardware, performance is optimized for the majority of memory references.

Figure 4-4 shows the format of the visible and hidden portions of the segment register. Except for the FS and GS segment base, software cannot directly read or write the hidden portion (shown as gray-shaded boxes in Figure 4-4).

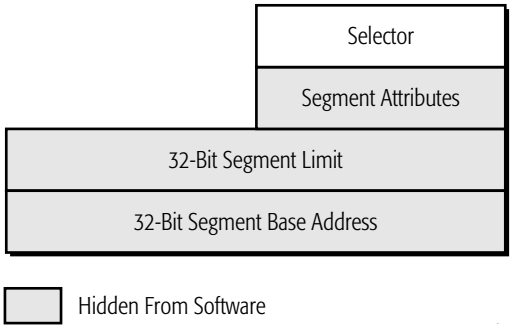

Figure 4-4. Segment-Register Format

CS Register. The CS register contains the segment selector referencing the current code-segment descriptor entry. All instruction fetches reference the CS descriptor. When a new selector is loaded into

the CS register, the current-privilege level (CPL) of the processor is set to that of the CS-segment descriptor-privilege level (DPL).

Data-Segment Registers. The DS register contains the segment selector referencing the default data-segment descriptor entry. The SS register contains the stack-segment selector. The ES, FS, and GS registers are optionally loaded with segment selectors referencing other data segments. Data accesses default to referencing the DS descriptor except in the following two cases:

- The ES descriptor is referenced for string-instruction destinations.
- The SS descriptor is referenced for stack operations.

4.5.3 Segment Registers in 64-Bit Mode

CS Register in 64-Bit Mode. In 64-bit mode, most of the hidden portion of the CS register is ignored. Only the L (long), D (default operation size), and DPL (descriptor privilege-level) attributes are recognized by 64-bit mode. Address calculations assume a CS.base value of 0. CS references do not check the CS.limit value, but instead check that the effective address is in canonical form.

DS, ES, and SS Registers in 64-Bit Mode. In 64-bit mode, the contents of the ES, DS, and SS segment registers are ignored. All fields (base, limit, and attribute) in the hidden portion of the segment registers are ignored.

Address calculations in 64-bit mode that reference the ES, DS, or SS segments are treated as if the segment base is 0. Instead of performing limit checks, the processor checks that all virtual-address references are in canonical form.

Neither enabling and activating long mode nor switching between 64-bit and compatibility modes changes the contents of the visible or hidden portions of the segment registers. These registers remain unchanged during 64-bit mode execution unless explicit segment loads are performed.

FS and GS Registers in 64-Bit Mode. Unlike the CS, DS, ES, and SS segments, the FS and GS segment overrides can be used in 64-bit mode. When FS and GS segment overrides are used in 64-bit mode, their respective base addresses are used in the effective-address (EA) calculation. The complete EA calculation then becomes (FS or GS).base + base + (scale ∗ index) + displacement. The FS.base and GS.base values are also expanded to the full 64-bit virtual-address size, as shown in Figure 4-5. Any overflow in the 64-bit linear address calculation is ignored and the resulting address instead wraps around to the other end of the address space.

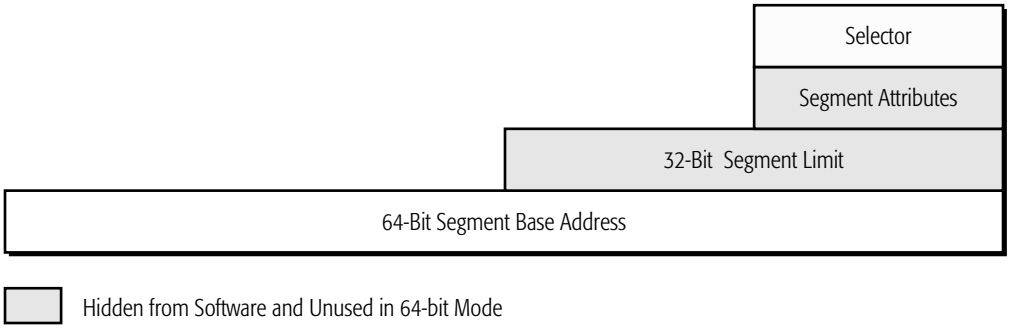

Figure 4-5. FS and GS Segment-Register Format—64-Bit Mode

In 64-bit mode, FS-segment and GS-segment overrides are not checked for limit or attributes. Instead, the processor checks that all virtual-address references are in canonical form.

Segment register-load instructions (MOV to Sreg and POP Sreg) load only a 32-bit base-address value into the hidden portion of the FS and GS segment registers. The base-address bits above the low 32 bits are cleared to 0 as a result of a segment-register load. When a null selector is loaded into FS or GS, the contents of the corresponding hidden descriptor register are not altered.

There are two methods to update the contents of the FS.base and GS.base hidden descriptor fields. The first is available exclusively to privileged software (CPL = 0). The FS.base and GS.base hidden descriptor-register fields are mapped to MSRs. Privileged software can load a 64-bit base address in canonical form into FS.base or GS.base using a single WRMSR instruction. The FS.base MSR address is C000_0100h while the GS.base MSR address is C000_0101h.

The second method of updating the FS and GS base fields is available to software running at any privilege level (when supported by the implementation and enabled by setting CR4[FSGSBASE]). The WRFSBASE and WRGSBASE instructions copy the contents of a GPR to the FS.base and GS.base fields respectively. When the operand size is 32 bits, the upper doubleword of the base is cleared. WRFSBASE and WRGSBASE are only supported in 64-bit mode.

The addresses written into the expanded FS.base and GS.base registers must be in canonical form. Any instruction that attempts to write a non-canonical address to these registers causes a general-protection exception (#GP) to occur.

When in compatibility mode, the FS and GS overrides operate as defined by the legacy x86 architecture regardless of the value loaded into the high 32 bits of the hidden descriptor-register base-address field. Compatibility mode ignores the high 32 bits when calculating an effective address.

4.6 Descriptor Tables

Descriptor tables are used by the segmentation mechanism when protected mode is enabled (CR0.PE=1). These tables hold descriptor entries that describe the location, size, and privilege attributes of a segment. All memory references in protected mode access a descriptor-table entry.

As previously mentioned, there are three types of descriptor tables supported by the x86 segmentation mechanism:

- Global descriptor table (GDT)
- Local descriptor table (LDT)
- Interrupt descriptor table (IDT)

Software establishes the location of a descriptor table in memory by initializing its corresponding descriptor-table register. The descriptor-table registers and the descriptor tables are described in the following sections.

4.6.1 Global Descriptor Table

Protected-mode system software must create a global descriptor table (GDT). The GDT contains code-segment and data-segment descriptor entries (user segments) for segments that can be shared by all tasks. In addition to the user segments, the GDT can also hold gate descriptors and other system-segment descriptors. System software can store the GDT anywhere in memory and should protect the segment containing the GDT from non-privileged software.

Segment selectors point to the GDT when the table-index (TI) bit in the selector is cleared to 0. The selector index portion of the segment selector references a specific entry in the GDT. Figure 4-6 on page 83 shows how the segment selector indexes into the GDT. One special form of a segment selector is the *null selector*. A null selector points to the first entry in the GDT (the selector index is 0 and TI=0). However, null selectors do not reference memory, so the first GDT entry cannot be used to describe a segment (see “Null Selector” on page 78 for information on using the null selector). The first usable GDT entry is referenced with a selector index of 1.

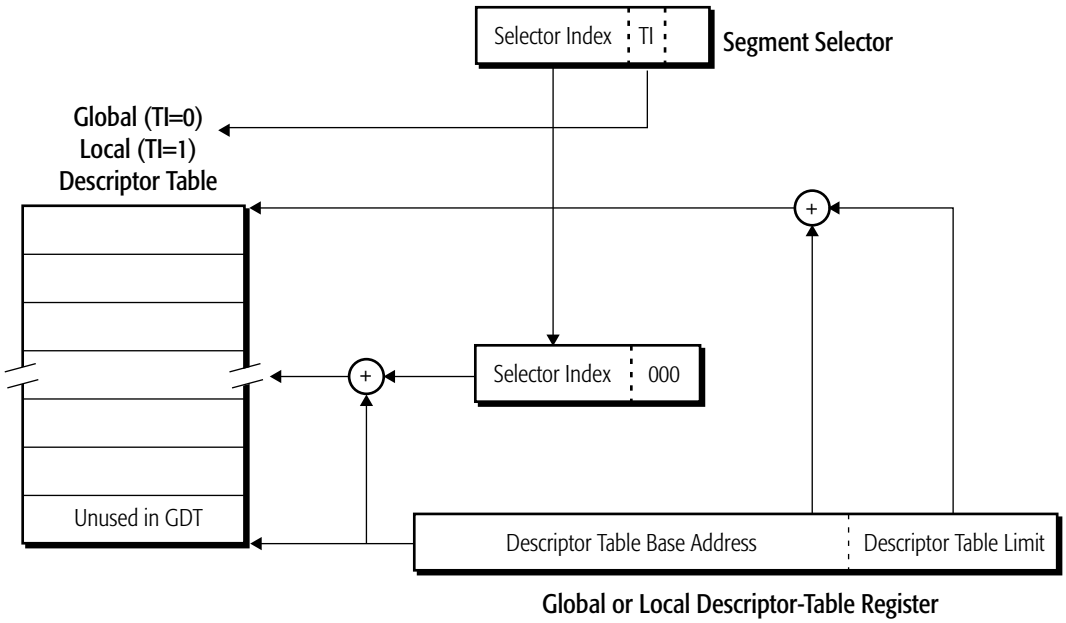

Figure 4-6. Global and Local Descriptor-Table Access

4.6.2 Global Descriptor-Table Register

The global descriptor-table register (GDTR) points to the location of the GDT in memory and defines its size. This register is loaded from memory using the LGDT instruction (see “LGDT and LIDT Instructions” on page 176). Figure 4-7 shows the format of the GDTR in legacy mode and compatibility mode.

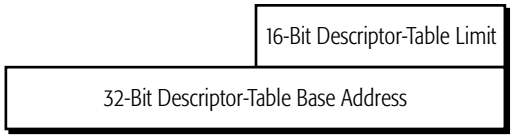

Figure 4-7. GDTR and IDTR Format—Legacy Modes

Figure 4-8 on page 84 shows the format of the GDTR in 64-bit mode.

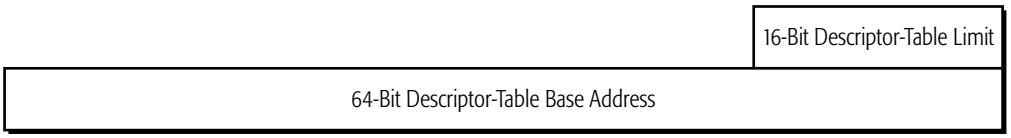

Figure 4-8. GDTR and IDTR Format—Long Mode

The GDTR contains two fields:

Limit. 2 bytes. These bits define the 16-bit limit, or size, of the GDT in bytes. The limit value is added to the base address to yield the ending byte address of the GDT. A general-protection exception (#GP) occurs if software attempts to access a descriptor beyond the GDT limit.

The offsets into the descriptor tables are not extended by the AMD64 architecture in support of long mode. Therefore, the GDTR and IDTR limit-field sizes are unchanged from the legacy sizes. The processor does check the limits in long mode during GDT and IDT accesses.

Base Address. 8 bytes. The base-address field holds the starting byte address of the GDT in virtual-memory space. The GDT can be located at any byte address in virtual memory, but system software should align the GDT on a quadword boundary to avoid the potential performance penalties associated with accessing unaligned data.

The AMD64 architecture increases the base-address field of the GDTR to 64 bits so that system software running in long mode can locate the GDT anywhere in the 64-bit virtual-address space. The processor ignores the high-order 4 bytes of base address when running in legacy mode.

4.6.3 Local Descriptor Table

Protected-mode system software can optionally create a local descriptor table (LDT) to hold segment descriptors belonging to a single task or even multiple tasks. The LDT typically contains code-segment and data-segment descriptors as well as gate descriptors referenced by the specified task. Like the GDT, system software can store the LDT anywhere in memory and should protect the segment containing the LDT from non-privileged software.

Segment selectors point to the LDT when the table-index bit (TI) in the selector is set to 1. The selector index portion of the segment selector references a specific entry in the LDT (see Figure 4-6 on page 83). Unlike the GDT, however, a selector index of 0 references the first entry in the LDT (when TI=1, the selector is not a null selector).

LDTs are described by system-segment descriptor entries located in the GDT, and a GDT can contain multiple LDT descriptors. The LDT system-segment descriptor defines the location, size, and privilege rights for the LDT. Figure 4-9 on page 85 shows the relationship between the LDT and GDT data structures.

Loading a null selector into the LDTR is useful if software does not use an LDT. This causes a #GP if an erroneous reference is made to the LDT.

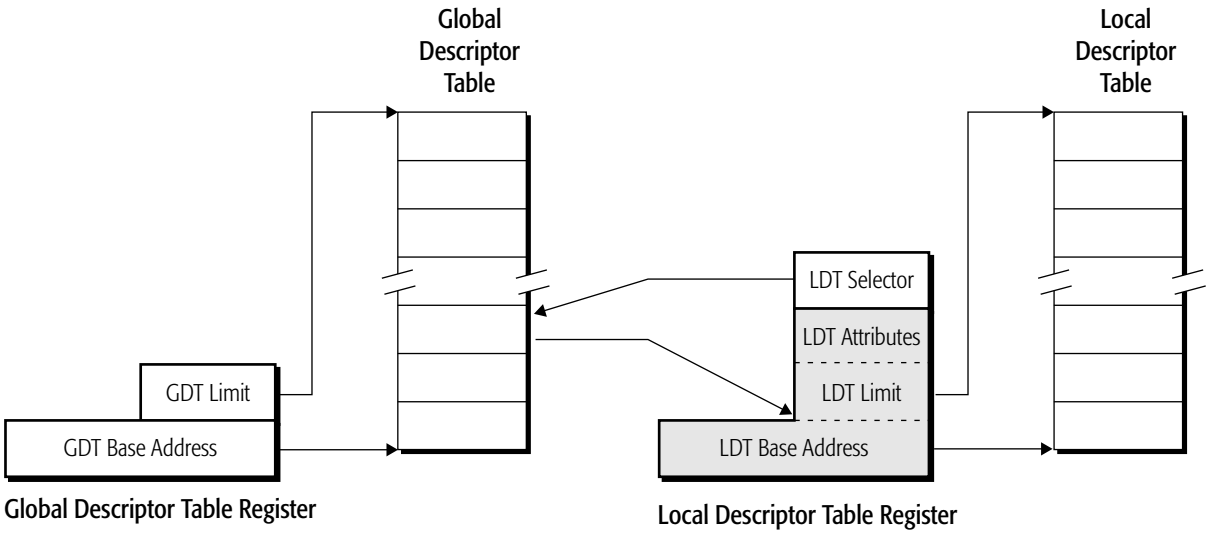

Figure 4-9. Relationship between the LDT and GDT

4.6.4 Local Descriptor-Table Register

The local descriptor-table register (LDTR) points to the location of the LDT in memory, defines its size, and specifies its attributes. The LDTR has two portions. A *visible* portion holds the LDT selector, and a *hidden* portion holds the LDT descriptor. When the LDT selector is loaded into the LDTR, the processor automatically loads the LDT descriptor from the GDT into the hidden portion of the LDTR. The LDTR is loaded in one of two ways:

- Using the LLDT instruction (see “LLDT and LTR Instructions” on page 177).
- Performing a task switch (see “Switching Tasks” on page 375).

Figure 4-10 on page 86 shows the format of the LDTR in legacy mode.

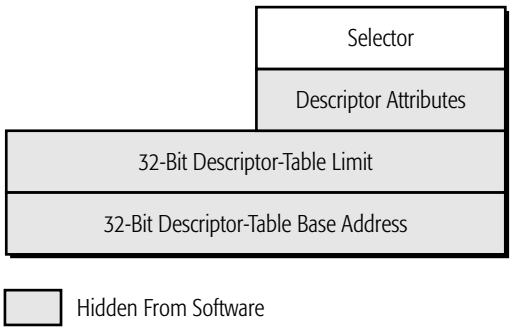

Figure 4-10. LDTR Format—Legacy Mode

Figure 4-11 shows the format of the LDTR in long mode (both compatibility mode and 64-bit mode).

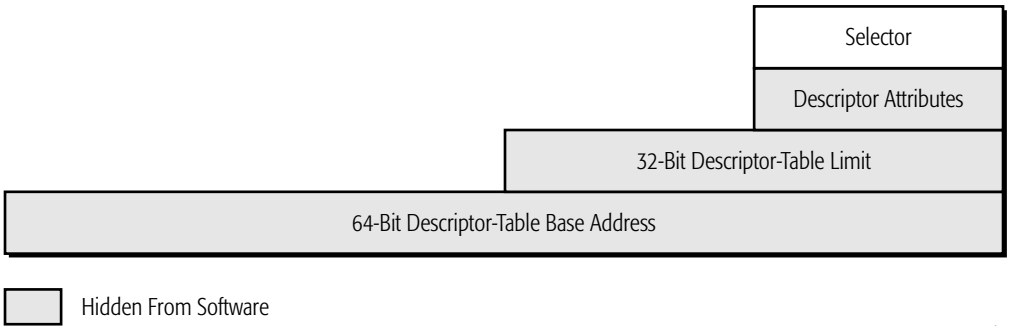

Figure 4-11. LDTR Format—Long Mode

The LDTR contains four fields:

LDT Selector. 2 bytes. These bits are loaded explicitly from the TSS during a task switch, or by using the LLDT instruction. The LDT selector must point to an LDT system-segment descriptor entry in the GDT. If it does not, a general-protection exception (#GP) occurs.

The following three fields are loaded automatically from the LDT descriptor in the GDT as a result of loading the LDT selector. The register fields are shown as shaded boxes in Figure 4-10 and Figure 4-11.

Base Address. The base-address field holds the starting byte address of the LDT in virtual-memory space. Like the GDT, the LDT can be located anywhere in system memory, but software should align the LDT on a quadword boundary to avoid performance penalties associated with accessing unaligned data.

The AMD64 architecture expands the base-address field of the LDTR to 64 bits so that system software running in long mode can locate an LDT anywhere in the 64-bit virtual-address space. The processor ignores the high-order 32 base-address bits when running in legacy mode. Because the LDTR is loaded from the GDT, the system-segment descriptor format (LDTs are system segments) has been expanded by the AMD64 architecture in support of 64-bit mode. See “Long Mode Descriptor Summary” on page 103 for more information on this expanded format. The high-order base-address bits are only loaded from 64-bit mode using the LLDT instruction (see “LLDT and LTR Instructions” on page 177 for more information on this instruction).

Limit. This field defines the limit, or size, of the LDT in bytes. The LDT limit as stored in the LDTR is 32 bits. When the LDT limit is loaded from the GDT descriptor entry, the 20-bit limit field in the descriptor is expanded to 32 bits and scaled based on the value of the descriptor granularity (G) bit. For details on the limit biasing and granularity, see “Granularity (G) Bit” on page 90.

If an attempt is made to access a descriptor beyond the LDT limit, a general-protection exception (#GP) occurs.

The offsets into the descriptor tables are not extended by the AMD64 architecture in support of long mode. Therefore, the LDTR limit-field size is unchanged from the legacy size. The processor does check the LDT limit in long mode during LDT accesses.

Attributes. This field holds the descriptor attributes, such as privilege rights, segment presence and segment granularity.

4.6.5 Interrupt Descriptor Table

The final type of descriptor table is the interrupt descriptor table (IDT). Multiple IDTs can be maintained by system software. System software selects a specific IDT by loading the interrupt descriptor table register (IDTR) with a pointer to the IDT. As with the GDT and LDT, system software can store the IDT anywhere in memory and should protect the segment containing the IDT from non-privileged software.

The IDT can contain only the following types of gate descriptors:

- Interrupt gates
- Trap gates
- Task gates.

The use of gate descriptors by the interrupt mechanism is described in Chapter 8, “Exceptions and Interrupts.” A general-protection exception (#GP) occurs if the IDT descriptor referenced by an interrupt or exception is not one of the types listed above.

IDT entries are selected using the interrupt vector number rather than a selector value. The interrupt vector number is scaled by the interrupt-descriptor entry size to form an offset into the IDT. The interrupt-descriptor entry size depends on the processor operating mode as follows:

- In long mode, interrupt descriptor-table entries are 16 bytes.

- In legacy mode, interrupt descriptor-table entries are eight bytes.

Figure 4-12 shows how the interrupt vector number indexes the IDT.

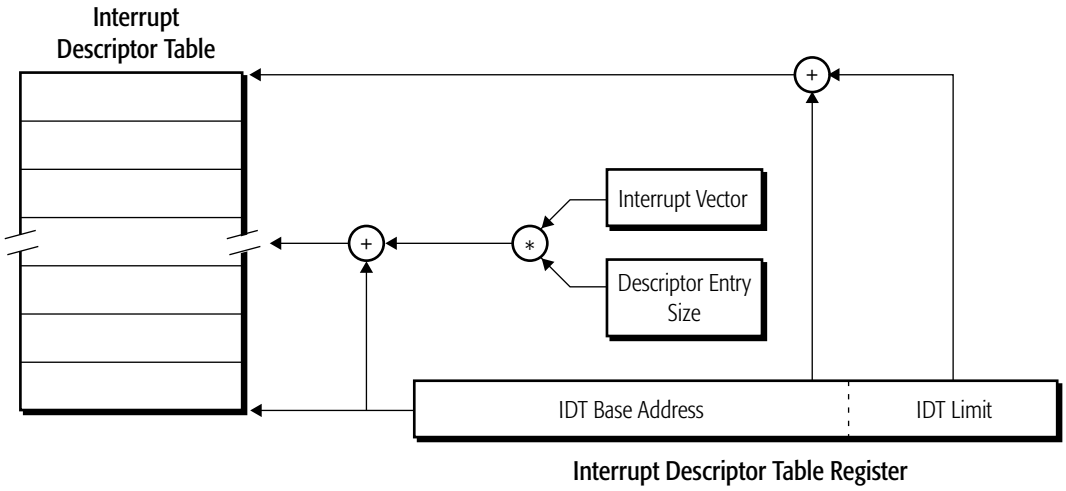

Figure 4-12. Indexing an IDT

4.6.6 Interrupt Descriptor-Table Register

The interrupt descriptor-table register (IDTR) points to the IDT in memory and defines its size. This register is loaded from memory using the LIDT instruction (see “LGDT and LIDT Instructions” on page 176). The format of the IDTR is identical to that of the GDTR in all modes. Figure 4-7 on page 83 shows the format of the IDTR in legacy mode. Figure 4-8 on page 84 shows the format of the IDTR in long mode.

The offsets into the descriptor tables are not extended by the AMD64 architecture in support of long mode. Therefore, the IDTR limit-field size is unchanged from the legacy size. The processor does check the IDT limit in long mode during IDT accesses.

4.7 Legacy Segment Descriptors

4.7.1 Descriptor Format

Segment descriptors define, protect, and isolate segments from each other. There are two basic types of descriptors, each of which are used to describe different segment (or gate) types:

- *User Segments*—These include code segments and data segments. Stack segments are a type of data segment.

- *System Segments*—System segments consist of LDT segments and task-state segments (TSS). Gate descriptors are another type of system-segment descriptor. Rather than describing segments, gate descriptors point to program entry points.

Figure 4-13 shows the generic format for user-segment and system-segment descriptors. User and system segments are differentiated using the S bit. S=1 indicates a user segment, and S=0 indicates a system segment. Gray shading indicates the field or bit is reserved. The format for a gate descriptor differs from the generic segment descriptor, and is described separately in “Gate Descriptors” on page 95.

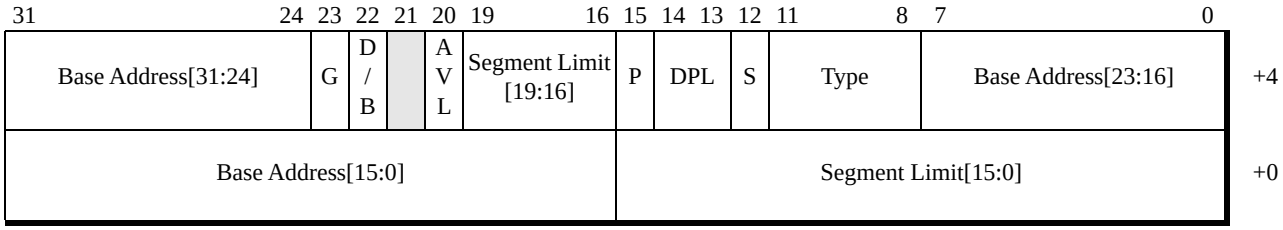

Figure 4-13. Generic Segment Descriptor—Legacy Mode

Figure 4-13 shows the fields in a generic, legacy-mode, 8-byte (two doubleword) segment descriptor. In this figure, the upper doubleword (located at byte offset +4) is shown on top and the lower doubleword (located at byte offset +0) is shown on the bottom. The fields are defined as follows:

Segment Limit. The 20-bit segment limit is formed by concatenating bits 19:16 of the upper doubleword with bits 15:0 of lower doubleword. The segment limit defines the segment size, in bytes. The granularity (G) bit controls how the segment-limit field is scaled (see “Granularity (G) Bit” on page 90). For data segments, the expand-down (E) bit determines whether the segment limit defines the lower or upper segment-boundary (see “Expand-Down (E) Bit” on page 93).

If software references a segment descriptor with an address beyond the segment limit, a general-protection exception (#GP) occurs. The #GP occurs if any part of the memory reference falls outside the segment limit. For example, a doubleword (4-byte) address reference causes a #GP if one or more bytes are located beyond the segment limit.

Base Address. The 32-bit base address is formed by concatenating bits 31:24 of the upper doubleword with bits 7:0 of the same doubleword and bits 15:0 of the lower doubleword. The segment-base address field locates the start of a segment in virtual-address space.

S Bit and Type Field. Bit 12 and bits 11:8 of the upper doubleword. The S and Type fields, together, specify the descriptor type and its access characteristics. Table 4-2 summarizes the descriptor types by S-field encoding and gives a cross reference to descriptions of the Type-field encodings.

Table 4-2. Descriptor Types

S Field	Descriptor Type	Type-Field Encoding
0 (System)	LDT	See Table 4-5 on page 94
	TSS	
	Gate	
1 (User)	Code	See Table 4-3 on page 92
	Data	See Table 4-4 on page 93

Descriptor Privilege-Level (DPL) Field. Bits 14:13 of the upper doubleword. The DPL field indicates the descriptor-privilege level of the segment. DPL can be set to any value from 0 to 3, with 0 specifying the most privilege and 3 the least privilege. See “Data-Access Privilege Checks” on page 106 and “Control-Transfer Privilege Checks” on page 109 for more information on how the DPL is used during segment privilege-checks.

Present (P) Bit. Bit 15 of the upper doubleword. The segment-present bit indicates that the segment referenced by the descriptor is loaded in memory. If a reference is made to a descriptor entry when P = 0, a segment-not-present exception (#NP) occurs. This bit is set and cleared by system software and is never altered by the processor.

Available To Software (AVL) Bit. Bit 20 of the upper doubleword. This field is available to software, which can write any value to it. The processor does not set or clear this field.

Default Operand Size (D/B) Bit. Bit 22 of the upper doubleword. The default operand-size bit is found in code-segment and data-segment descriptors but not in system-segment descriptors. Setting this bit to 1 indicates a 32-bit default operand size, and clearing it to 0 indicates a 16-bit default size. The effect this bit has on a segment depends on the segment-descriptor type. See “Code-Segment Default-Operand Size (D) Bit” on page 92 for a description of the D bit in code-segment descriptors. “Data-Segment Default Operand Size (D/B) Bit” on page 94 describes the D bit in data-segment descriptors, including stack segments, where the bit is referred to as the “B” bit.

Granularity (G) Bit. Bit 23 of the upper doubleword. The granularity bit specifies how the segment-limit field is scaled. Clearing the G bit to 0 indicates that the limit field is not scaled. In this case, the limit equals the number of bytes available in the segment. Setting the G bit to 1 indicates that the limit field is scaled by 4 Kbytes (4096 bytes). Here, the limit field equals the number of 4-Kbyte *blocks* available in the segment.

Setting a limit of 0 indicates a 1-byte segment limit when G = 0. Setting the same limit of 0 when G = 1 indicates a segment limit of 4095.

Reserved Bits. Generally, software should clear all reserved bits to 0, so they can be defined in future revisions to the AMD64 architecture.

4.7.2 Code-Segment Descriptors

Figure 4-14 shows the code-segment descriptor format (gray shading indicates the bit is reserved). All software tasks require that a segment selector, referencing a valid code-segment descriptor, is loaded into the CS register. Code segments establish the processor operating mode and execution privilege-level. The segments generally contain only instructions and are execute-only, or execute and read-only. Software cannot write into a segment whose selector references a code-segment descriptor.

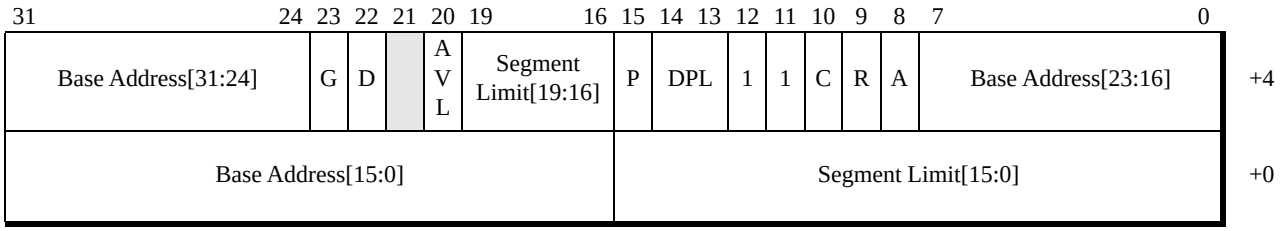

Figure 4-14. Code-Segment Descriptor—Legacy Mode

Code-segment descriptors have the S bit set to 1, identifying the segments as user segments. Type-field bit 11 differentiates code-segment descriptors (bit 11 set to 1) from data-segment descriptors (bit 11 cleared to 0). The remaining type-field bits (10:8) define the access characteristics for the code-segment, as follows:

Conforming (C) Bit. Bit 10 of the upper doubleword. Setting this bit to 1 identifies the code segment as *conforming*. When control is transferred to a higher-privilege conforming code-segment (C=1) from a lower-privilege code segment, the processor CPL does not change. Transfers to non-conforming code-segments (C = 0) with a higher privilege-level than the CPL can occur only through gate descriptors. See “Control-Transfer Privilege Checks” on page 109 for more information on conforming and non-conforming code-segments.

Readable (R) Bit. Bit 9 of the upper doubleword. Setting this bit to 1 indicates the code segment is both executable and readable as data. When this bit is cleared to 0, the code segment is executable, but attempts to read data from the code segment cause a general-protection exception (#GP) to occur.

Accessed (A) Bit. Bit 8 of the upper doubleword. The accessed bit is set to 1 by the processor when the descriptor is copied from the GDT or LDT into the CS register. This bit is only cleared by software.

Table 4-3 on page 92 summarizes the code-segment type-field encodings.

Table 4-3. Code-Segment Descriptor Types

Hex Value	Type Field				Description
	Bit 11 (Code/Data)	Bit 10	Bit 9	Bit 8	
		Conforming (C)	Readable (R)	Accessed (A)	
8	1	0	0	0	Execute-Only
9		0	0	1	Execute-Only — Accessed
A		0	1	0	Execute/Readable
B		0	1	1	Execute/Readable — Accessed
C		1	0	0	Conforming, Execute-Only
D		1	0	1	Conforming, Execute-Only — Accessed
E		1	1	0	Conforming, Execute/Readable
F		1	1	1	Conforming, Execute/Readable — Accessed

Code-Segment Default-Operand Size (D) Bit. Bit 22 of byte +4. In code-segment descriptors, the D bit selects the default operand size and address sizes. In legacy mode, when D=0 the default operand size and address size is 16 bits and when D=1 the default operand size and address size is 32 bits. Instruction prefixes can be used to override the operand size or address size, or both.

4.7.3 Data-Segment Descriptors

Figure 4-15 shows the data-segment descriptor format. Data segments contain non-executable information and can be accessed as read-only or read/write. They are referenced using the DS, ES, FS, GS, or SS data-segment registers. The DS data-segment register holds the segment selector for the default data segment. The ES, FS and GS data-segment registers hold segment selectors for additional data segments usable by the current software task.

The stack segment is a special form of data-segment register. It is referenced using the SS segment register and must be read/write. When loading the SS register, the processor requires that the selector reference a valid, writable data-segment descriptor.

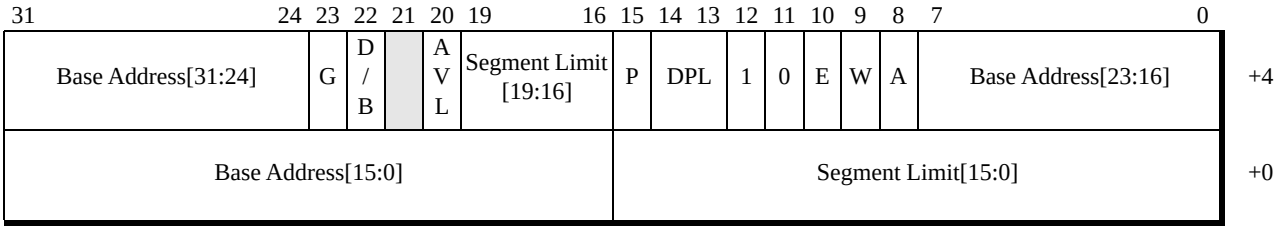

Figure 4-15. Data-Segment Descriptor—Legacy Mode

Data-segment descriptors have the S bit set to 1, identifying them as user segments. Type-field bit 11 differentiates data-segment descriptors (bit 11 cleared to 0) from code-segment descriptors (bit 11 set to 1). The remaining type-field bits (10:8) define the data-segment access characteristics, as follows:

Expand-Down (E) Bit. Bit 10 of the upper doubleword. Setting this bit to 1 identifies the data segment as *expand-down*. In expand-down segments, the segment limit defines the *lower* segment boundary while the base is the upper boundary. Valid segment offsets in expand-down segments lie in the byte range limit+1 to FFFFh or FFFF_FFFFh, depending on the value of the data segment default operand size (D/B) bit.

Expand-down segments are useful for stacks, which grow in the downward direction as elements are pushed onto the stack. The stack pointer, ESP, is *decremented* by an amount equal to the operand size as a result of executing a PUSH instruction.

Clearing the E bit to 0 identifies the data segment as expand-up. Valid segment offsets in expand-up segments lie in the byte range 0 to segment limit.

Writable (W) Bit. Bit 9 of the upper doubleword. Setting this bit to 1 identifies the data segment as read/write. When this bit is cleared to 0, the segment is read-only. A general-protection exception (#GP) occurs if software attempts to write into a data segment when W=0.

Accessed (A) Bit. Bit 8 of the upper doubleword. The accessed bit is set to 1 by the processor when the descriptor is copied from the GDT or LDT into one of the data-segment registers or the stack-segment register. This bit is only cleared by software.

Table 4-4 summarizes the data-segment type-field encodings.

Table 4-4. Data-Segment Descriptor Types

Hex Value	Type Field				Description
	Bit 11 (Code/Data)	Bit 10	Bit 9	Bit 8	
		Expand-Down (E)	Writable (W)	Accessed (A)	
0	0	0	0	0	Read-Only
1		0	0	1	Read-Only — Accessed
2		0	1	0	Read/Write
3		0	1	1	Read/Write — Accessed
4		1	0	0	Expand-down, Read-Only
5		1	0	1	Expand-down, Read-Only — Accessed
6		1	1	0	Expand-down, Read/Write
7		1	1	1	Expand-down, Read/Write — Accessed

Data-Segment Default Operand Size (D/B) Bit. Bit 22 of the upper doubleword. For expand-down data segments (E=1), setting D=1 sets the upper bound of the segment at 0_FFFF_FFFFh. Clearing D=0 sets the upper bound of the segment at 0_FFFFh.

In the case where a data segment is referenced by the stack selector (SS), the D bit is referred to as the B bit. For stack segments, the B bit sets the default stack size. Setting B=1 establishes a 32-bit stack referenced by the 32-bit ESP register. Clearing B=0 establishes a 16-bit stack referenced by the 16-bit SP register.

4.7.4 System Descriptors

There are two general types of system descriptors: system-segment descriptors and gate descriptors. System-segment descriptors are used to describe the LDT and TSS segments. Gate descriptors do not describe segments, but instead hold pointers to code-segment descriptors. Gate descriptors are used for protected-mode control transfers between less-privileged and more-privileged software.

System-segment descriptors have the S bit cleared to 0. The type field is used to differentiate the various LDT, TSS, and gate descriptors from one another. Table 4-5 summarizes the system-segment type-field encodings.

Table 4-5. System-Segment Descriptor Types (S=0)—Legacy Mode

Hex Value	Type Field (Bits 11:8)	Description
0	0000	Reserved (Illegal)
1	0001	Available 16-bit TSS
2	0010	LDT
3	0011	Busy 16-bit TSS
4	0100	16-bit Call Gate
5	0101	Task Gate
6	0110	16-bit Interrupt Gate
7	0111	16-bit Trap Gate
8	1000	Reserved (Illegal)
9	1001	Available 32-bit TSS
A	1010	Reserved (Illegal)
B	1011	Busy 32-bit TSS
C	1100	32-bit Call Gate
D	1101	Reserved (Illegal)
E	1110	32-bit Interrupt Gate
F	1111	32-bit Trap Gate

Figure 4-16 shows the legacy-mode system-segment descriptor format used for referencing LDT and TSS segments (gray shading indicates the bit is reserved). This format is also used in compatibility mode. The system-segments are used as follows:

- The LDT typically holds segment descriptors belonging to a single task (see “Local Descriptor Table” on page 84).
- The TSS is a data structure for holding processor-state information. Processor state is saved in a TSS when a task is suspended, and state is restored from the TSS when a task is restarted. System software must create at least one TSS referenced by the task register, TR. See “Legacy Task-State Segment” on page 367 for more information on the TSS.

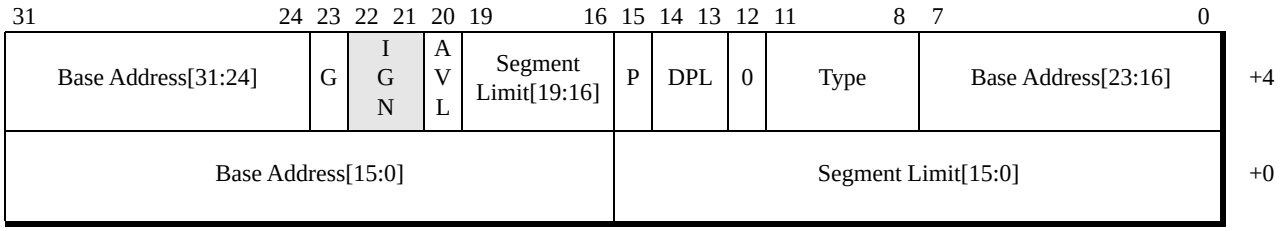

Figure 4-16. LDT and TSS Descriptor—Legacy/Compatibility Modes

4.7.5 Gate Descriptors

Gate descriptors hold pointers to code segments and are used to control access between code segments with different privilege levels. There are four types of gate descriptors:

- *Call Gates*—These gates (Figure 4-17 on page 96) are located in the GDT or LDT and are used to control access between code segments in the same task or in different tasks. See “Control Transfers Through Call Gates” on page 113 for information on how call gates are used to control access between code segments operating in the same task. The format of a call-gate descriptor is shown in Figure 4-17 on page 96.
- *Interrupt Gates* and *Trap Gates*—These gates (Figure 4-18 on page 96) are located in the IDT and are used to control access to interrupt-service routines. “Legacy Protected-Mode Interrupt Control Transfers” on page 261 contains information on using these gates for interrupt-control transfers. The format of interrupt-gate and trap-gate descriptors is shown in Figure 4-17 on page 96.
- *Task Gates*—These gates (Figure 4-19 on page 96) are used to control access between different tasks. They are also used to transfer control to interrupt-service routines if those routines are themselves a separate task. See “Task-Management Resources” on page 362 for more information on task gates and their use.

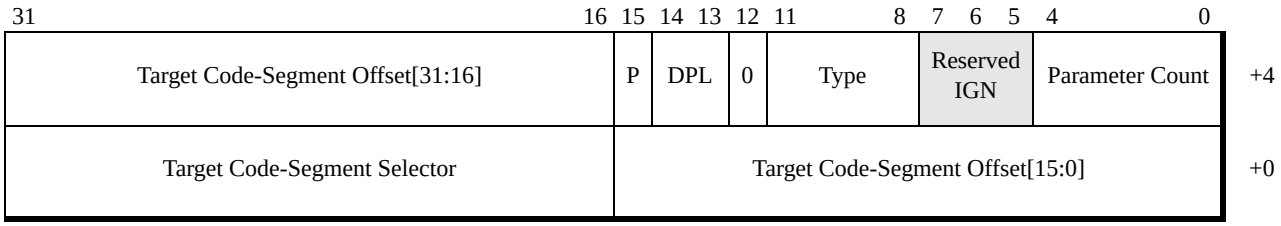

Figure 4-17. Call-Gate Descriptor—Legacy Mode

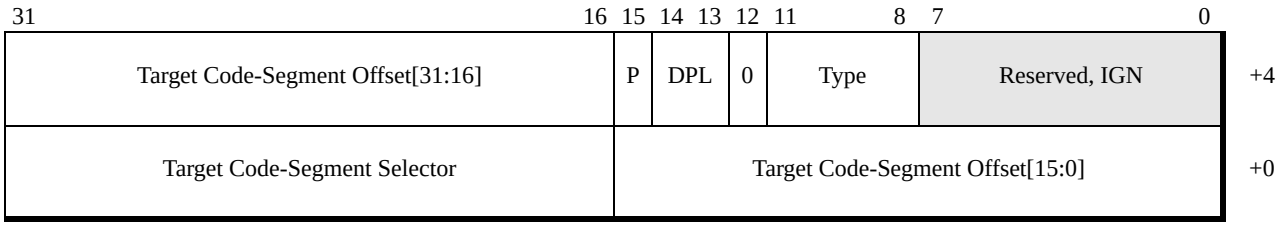

Figure 4-18. Interrupt-Gate and Trap-Gate Descriptors—Legacy Mode

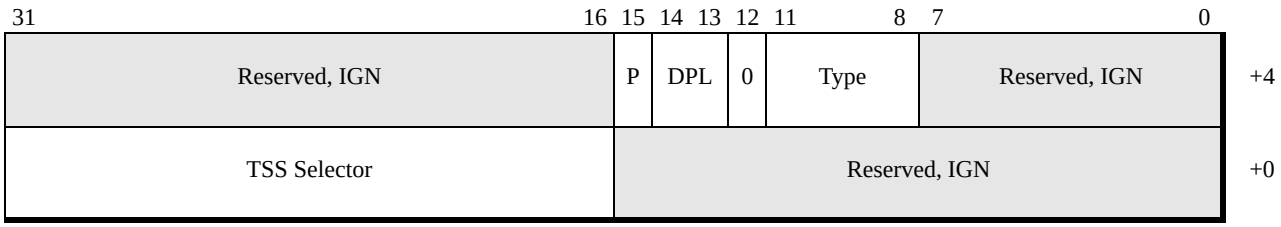

Figure 4-19. Task-Gate Descriptor—Legacy Mode

There are several differences between the gate-descriptor format and the system-segment descriptor format. These differences are described as follows, from least-significant to most-significant bit positions:

Target Code-Segment Offset. The 32-bit segment offset is formed by concatenating bits 31:16 of byte +4 with bits 15:0 of byte +0. The segment-offset field specifies the target-procedure entry point (offset) into the segment. This field is loaded into the EIP register as a result of a control transfer using the gate descriptor.

Target Code-Segment Selector. Bits 31:16 of byte +0. The segment-selector field identifies the target-procedure segment descriptor, located in either the GDT or LDT. The segment selector is loaded into the CS segment register as a result of a control transfer using the gate descriptor.

TSS Selector. Bits 31:16 of byte +0 (task gates only). This field identifies the target-task TSS descriptor, located in any of the three descriptor tables (GDT, LDT, and IDT).

Parameter Count (Call Gates Only). Bits 4:0 of byte +4. Legacy-mode call-gate descriptors contain a 5-bit *parameter-count* field. This field specifies the number of parameters to be copied from the currently-executing program stack to the target program stack during an automatic stack switch. Automatic stack switches are performed by the processor during a control transfer through a call gate to a greater privilege-level. The parameter size depends on the call-gate size as specified in the type field. 32-bit call gates copy 4-byte parameters, and 16-bit call gates copy 2-byte parameters. See “Stack Switching” on page 117 for more information on call-gate parameter copying.

4.8 Long-Mode Segment Descriptors

The interpretation of descriptor fields is changed in long mode, and in some cases the format is expanded. The changes depend on the operating mode (compatibility mode or 64-bit mode) and on the descriptor type. The following sections describe the changes.

4.8.1 Code-Segment Descriptors

Code segments continue to exist in long mode. Code segments and their associated descriptors and selectors are needed to establish the processor operating mode as well as execution privilege-level. The new L attribute specifies whether the processor is running in compatibility mode or 64-bit mode (see “Long (L) Attribute Bit” on page 98). Figure 4-20 shows the long-mode code-segment descriptor format. In compatibility mode, the code-segment descriptor is interpreted and behaves just as it does in legacy mode as described in “Code-Segment Descriptors” on page 91.

In Figure 4-20, gray shading indicates the code-segment descriptor fields that are *ignored in 64-bit mode* when the descriptor is used during a memory reference. However, the fields are loaded whenever the segment register is loaded in 64-bit mode.

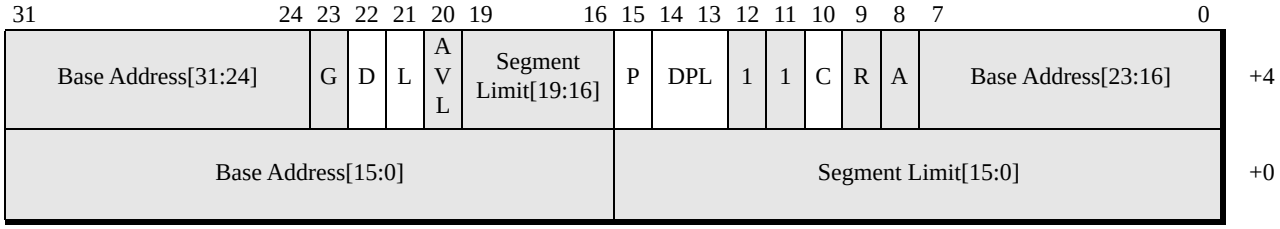

Figure 4-20. Code-Segment Descriptor—Long Mode

Fields Ignored in 64-Bit Mode. Segmentation is disabled in 64-bit mode, and code segments span all of virtual memory. In this mode, code-segment base addresses are ignored. For the purpose of virtual-address calculations, the base address is treated as if it has a value of zero.

Segment-limit checking is not performed, and both the segment-limit field and granularity (G) bit are ignored. Instead, the virtual address is checked to see if it is in canonical-address form.

The readable (R) and accessed (A) attributes in the type field are also ignored.

Long (L) Attribute Bit. Bit 21 of byte +4. Long mode introduces a new attribute, the *long* (L) bit, in code-segment descriptors. This bit specifies that the processor is running in 64-bit mode (L=1) or compatibility mode (L=0). When the processor is running in legacy mode, this bit is reserved.

Compatibility mode maintains binary compatibility with legacy 16-bit and 32-bit applications. Compatibility mode is selected on a code-segment basis, and it allows legacy applications to coexist under the same 64-bit system software along with 64-bit applications running in 64-bit mode. System software running in long mode can execute existing 16-bit and 32-bit applications by clearing the L bit of the code-segment descriptor to 0.

When L=0, the legacy meaning of the code-segment D bit (see “Code-Segment Default-Operand Size (D) Bit” on page 92)—and the address-size and operand-size prefixes—are observed. Segmentation is enabled when L=0. From an application viewpoint, the processor is in a legacy 16-bit or 32-bit operating environment (depending on the D bit), even though long mode is activated.

If the processor is running in 64-bit mode (L=1), the only valid setting of the D bit is 0. This setting produces a default operand size of 32 bits and a default address size of 64 bits. The combination L=1 and D=1 is reserved for future use.

“Instruction Prefixes” in Volume 3 describes the effect of the code-segment L and D bits on default operand and address sizes when long mode is activated. These default sizes can be overridden with operand size, address size, and REX prefixes.

4.8.2 Data-Segment Descriptors

Data segments continue to exist in long mode. Figure 4-21 shows the long-mode data-segment descriptor format. In compatibility mode, data-segment descriptors are interpreted and behave just as they do in legacy mode.

In Figure 4-21, gray shading indicates the fields that are *ignored in 64-bit mode* when the descriptor is used during a memory reference. However, the fields are loaded whenever the segment register is loaded in 64-bit mode.

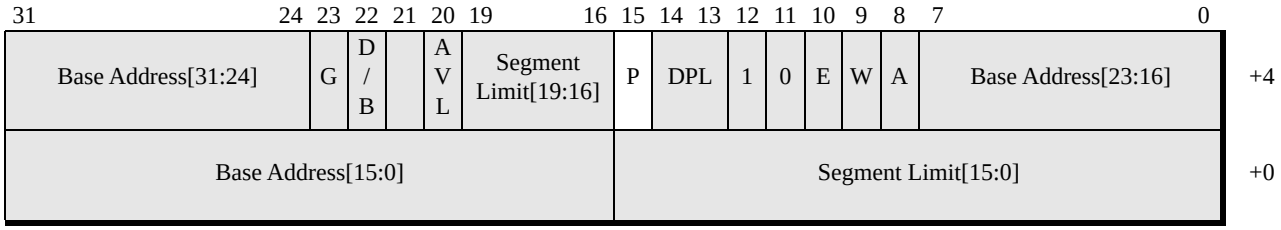

Figure 4-21. Data-Segment Descriptor—Long Mode

Fields Ignored in 64-Bit Mode. Segmentation is disabled in 64-bit mode. The interpretation of the segment-base address depends on the segment register used:

- In data-segment descriptors referenced by the DS, ES and SS segment registers, the base-address field is ignored. For the purpose of virtual-address calculations, the base address is treated as if it has a value of zero.
- Data segments referenced by the FS and GS segment registers receive special treatment in 64-bit mode. For these segments, the base address field is not ignored, and a non-zero value can be used in virtual-address calculations. A 64-bit segment-base address can be specified using model-specific registers. See “FS and GS Registers in 64-Bit Mode” on page 80 for more information.

Segment-limit checking is not performed on any data segments in 64-bit mode, and both the segment-limit field and granularity (G) bit are ignored. The D/B bit is unused in 64-bit mode.

The expand-down (E), writable (W), and accessed (A) type-field attributes are ignored.

A data-segment-descriptor DPL field is ignored in 64-bit mode, and segment-privilege checks are not performed on data segments. System software can use the page-protection mechanisms to isolate and protect data from unauthorized access.

4.8.3 System Descriptors

In long mode, the allowable system-descriptor types encoded by the type field are changed. Some descriptor types are modified, and others are illegal. The changes are summarized in Table 4-6. An attempt to use an illegal descriptor type causes a general-protection exception (#GP).

Table 4-6. System-Segment Descriptor Types—Long Mode

Hex Value	Type Field				Description
	Bit 11	Bit 10	Bit 9	Bit 8	
0	0	0	0	0	Reserved (Illegal)
1	0	0	0	1	
2	0	0	1	0	64-bit LDT[1]
3	0	0	1	1	Reserved (Illegal)
4	0	1	0	0	
5	0	1	0	1	
6	0	1	1	0	
7	0	1	1	1	
8	1	0	0	0	
9	1	0	0	1	Available 64-bit TSS
A	1	0	1	0	Reserved (Illegal)
B	1	0	1	1	Busy 64-bit TSS
C	1	1	0	0	64-bit Call Gate

Note(s):
1. In 64-bit mode only. In compatibility mode, the type specifies a 32-bit LDT.

Table 4-6. System-Segment Descriptor Types—Long Mode (continued)

Hex Value	Type Field				Description
	Bit 11	Bit 10	Bit 9	Bit 8	
D	1	1	0	1	Reserved (Illegal)
E	1	1	1	0	64-bit Interrupt Gate
F	1	1	1	1	64-bit Trap Gate

Note(s):
1. In 64-bit mode only. In compatibility mode, the type specifies a 32-bit LDT.

In long mode, the modified system-segment descriptor types are:

- The 32-bit LDT (02h), which is redefined as the 64-bit LDT.
- The available 32-bit TSS (09h), which is redefined as the available 64-bit TSS.
- The busy 32-bit TSS (0Bh), which is redefined as the busy 64-bit TSS.

In 64-bit mode, the LDT and TSS system-segment descriptors are expanded by 64 bits, as shown in Figure 4-22. In this figure, gray shading indicates the fields that are *ignored in 64-bit mode*. Expanding the descriptors allows them to hold 64-bit base addresses, so their segments can be located anywhere in the virtual-address space. The expanded descriptor can be loaded into the corresponding descriptor-table register (LDTR or TR) only from 64-bit mode. In compatibility mode, the legacy system-segment descriptor format, shown in Figure 4-16 on page 95, is used. See “LLDT and LTR Instructions” on page 177 for more information.

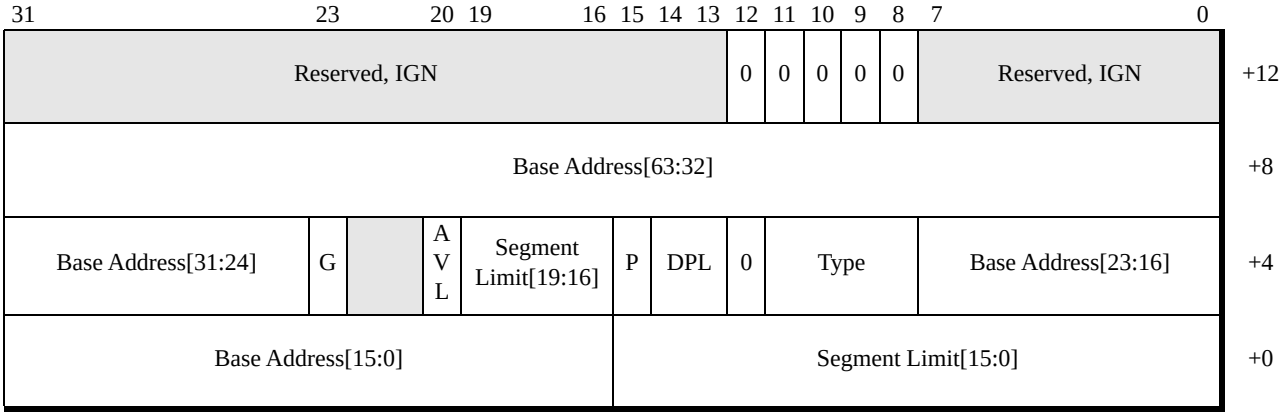

Figure 4-22. System-Segment Descriptor—64-Bit Mode

The 64-bit system-segment base address must be in canonical form. Otherwise, a general-protection exception occurs with a selector error-code, #GP(selector), when the system segment is loaded. System-segment limit values are checked by the processor in both 64-bit and compatibility modes, under the control of the granularity (G) bit.

Figure 4-22 shows that bits 12:8 of doubleword +12 must be cleared to 0. These bits correspond to the S and Type fields in a legacy descriptor. Clearing these bits to 0 corresponds to an illegal type in legacy

mode and causes a #GP if an attempt is made to access the upper half of a 64-bit mode system-segment descriptor as a legacy descriptor or as the lower half of a 64-bit mode system-segment descriptor.

4.8.4 Gate Descriptors

As shown in Table 4-6 on page 99, the allowable gate-descriptor types are changed in long mode. Some gate-descriptor types are modified and others are illegal. The modified gate-descriptor types in long mode are:

- The 32-bit call gate (0Ch), which is redefined as the 64-bit call gate.
- The 32-bit interrupt gate (0Eh), which is redefined as the 64-bit interrupt gate.
- The 32-bit trap gate (0Fh), which is redefined as the 64-bit trap gate.

In long mode, several gate-descriptor types are illegal. An attempt to use these gates causes a general-protection exception (#GP) to occur. The illegal gate types are:

- The 16-bit call gate (04h).
- The task gate (05h).
- The 16-bit interrupt gate (06h).
- The 16-bit trap gate (07h).

In long mode, gate descriptors are expanded by 64 bits, allowing them to hold 64-bit offsets. The 64-bit call-gate descriptor is shown in Figure 4-23 and the 64-bit interrupt gate and trap gate are shown in Figure 4-24 on page 102. In these figures, gray shading indicates the fields that are *ignored in long mode*. The interrupt and trap gates contain an additional field, the IST, that is not present in the call gate—see “IST Field (Interrupt and Trap Gates)” on page 102.

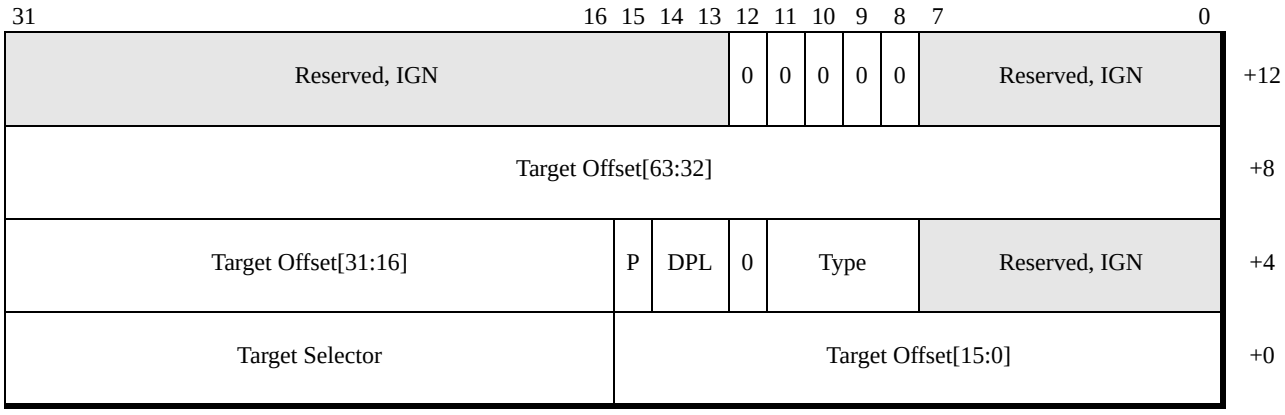

Figure 4-23. Call-Gate Descriptor—Long Mode

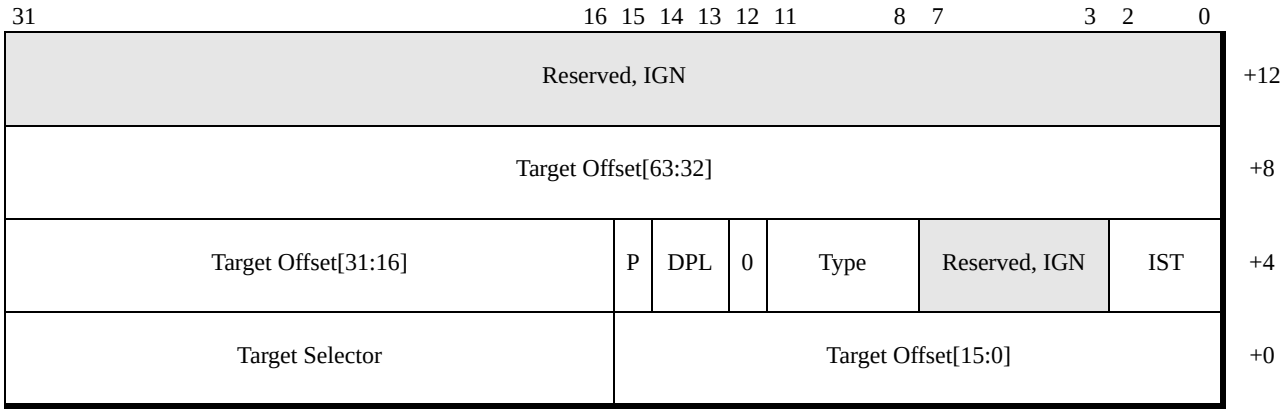

Figure 4-24. Interrupt-Gate and Trap-Gate Descriptors—Long Mode

The target code segment referenced by a long-mode gate descriptor must be a 64-bit code segment (CS.L=1, CS.D=0). If the target is not a 64-bit code segment, a general-protection exception, #GP(error), occurs. The error code reported depends on the gate type:

- Call gates report the target code-segment selector as the error code.
- Interrupt and trap gates report the interrupt vector number as the error code.

A general-protection exception, #GP(0), occurs if software attempts to reference a long-mode gate descriptor with a target-segment offset that is not in canonical form.

It is possible for software to store legacy and long mode gate descriptors in the same descriptor table. Figure 4-23 on page 101 shows that bits 12:8 of byte +12 in a long-mode call gate must be cleared to 0. These bits correspond to the S and Type fields in a legacy call gate. Clearing these bits to 0 corresponds to an illegal type in legacy mode and causes a #GP if an attempt is made to access the upper half of a 64-bit mode call-gate descriptor as a legacy call-gate descriptor.

It is not necessary to clear these same bits in a long-mode interrupt gate or trap gate. In long mode, the interrupt-descriptor table (IDT) must contain 64-bit interrupt gates or trap gates. The processor automatically indexes the IDT by scaling the interrupt vector by 16. This makes it impossible to access the upper half of a long-mode interrupt gate, or trap gate, as a legacy gate when the processor is running in long mode.

IST Field (Interrupt and Trap Gates). Bits 2:0 of byte +4. Long-mode interrupt gate and trap gate descriptors contain a new, 3-bit interrupt-stack-table (IST) field not present in legacy gate descriptors. The IST field is used as an index into the IST portion of a long-mode TSS. If the IST field is not 0, the index references an IST pointer in the TSS, which the processor loads into the RSP register when an interrupt occurs. If the IST index is 0, the processor uses the legacy stack-switching mechanism (with some modifications) when an interrupt occurs. See “Interrupt-Stack Table” on page 276 for more information.

Count Field (Call Gates). The count field found in legacy call-gate descriptors is not supported in long-mode call gates. In long mode, the field is reserved and should be cleared to zero.

4.8.5 Long Mode Descriptor Summary

System descriptors and gate descriptors are expanded by 64 bits to handle 64-bit base addresses in long mode or 64-bit mode. The mode in which the expansion occurs depends on the purpose served by the descriptor, as follows:

- *Expansion Only In 64-Bit Mode*—The system descriptors and pseudo-descriptors that are loaded into the GDTR, IDTR, LDTR, and TR registers are expanded only in 64-bit mode. They are not expanded in compatibility mode.
- *Expansion In Long Mode*—Gate descriptors (call gates, interrupt gates, and trap gates) are expanded in long mode (both 64-bit mode and compatibility mode). Task gates and 16-bit gate descriptors are illegal in long mode.

The AMD64 architecture redefines several of the descriptor-entry fields in support of long mode. The specific change depends on whether the processor is in 64-bit mode or compatibility mode. Table 4-7 summarizes the changes in the descriptor entry field when the descriptor entry is loaded into a segment register (as opposed to when the segment register is subsequently used to access memory).

4.9 Segment-Protection Overview

The AMD64 architecture is designed to fully support the legacy segment-protection mechanism. The segment-protection mechanism provides system software with the ability to restrict program access into other software routines and data.

Segment-level protection remains enabled in compatibility mode. 64-bit mode eliminates most type checking, and limit checking is not performed, except on accesses to system-descriptor tables.

The preferred method of implementing memory protection in a long-mode operating system is to rely on the page-protection mechanism as described in “Page-Protection Checks” on page 158. System software still needs to create basic segment-protection data structures for 64-bit mode. These structures are simplified, however, by the use of the flat-memory model in 64-bit mode, and the limited segmentation checks performed when executing in 64-bit mode.

4.9.1 Privilege-Level Concept

Segment protection is used to isolate and protect programs and data from each other. The segment-protection mechanism supports four privilege levels in protected mode. The privilege levels are designated with a numerical value from 0 to 3, with 0 being the most privileged and 3 being the least privileged. System software typically assigns the privilege levels in the following manner:

- *Privilege-level 0 (most privilege)*—This level is used by critical system-software components that require direct access to, and control over, all processor and system resources. This can include platform firmware, memory-management functions, and interrupt handlers.
- *Privilege-levels 1 and 2 (moderate privilege)*—These levels are used by less-critical system-software services that can access and control a limited scope of processor and system resources. Software running at these privilege levels might include some device drivers and library routines. These software routines can call more-privileged system-software services to perform functions such as memory garbage-collection and file allocation.
- *Privilege-level 3 (least privilege)*—This level is used by application software. Software running at privilege-level 3 is normally prevented from directly accessing most processor and system resources. Instead, applications request access to the protected processor and system resources by calling more-privileged service routines to perform the accesses.

Figure 4-25 shows the relationship of the four privilege levels to each other.

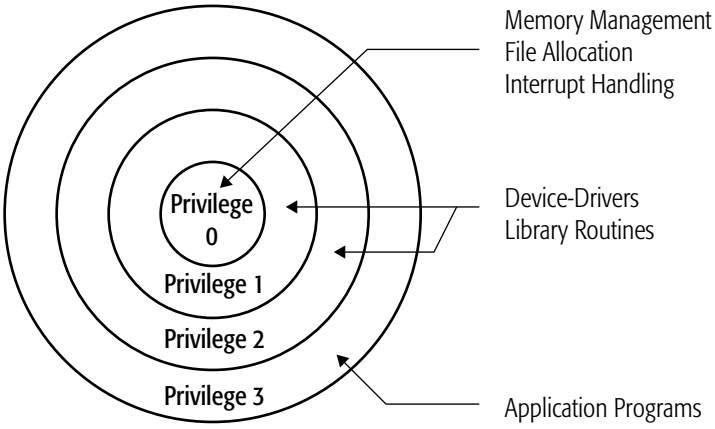

Figure 4-25. Privilege-Level Relationships

4.9.2 Privilege-Level Types

There are three types of privilege levels the processor uses to control access to segments. These are CPL, DPL, and RPL.

Current Privilege-Level. The current privilege-level (CPL) is the privilege level at which the processor is currently executing. The CPL is stored in an internal processor register that is invisible to

software. Software changes the CPL by performing a control transfer to a different code segment with a new privilege level.

Descriptor Privilege-Level. The descriptor privilege-level (DPL) is the privilege level that system software assigns to individual segments. The DPL is used in privilege checks to determine whether software can access the segment referenced by the descriptor. In the case of gate descriptors, the DPL determines whether software can access the descriptor reference by the gate. The DPL is stored in the segment (or gate) descriptor.

Requestor Privilege-Level. The requestor privilege-level (RPL) reflects the privilege level of the program that created the selector. The RPL can be used to let a called program know the privilege level of the program that initiated the call. The RPL is stored in the selector used to reference the segment (or gate) descriptor.

The following sections describe how the CPL, DPL, and RPL are used by the processor in performing privilege checks on data accesses and control transfers. Failure to pass a protection check generally causes an exception to occur.

4.10 Data-Access Privilege Checks

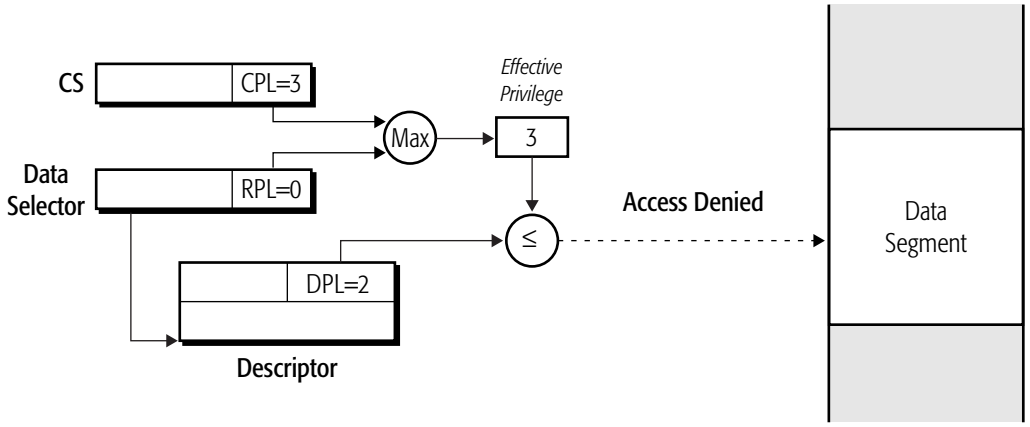
4.10.1 Accessing Data Segments

Before loading a data-segment register (DS, ES, FS, or GS) with a segment selector, the processor checks the privilege levels as follows to see if access is allowed:

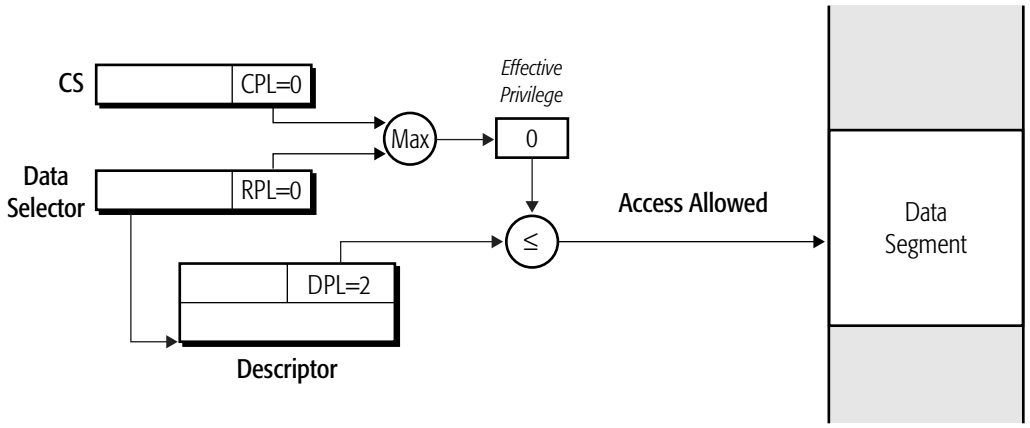
1. The processor compares the CPL with the RPL in the data-segment selector and determines the effective privilege level for the data access. The processor sets the effective privilege level to the lowest privilege (numerically-higher value) indicated by the comparison.
2. The processor compares the effective privilege level with the DPL in the descriptor-table entry referenced by the segment selector. If the effective privilege level is greater than or equal to (numerically lower-than or equal-to) the DPL, then the processor loads the segment register with the data-segment selector. The processor automatically loads the corresponding descriptor-table entry into the hidden portion of the segment register.

   If the effective privilege level is lower than (numerically greater-than) the DPL, a general-protection exception (#GP) occurs and the segment register is not loaded.

Figure 4-26 on page 107 shows two examples of data-access privilege checks.



Example 1: Privilege Check Fails



Example 2: Privilege Check Passes

Figure 4-26. Data-Access Privilege-Check Examples

Example 1 in Figure 4-26 shows a failing data-access privilege check. The effective privilege level is 3 because CPL=3. This value is greater than the descriptor DPL, so access to the data segment is denied.

Example 2 in Figure 4-26 shows a passing data-access privilege check. Here, the effective privilege level is 0 because both the CPL and RPL have values of 0. This value is less than the descriptor DPL, so access to the data segment is allowed, and the data-segment register is successfully loaded.

4.10.2 Accessing Stack Segments

Before loading the stack segment register (SS) with a segment selector, the processor checks the privilege levels as follows to see if access is allowed:

1. The processor checks that the CPL and the stack-selector RPL are *equal*. If they are not equal, a general-protection exception (#GP) occurs and the SS register is not loaded.
2. The processor compares the CPL with the DPL in the descriptor-table entry referenced by the segment selector. The two values *must be equal*. If they are not equal, a #GP occurs and the SS register is not loaded.

Figure 4-27 shows two examples of stack-access privilege checks. In Example 1 the CPL, stack-selector RPL, and stack segment-descriptor DPL are all equal, so access to the stack segment using the SS register is allowed. In Example 2, the stack-selector RPL and stack segment-descriptor DPL are both equal. However, the CPL is not equal to the stack segment-descriptor DPL, and access to the stack segment through the SS register is denied.

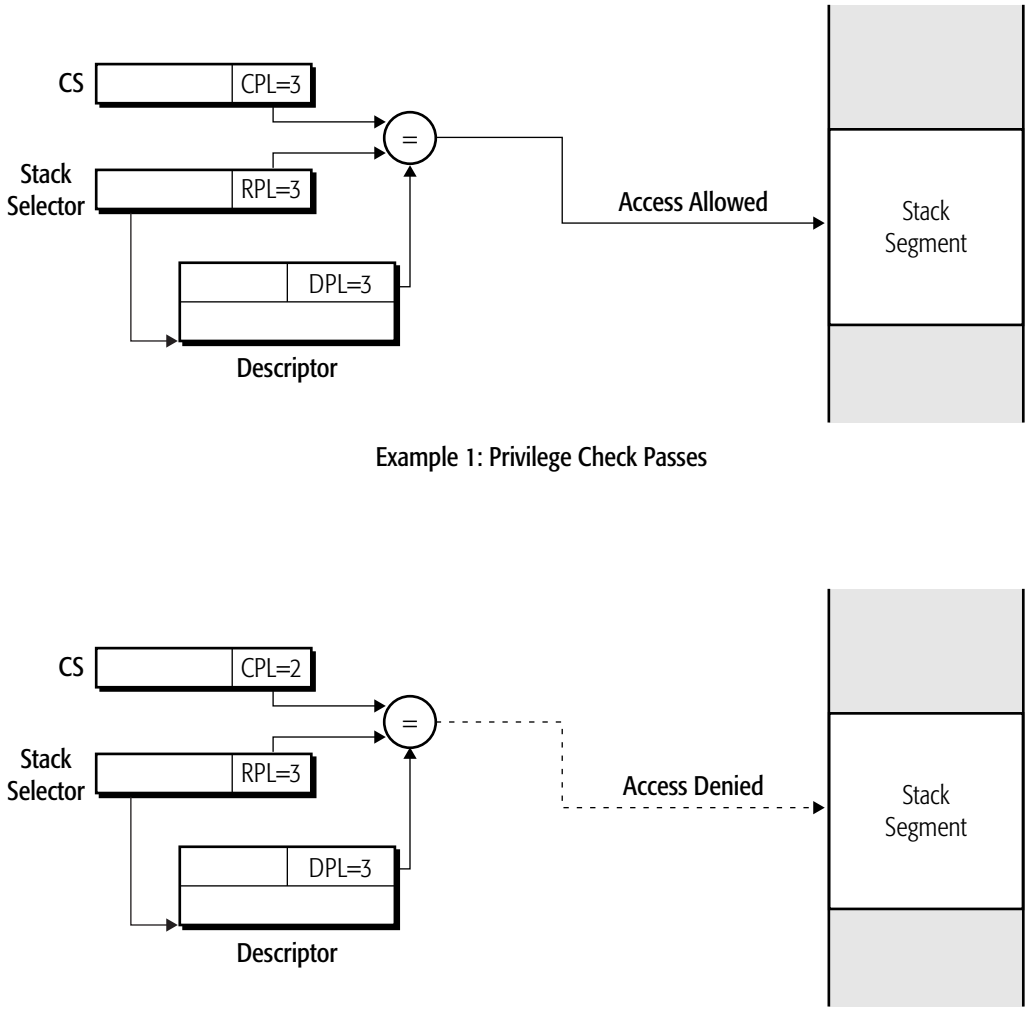


Figure 4-27. Stack-Access Privilege-Check Examples

4.11 Control-Transfer Privilege Checks

Control transfers between code segments (also called *far control transfers*) cause the processor to perform privilege checks to determine whether the source program is allowed to transfer control to the target program. If the privilege checks pass, access to the target code-segment is granted. When access is granted, the target code-segment selector is loaded into the CS register. The rIP register is updated with the target CS offset taken from either the far-pointer operand or the gate descriptor. Privilege checks are not performed during *near control transfers* because such transfers do not change segments.

The following mechanisms can be used by software to perform far control transfers:

- System-software control transfers using the *system-call* and *system-return* instructions. See "SYSCALL and SYSRET" on page 171 and "SYSENTER and SYSEXIT (Legacy Mode Only)" on page 173 for more information on these instructions. SYSCALL and SYSRET are the preferred method of performing control transfers in long mode. *SYSENTER and SYSEXIT are not supported in long mode.*
- Direct control transfers using CALL and JMP instructions. These are discussed in the next section, "Direct Control Transfers."
- Call-gate control transfers using CALL and JMP instructions. These are discussed in "Control Transfers Through Call Gates" on page 113.
- Return control transfers using the RET instruction. These are discussed in "Return Control Transfers" on page 120.
- Interrupts and exceptions, including the INT*n* and IRET instructions. These are discussed in Chapter 8, "Exceptions and Interrupts."
- Task switches initiated by CALL and JMP instructions. Task switches are discussed in Chapter 12, "Task Management." *The hardware task-switch mechanism is not supported in long mode.*

4.11.1 Direct Control Transfers

A *direct control transfer* occurs when software executes a far-CALL or a far-JMP instruction without using a call gate. The privilege checks and type of access allowed as a result of a direct control transfer depends on whether the target code segment is conforming or nonconforming. The code-segment-descriptor conforming (C) bit indicates whether or not the target code-segment is conforming (see "Conforming (C) Bit" on page 91 for more information on the conforming bit).

Privilege levels are not changed as a result of a direct control transfer. Program stacks are not automatically switched by the processor as they are with privilege-changing control transfers through call gates (see "Stack Switching" on page 117 for more information on automatic stack switching during privilege-changing control transfers).

Nonconforming Code Segments. Software can perform a direct control transfer to a nonconforming code segment only if the target code-segment descriptor DPL and the CPL are equal and the RPL is less than or equal to the CPL. Software must use a call gate to transfer control to a

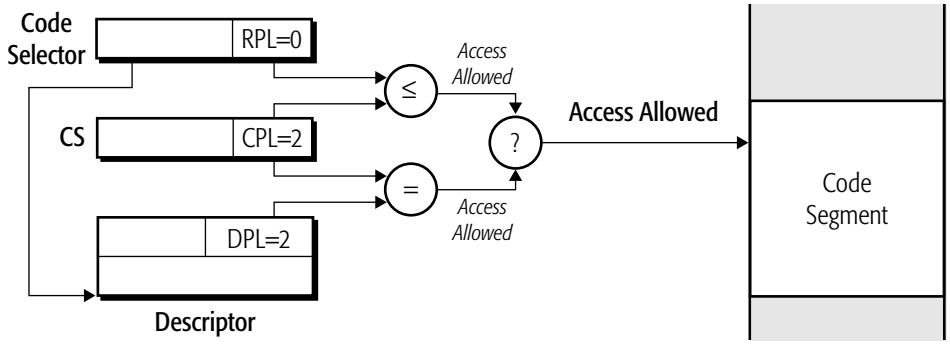
more-privileged, nonconforming code segment (see “Control Transfers Through Call Gates” on page 113 for more information).

In far calls and jumps, the far pointer (CS:rIP) references the target code-segment descriptor. Before loading the CS register with a nonconforming code-segment selector, the processor checks as follows to see if access is allowed:

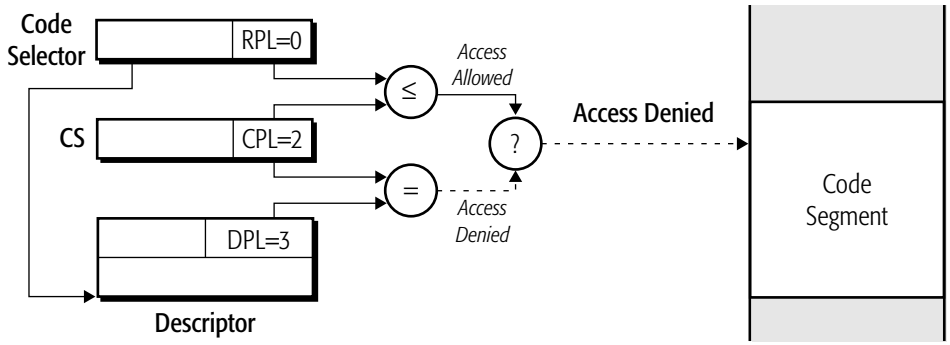
1. *DPL = CPL Check*—The processor compares the target code-segment descriptor DPL with the currently executing program CPL. If they are equal, the processor performs the next check. If they are not equal, a general-protection exception (#GP) occurs.
2. *RPL ≤ CPL Check*—The processor compares the target code-segment selector RPL with the currently executing program CPL. If the RPL is less than or equal to the CPL, access is allowed. If the RPL is greater than the CPL, a #GP exception occurs.

If access is allowed, the processor loads the CS and rIP registers with their new values and begins executing from the target location. The CPL is *not changed*—the target-CS selector RPL value is disregarded when the selector is loaded into the CS register.

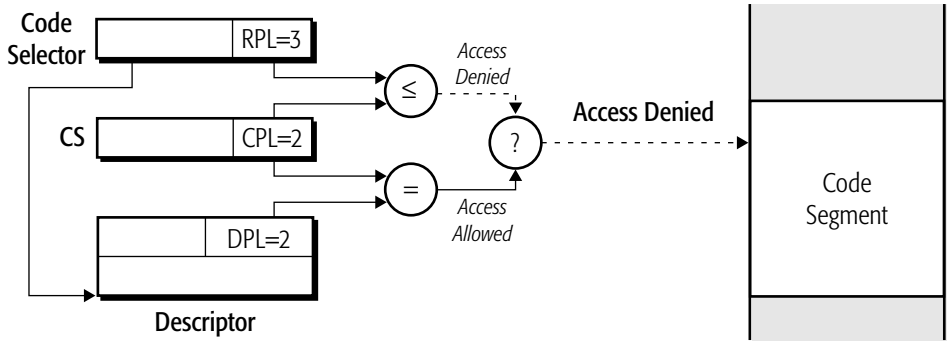
Figure 4-28 on page 111 shows three examples of privilege checks performed as a result of a far control transfer to a nonconforming code-segment. In Example 1, access is allowed because CPL = DPL and RPL ≤ CPL. In Example 2, access is denied because CPL ≠ DPL. In Example 3, access is denied because RPL > CPL.



Example 1: Privilege Check Passes



Example 2: Privilege Check Fails



Example 3: Privilege Check Fails

Figure 4-28. Nonconforming Code-Segment Privilege-Check Examples

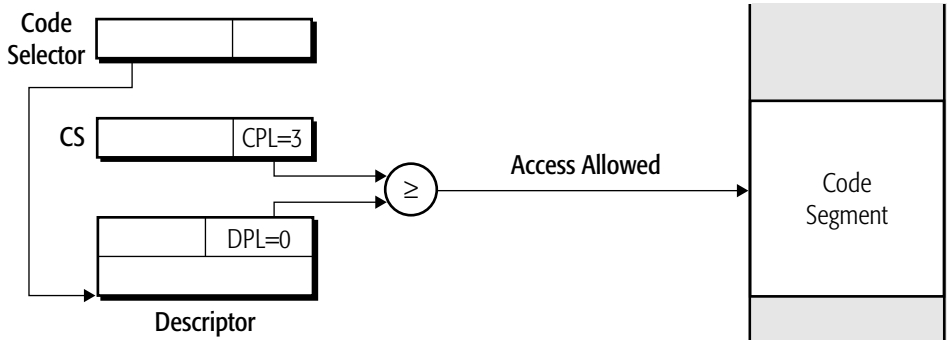
Conforming Code Segments. On a direct control transfer to a conforming code segment, the target code-segment descriptor DPL can be lower than (at a greater privilege) the CPL. Before loading the

CS register with a conforming code-segment selector, the processor compares the target code-segment descriptor DPL with the currently-executing program CPL. If the DPL is less than or equal to the CPL, access is allowed. If the DPL is greater than the CPL, a #GP exception occurs.

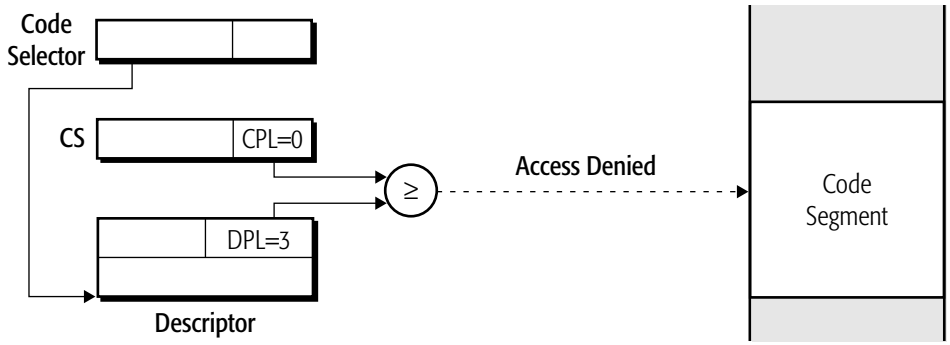
On an access to a conforming code segment, the RPL is ignored and not involved in the privilege check.

When access is allowed, the processor loads the CS and rIP registers with their new values and begins executing from the target location. The CPL is *not changed*—the target CS-descriptor DPL value is disregarded when the selector is loaded into the CS register. The target program runs at the same privilege as the program that called it.

Figure 4-29 shows two examples of privilege checks performed as a result of a direct control transfer to a conforming code segment. In Example 1, access is allowed because the CPL of 3 is greater than the DPL of 0. As the target code selector is loaded into the CS register, the old CPL value of 3 replaces the target-code selector RPL value, and the target program executes with CPL=3. In Example 2, access is denied because CPL < DPL.



Example 1: Privilege Check Passes



Example 2: Privilege Check Fails

Figure 4-29. Conforming Code-Segment Privilege-Check Examples

4.11.2 Control Transfers Through Call Gates

Control transfers to more-privileged code segments are accomplished through the use of *call gates*. Call gates are a type of descriptor that contain pointers to code-segment descriptors and control access to those descriptors. System software uses call gates to establish protected entry points into system-service routines.

Transfer Mechanism. The pointer operand of a far-CALL or far-JMP instruction consists of two pieces: a code-segment selector (CS) and a code-segment offset (rIP). In a call-gate transfer, the CS selector points to a call-gate descriptor rather than a code-segment descriptor, and the rIP is ignored (but required by the instruction).

Figure 4-30 shows a call-gate control transfer in legacy mode. The call-gate descriptor contains segment-selector and segment-offset fields (see “Gate Descriptors” on page 95 for a detailed description of the call-gate format and fields). These two fields perform the same function as the pointer operand in a direct control-transfer instruction. The segment-selector field points to the target code-segment descriptor, and the segment-offset field is the instruction-pointer offset into the target code-segment. The code-segment base taken from the code-segment descriptor is added to the offset field in the call-gate descriptor to create the target virtual address (linear address).

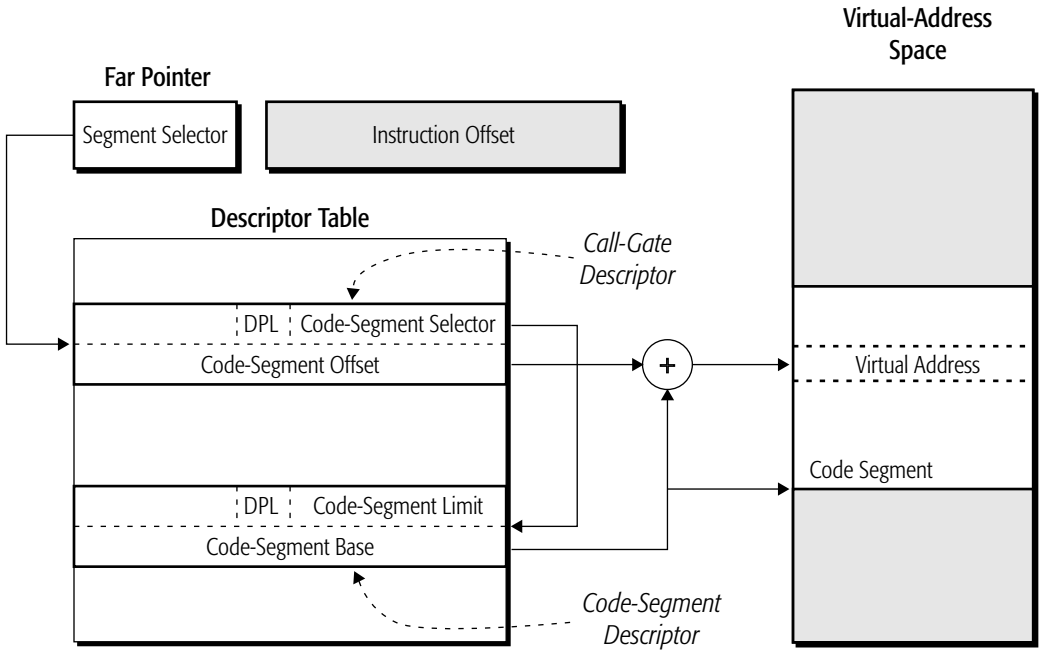


Figure 4-30. Legacy-Mode Call-Gate Transfer Mechanism

Figure 4-31 shows a call-gate control transfer in long mode. The long-mode call-gate descriptor format is expanded by 64 bits to hold a full 64-bit offset into the virtual-address space. Only long-mode call gates can be referenced in long mode (64-bit mode and compatibility mode). The legacy-mode 32-bit call-gate types are redefined in long mode as 64-bit types, and 16-bit call-gate types are illegal.

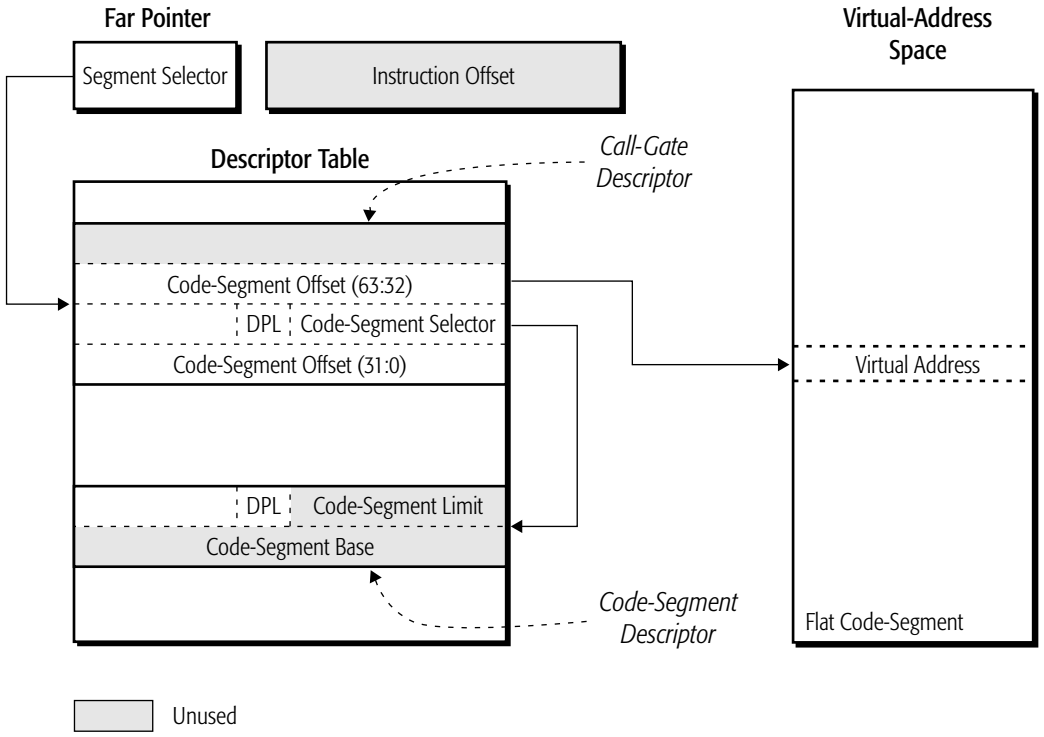

Figure 4-31. Long-Mode Call-Gate Access Mechanism

A long-mode call gate must reference a 64-bit code-segment descriptor. In 64-bit mode, the code-segment descriptor base-address and limit fields are ignored. The target virtual-address is the 64-bit offset field in the expanded call-gate descriptor.

Privilege Checks. Before loading the CS register with the code-segment selector located in the call gate, the processor performs three privilege checks. The following checks are performed when either conforming or nonconforming code segments are referenced:

1. The processor compares the CPL with the call-gate DPL from the call-gate descriptor (DPL_G). The CPL must be numerically *less than or equal to* DPL_G for this check to pass. In other words, the following expression must be true: $CPL \leq DPL_G$.

2. The processor compares the RPL in the call-gate selector with DPL_G. The RPL must be numerically *less than or equal to* DPL_G for this check to pass. In other words, the following expression must be true: $RPL \leq DPL_G$.
3. The processor compares the CPL with the target code-segment DPL from the code-segment descriptor (DPL_S). The type of comparison varies depending on the type of control transfer.
   - When a call—or a jump to a *conforming* code segment—is used to transfer control through a call gate, the CPL must be numerically *greater than or equal to* DPL_S for this check to pass. (This check prevents control transfers to less-privileged programs.) In other words, the following expression must be true: CPL DPL_S.
   - When a JMP instruction is used to transfer control through a call gate to a *nonconforming* code segment, the CPL must be numerically *equal to* DPL_S for this check to pass. (JMP instructions cannot change CPL.) In other words, the following expression must be true: $CPL = DPL_S$.

Figure 4-32 on page 116 shows two examples of call-gate privilege checks. In Example 1, all privilege checks pass as follows:

- The call-gate DPL (DPL_G) is at the lowest privilege (3), specifying that software running at any privilege level (CPL) can access the gate.
- The selector referencing the call gate passes its privilege check because the RPL is numerically less than or equal to DPL_G.
- The target code segment is at the highest privilege level ($DPL_S = 0$). This means software running at any privilege level can access the target code segment through the call gate.

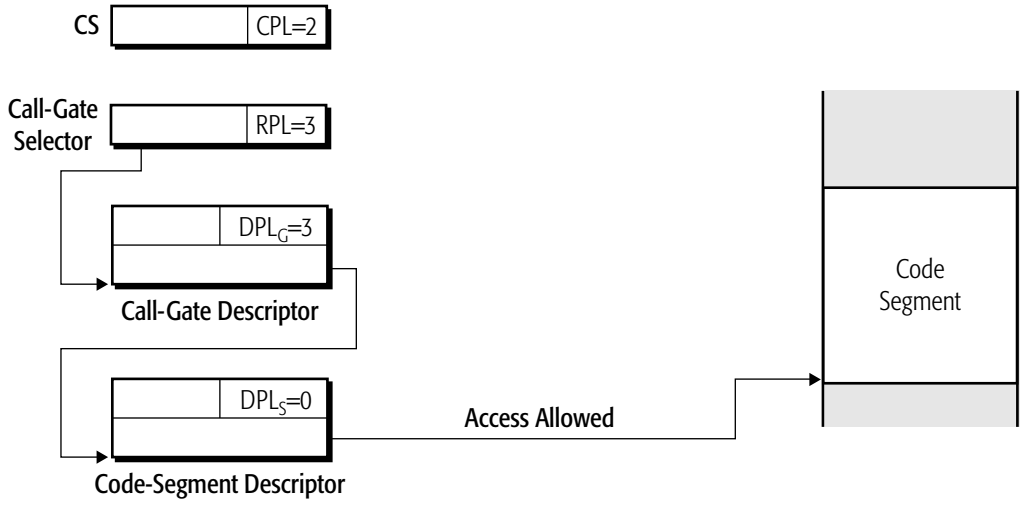

Figure 4-32. Privilege-Check Examples for Call Gates

In Example 2, all privilege checks fail as follows:

- The call-gate DPL (DPL_G) specifies that only software at privilege-level 0 can access the gate. The current program does not have enough privilege to access the call gate because its CPL is 2.
- The selector referencing the call-gate descriptor does not have enough privilege to complete the reference. Its RPL is numerically greater than DPL_G.

- The target code segment is at a lower privilege (DPL_S = 3) than the currently running software (CPL = 2). Transitions from more-privileged software to less-privileged software are not allowed, so this privilege check fails as well.

Although all three privilege checks failed in Example 2, failing only one check is sufficient to deny access into the target code segment.

Stack Switching. The processor performs an automatic stack switch when a control transfer causes a change in privilege levels to occur. Switching stacks isolates more-privileged software stacks from less-privileged software stacks and provides a mechanism for saving the return pointer back to the program that initiated the call.

When switching to more-privileged software, as is done when transferring control using a call gate, the processor uses the corresponding stack pointer (privilege-level 0, 1, or 2) stored in the task-state segment (TSS). The format of the stack pointer stored in the TSS depends on the system-software operating mode:

- Legacy-mode system software stores a 32-bit ESP value (stack offset) and 16-bit SS selector register value in the TSS for each of three privilege levels 0, 1, and 2.
- Long-mode system software stores a 64-bit RSP value in the TSS for privilege levels 0, 1, and 2. No SS register value is stored in the TSS because in long mode a call gate *must* reference a 64-bit code-segment descriptor. 64-bit mode does not use segmentation, and the stack pointer consists solely of the 64-bit RSP. Any value loaded in the SS register is ignored.

See “Task-Management Resources” on page 362 for more information on the legacy-mode and long-mode TSS formats.

Figure 4-33 on page 118 shows a 32-bit stack in legacy mode before and after the automatic stack switch. This particular example assumes that parameters are passed from the current program to the target program. The process followed by legacy mode in switching stacks and copying parameters is:

1. The target code-segment DPL is read by the processor and used as an index into the TSS for selecting the new stack pointer (SS:ESP). For example, if DPL=1 the processor selects the SS:ESP for privilege-level 1 from the TSS.
2. The SS and ESP registers are loaded with the new SS:ESP values read from the TSS.
3. The old values of the SS and ESP registers are pushed onto the stack pointed to by the new SS:ESP.
4. The 5-bit count field is read from the call-gate descriptor.
5. The number of parameters specified in the count field (up to 31) are copied from the old stack to the new stack. The size of the parameters copied by the processor depends on the call-gate size: 32-bit call gates copy 4-byte parameters and 16-bit call gates copy 2-byte parameters.
6. The return pointer is pushed onto the stack. The return pointer consists of the current CS-register value and the EIP of the instruction following the calling instruction.

7. The CS register is loaded from the segment-selector field in the call-gate descriptor, and the EIP is loaded from the offset field in the call-gate descriptor.
8. The target program begins executing with the instruction referenced by new CS:EIP.

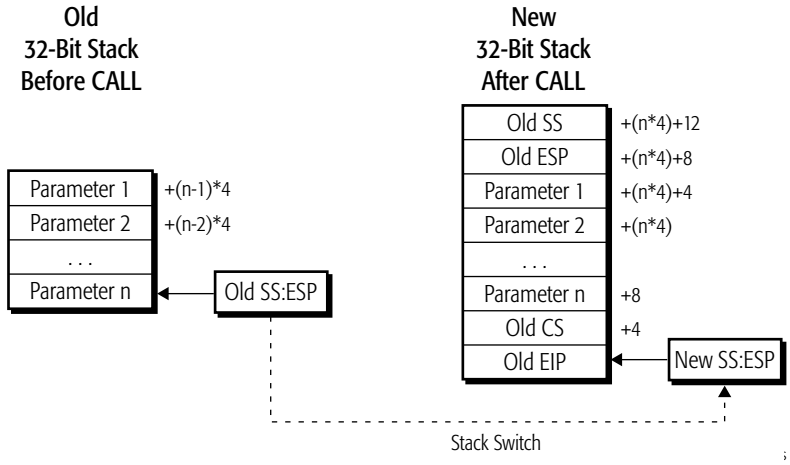

Figure 4-33. Legacy-Mode 32-Bit Stack Switch, with Parameters

Figure 4-34 shows a 32-bit stack in legacy mode before and after the automatic stack switch when no parameters are passed (count=0). Most software does not use the call-gate descriptor count-field to pass parameters. System software typically defines linkage mechanisms that do not rely on automatic parameter copying.

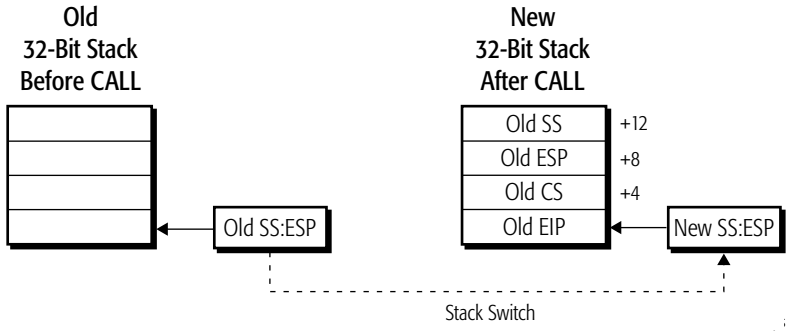

Figure 4-34. 32-Bit Stack Switch, No Parameters—Legacy Mode

Figure 4-35 on page 119 shows a long-mode stack switch. In long mode, all call gates *must* reference 64-bit code-segment descriptors, so a long-mode stack switch uses a 64-bit stack. The process of

switching stacks in long mode is similar to switching in legacy mode when no parameters are passed. The process is as follows:

1. The target code-segment DPL is read by the processor and used as an index into the 64-bit TSS for selecting the new stack pointer (RSP).
2. The RSP register is loaded with the new RSP value read from the TSS. The SS register is loaded with a null selector (SS=0). Setting the new SS selector to null allows proper handling of nested control transfers in 64-bit mode. See “Nested Returns to 64-Bit Mode Procedures” on page 121 for additional information.

   As in legacy mode, it is desirable to keep the stack-segment requestor privilege-level (SS.RPL) equal to the current privilege-level (CPL). When using a call gate to change privilege levels, the SS.RPL is updated to reflect the new CPL. The SS.RPL is restored from the return-target CS.RPL on the subsequent privilege-level-changing far return.
3. The old values of the SS and RSP registers are pushed onto the stack pointed to by the new RSP. The old SS value is popped on a subsequent far return. This allows system software to set up the SS selector for a compatibility-mode process by executing a RET (or IRET) that changes the privilege level.
4. The return pointer is pushed onto the stack. The return pointer consists of the current CS-register value and the RIP of the instruction following the calling instruction.
5. The CS register is loaded from the segment-selector field in the long-mode call-gate descriptor, and the RIP is loaded from the offset field in the long-mode call-gate descriptor.

The target program begins execution with the instruction referenced by the new RIP.

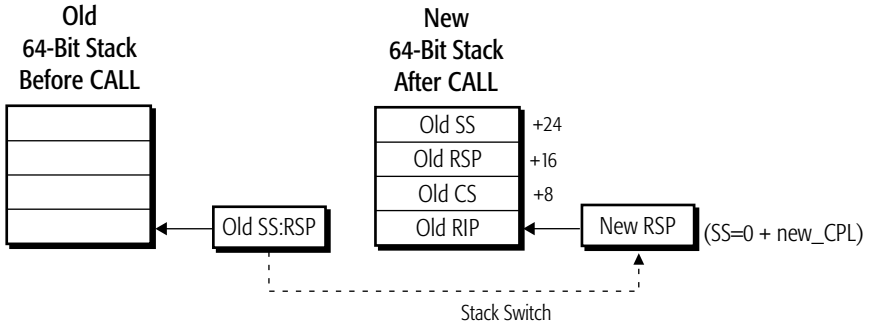

Figure 4-35. Stack Switch—Long Mode

All long-mode stack pushes resulting from a privilege-level-changing far call are eight-bytes wide and increment the RSP by eight. Long mode ignores the call-gate count field and does not support the automatic parameter-copy feature found in legacy mode. Software can access parameters on the old stack, if necessary, by referencing the old stack segment selector and stack pointer saved on the new process stack.

4.11.3 Return Control Transfers

Returns to calling programs can be performed by using the RET instruction. The following types of returns are possible:

- *Near Return*—Near returns perform control transfers within the same code segment, so the CS register is unchanged. The new offset is popped off the stack and into the rIP register. No privilege checks are performed.
- *Far Return, Same Privilege*—A far return transfers control from one code segment to another. When the original code segment is at the same privilege level as the target code segment, a far pointer (CS:rIP) is popped off the stack and the RPL of the new code segment (CS) is checked. If the requested privilege level (RPL) matches the current privilege level (CPL), then a return is made to the same privilege level. This prevents software from changing the CS value on the stack in an attempt to return to higher-privilege software.
- *Far Return, Less Privilege*—Far returns can change privilege levels, but only to a *lower*-privilege level. In this case a stack switch is performed between the current, higher-privilege program and the lower-privilege return program. The CS-register and rIP-register values are popped off the stack. The lower-privilege stack pointer is also popped off the stack and into the SS register and rSP register. The processor checks both the CS and SS privilege levels to ensure they are equal and at a lesser privilege than the current CS.

  In the case of nested returns to 64-bit mode, a null selector can be popped into the SS register. See “Nested Returns to 64-Bit Mode Procedures” on page 121.

  Far returns also check the privilege levels of the DS, ES, FS and GS selector registers. If any of these segment registers have a selector with a higher privilege than the return program, the segment register is loaded with the null selector.

Stack Switching. The stack switch performed by a far return to a lower-privilege level reverses the stack switch of a call gate to a higher-privilege level, except that parameters are never automatically copied as part of a return. The process followed by a far-return stack switch in long mode and legacy mode is:

1. The return code-segment RPL is read by the processor from the CS value stored on the stack to determine that a lower-privilege control transfer is occurring.
2. The return-program instruction pointer is popped off the current-program (higher privilege) stack and loaded into the CS and rIP registers.
3. The return instruction can include an immediate operand that specifies the number of additional bytes to be popped off of the stack. These bytes may correspond to the parameters pushed onto the stack previously by a call through a call gate containing a non-zero parameter-count field. If the return includes the immediate operand, then the stack pointer is adjusted upward by adding the specified number of bytes to the rSP.
4. The return-program stack pointer is popped off the current-program (higher privilege) stack and loaded into the SS and rSP registers. In the case of nested returns to 64-bit mode, a null selector can be popped into the SS register.

The operand size of a far return determines the size of stack pops when switching stacks. If a far return is used in 64-bit mode to return from a prior call through a long-mode call gate, the far return must use a 64-bit operand size. The 64-bit operand size allows the far return to properly read the stack established previously by the far call.

Nested Returns to 64-Bit Mode Procedures. In long mode, a far call that changes privilege levels causes the SS register to be loaded with a null selector (this is the same action taken by an interrupt in long mode). If the called procedure performs another far call to a higher-privileged procedure, or is interrupted, the null SS selector is pushed onto the stack frame, and another null selector is loaded into the SS register. Using a null selector in this way allows the processor to properly handle returns nested within 64-bit-mode procedures and interrupt handlers.

Normally, a RET that pops a null selector into the SS register causes a general-protection exception (#GP) to occur. However, in long mode, the null selector acts as a flag indicating the existence of nested interrupt handlers or other privileged software in 64-bit mode. Long mode allows RET to pop a null selector into SS from the stack under the following conditions:

- The target mode is 64-bit mode.
- The target CPL is less than 3.

In this case, the processor does not load an SS descriptor, and the null selector is loaded into SS without causing a #GP exception.

4.12 Limit Checks

Except in 64-bit mode, limit checks are performed by all instructions that reference memory. Limit checks detect attempts to access memory outside the current segment boundary, attempts at executing instructions outside the current code segment, and indexing outside the current descriptor table. If an instruction fails a limit check, either (1) a general-protection exception occurs for all other segment-limit violations or (2) a stack-fault exception occurs for stack-segment limit violations.

In 64-bit mode, segment limits are *not checked* during accesses to any segment referenced by the CS, DS, ES, FS, GS, and SS selector registers. Instead, the processor checks that the virtual addresses used to reference memory are in canonical-address form. In 64-bit mode, as with legacy mode and compatibility mode, descriptor-table limits *are checked*.

4.12.1 Determining Limit Violations

To determine segment-limit violations, the processor checks a virtual (linear) address to see if it falls outside the valid range of segment offsets determined by the segment-limit field in the descriptor. If any part of an operand or instruction falls outside the segment-offset range, a limit violation occurs. For example, a doubleword access, two bytes from an upper segment boundary, causes a segment violation because half of the doubleword is outside the segment.

Three bits from the descriptor entry are used to control how the segment-limit field is interpreted: the granularity (G) bit, the default operand-size (D) bit, and for data segments, the expand-down (E) bit. See “Legacy Segment Descriptors” on page 88 for a detailed description of each bit.

For all segments other than expand-down segments, the minimum segment-offset is 0. The maximum segment-offset depends on the value of the G bit:

- If G=0 (byte granularity), the maximum allowable segment-offset is equal to the value of the segment-limit field.
- If G=1 (4096-byte granularity), the segment-limit field is first scaled by 4096 (1000h). Then 4095 (0FFFh) is added to the scaled value to arrive at the maximum allowable segment-offset, as shown in the following equation:

  maximum segment-offset = (limit × 1000h) + 0FFFh

  For example, if the segment-limit field is 0100h, then the maximum allowable segment-offset is

  (0100h × 1000h) + 0FFFh = 10_1FFFh.

In both cases, the maximum segment-size is specified when the descriptor segment-limit field is 0F_FFFFh.

Expand-Down Segments. Expand-down data segments are supported in legacy mode and compatibility mode but not in 64-bit mode. With expand-down data segments, the maximum segment offset depends on the value of the D bit in the data-segment descriptor:

- If D=0 the maximum segment-offset is 0_FFFFh.
- If D=1 the maximum segment-offset is 0_FFFF_FFFFh.

The minimum allowable segment offset in expand-down segments depends on the value of the G bit:

- If G=0 (byte granularity), the minimum allowable segment offset is the segment-limit value plus 1.

  For example, if the segment-limit field is 0100h, then the minimum allowable segment-offset is 0101h.
- If G=1 (4096-byte granularity), the segment-limit value in the descriptor is first scaled by 4096 (1000h), and then 4095 (0FFFh) is added to the scaled value to arrive at a scaled segment-limit value. The minimum allowable segment-offset is this scaled segment-limit value plus 1, as shown in the following equation:

  minimum segment-offset = (limit × 1000) + 0FFFh + 1

  For example, if the segment-limit field is 0100h, then the minimum allowable segment-offset is

  (0100h × 1000h) + 0FFFh + 1 = 10_1000h.

For expand-down segments, the maximum segment size is specified when the segment-limit value is 0.

4.12.2 Data Limit Checks in 64-bit Mode

In 64-bit mode, data reads and writes are not normally checked for segment-limit violations. When EFER.LMSLE = 1, reads and writes in 64-bit mode at CPL > 0, using the DS, ES, FS, or SS segments, have a segment-limit check applied.

This limit-check uses the 32-bit segment-limit to find the maximum allowable address in the top 4GB of the 64-bit virtual (linear) address space.

Table 4-8. Segment Limit Checks in 64-Bit Mode

Memory Address	Effect of Limit Check
Linear Address £ (0FFFFFFFF_00000000h + 32-bit Limit)	Access OK.
Linear Address > (0FFFFFFFF_00000000h + 32-bit Limit)	Exception (#GP or #SS)

This segment-limit check does not apply to accesses through the GS segment, or to code reads. If the DS, ES, FS, or SS segment is null or expand-down, the effect of the limit check is undefined. Data segment limit checking in 64-bit mode is not supported by all processor implementations and has been deprecated. If CPUID Fn8000_0008_EBX[EferLmlseUnsupported](bit 20) = 1, 64-bit mode segment limit checking is not supported and attempting to enable this feature by setting EFER.LMSLE =1 will result in a #GP exception.

4.13 Type Checks

Type checks prevent software from using descriptors in invalid ways. Failing a type check results in an exception. Type checks are performed using five bits from the descriptor entry: the S bit and the 4-bit Type field. Together, these five bits are used to specify the descriptor type (code, data, segment, or gate) and its access characteristics. See “Legacy Segment Descriptors” on page 88 for a detailed description of the S bit and Type-field encodings. Type checks are performed by the processor in compatibility mode as well as legacy mode. Limited type checks are performed in 64-bit mode.

4.13.1 Type Checks in Legacy and Compatibility Modes

The type checks performed in legacy mode and compatibility mode are listed in the following sections.

Descriptor-Table Register Loads. Loads into the LDTR and TR descriptor-table registers are checked for the appropriate system-segment type. The LDTR can only be loaded with an LDT descriptor, and the TR only with a TSS descriptor. The checks are performed during any action that causes these registers to be loaded. This includes execution of the LLDT and LTR instructions and during task switches.

Segment Register Loads. The following restrictions are placed on the segment-descriptor types that can be loaded into the six user segment registers:

- Only code segments can be loaded into the CS register.
- Only writable data segments can be loaded into the SS register.

- Only the following segment types can be loaded into the DS, ES, FS, or GS registers:
  - Read-only or read/write data segments.
  - Readable code segments.

These checks are performed during any action that causes the segment registers to be loaded. This includes execution of the MOV segment-register instructions, control transfers, and task switches.

Control Transfers. Control transfers (branches and interrupts) place additional restrictions on the segment types that can be referenced during the transfer:

- The segment-descriptor type referenced by far CALLs and far JMPs must be one of the following:
  - A code segment
  - A call gate or a task gate
  - An available TSS (only allowed in legacy mode)
  - A task gate (only allowed in legacy mode)
- Only code-segment descriptors can be referenced by call-gate, interrupt-gate, and trap-gate descriptors.
- Only TSS descriptors can be referenced by task-gate descriptors.
- The link field (selector) in the TSS can only point to a TSS descriptor. This is checked during an IRET control transfer to a task.
- The far RET and far IRET instructions can only reference code-segment descriptors.
- The interrupt-descriptor table (IDT), which is referenced during interrupt control transfers, can only contain interrupt gates, trap gates, and task gates.

Segment Access. After a segment descriptor is successfully loaded into one of the segment registers, reads and writes into the segments are restricted in the following ways:

- Writes are not allowed into read-only data-segment types.
- Writes are not allowed into code-segment types (executable segments).
- Reads from code-segment types are not allowed if the readable (R) type bit is cleared to 0.

These checks are generally performed during execution of instructions that access memory.

4.13.2 Long Mode Type Check Differences

Compatibility Mode and 64-Bit Mode. The following type checks differ in long mode (64-bit mode and compatibility mode) as compared to legacy mode:

- *System Segments*—System-segment types are checked, but the following types that are valid in legacy mode are illegal in long mode:
  - 16-bit available TSS.
  - 16-bit busy TSS.

  - Type-field encoding of 00h in the upper half of a system-segment descriptor to indicate an illegal type and prevent access as a legacy descriptor.
- *Gates*—Gate-descriptor types are checked, but the following types that are valid in legacy mode are illegal in long mode:
  - 16-bit call gate.
  - 16-bit interrupt gate.
  - 16-bit trap gate.
  - Task gate.

64-Bit Mode. 64-bit mode disables segmentation, and most of the segment-descriptor fields are ignored. The following list identifies situations where type checks in 64-bit mode differ from those in compatibility mode and legacy mode:

- *Code Segments*—The readable (R) type bit is ignored in 64-bit mode. None of the legacy type-checks that prevent reads from or writes into code segments are performed in 64-bit mode.
- *Data Segments*—Data-segment type attributes are ignored in 64-bit mode. The writable (W) and expand-down (E) type bits are ignored. All data segments are treated as writable.

5 Page Translation and Protection

The x86 page-translation mechanism (or simply *paging mechanism*) enables system software to create separate address spaces for each process or application. These address spaces are known as *virtual-address* spaces. System software uses the paging mechanism to selectively map individual pages of physical memory into the virtual-address space using a set of hierarchical address-translation tables known collectively as *page tables*.

The paging mechanism and the page tables are used to provide each process with its own private region of physical memory for storing its code and data. Processes can be protected from each other by isolating them within the virtual-address space. A process cannot access physical memory that is not mapped into its virtual-address space by system software.

System software can use the paging mechanism to selectively map physical-memory pages into multiple virtual-address spaces. Mapping physical pages in this manner allows them to be shared by multiple processes and applications. The physical pages can be configured by the page tables to allow read-only access. This prevents applications from altering the pages and ensures their integrity for use by all applications.

Shared mapping is typically used to allow access of shared-library routines by multiple applications. A read-only copy of the library routine is mapped to each application virtual-address space, but only a single copy of the library routine is present in physical memory. This capability also allows a copy of the operating-system kernel and various device drivers to reside within the application address space. Applications are provided with efficient access to system services without requiring costly address-space switches.

The system-software portion of the address space necessarily includes system-only data areas that must be protected from accesses by applications. System software uses the page tables to protect this memory by designating the pages as *supervisor* pages. Such pages are only accessible by system software.

When the supervisor mode execution prevention (SMEP) feature is supported and enabled, attempted instruction fetches from user-mode accessible pages while in supervisor-mode triggers a page fault (#PF). This protects the integrity of system software by preventing the execution of instructions at a supervisor privilege level (CPL < 3) when these instructions could have been written or modified by user-mode code.

When the supervisor mode access prevention (SMAP) feature is supported and enabled and RFLAGS.AC=0, some attempted explicit data accesses from user-mode accessible pages while in supervisor-mode trigger a page fault (#PF). This protects the integrity of system software by preventing the use of data at a supervisor privilege level (CPL < 3) that could have been modified by user-mode code. Supervisor software that requires access to data which is marked as user-mode accessible may temporarily suppress SMAP checks by modifying RFLAGS.AC, such as with the CLAC/STAC instructions.

Finally, system software can use the paging mechanism to map multiple, large virtual-address spaces into a much smaller amount of physical memory. Each application can use the entire 32-bit or 64-bit virtual-address space. System software actively maps the most-frequently-used virtual-memory pages into the available pool of physical-memory pages. The least-frequently-used virtual-memory pages are swapped out to the hard drive. This process is known as *demand-paged virtual memory*.

5.1 Page Translation Overview

The legacy x86 architecture provides support for translating 32-bit virtual addresses into 32-bit physical addresses (larger physical addresses, such as 36-bit or 40-bit addresses, are supported as a special mode). The AMD64 architecture enhances this support to allow translation of 64-bit virtual addresses into 52-bit physical addresses, although processor implementations can support smaller virtual-address and physical-address spaces.

Virtual addresses are translated to physical addresses through hierarchical translation tables created and managed by system software. Each table contains a set of entries that point to the next-lower table in the translation hierarchy. A single table at one level of the hierarchy can have hundreds of entries, each of which points to a unique table at the next-lower hierarchical level. Each lower-level table can in turn have hundreds of entries pointing to tables further down the hierarchy. The lowest-level table in the hierarchy points to the translated physical page.

Figure 5-1 on page 130 shows an overview of the page-translation hierarchy used in long mode. Legacy mode paging uses a subset of this translation hierarchy (the page-map level-4 table does not exist in legacy mode and the PDP table may or may not be used, depending on which paging mode is enabled). As this figure shows, a virtual address is divided into fields, each of which is used as an offset into a translation table. The complete translation chain is made up of all table entries referenced by the virtual-address fields. The lowest-order virtual-address bits are used as the byte offset into the physical page.

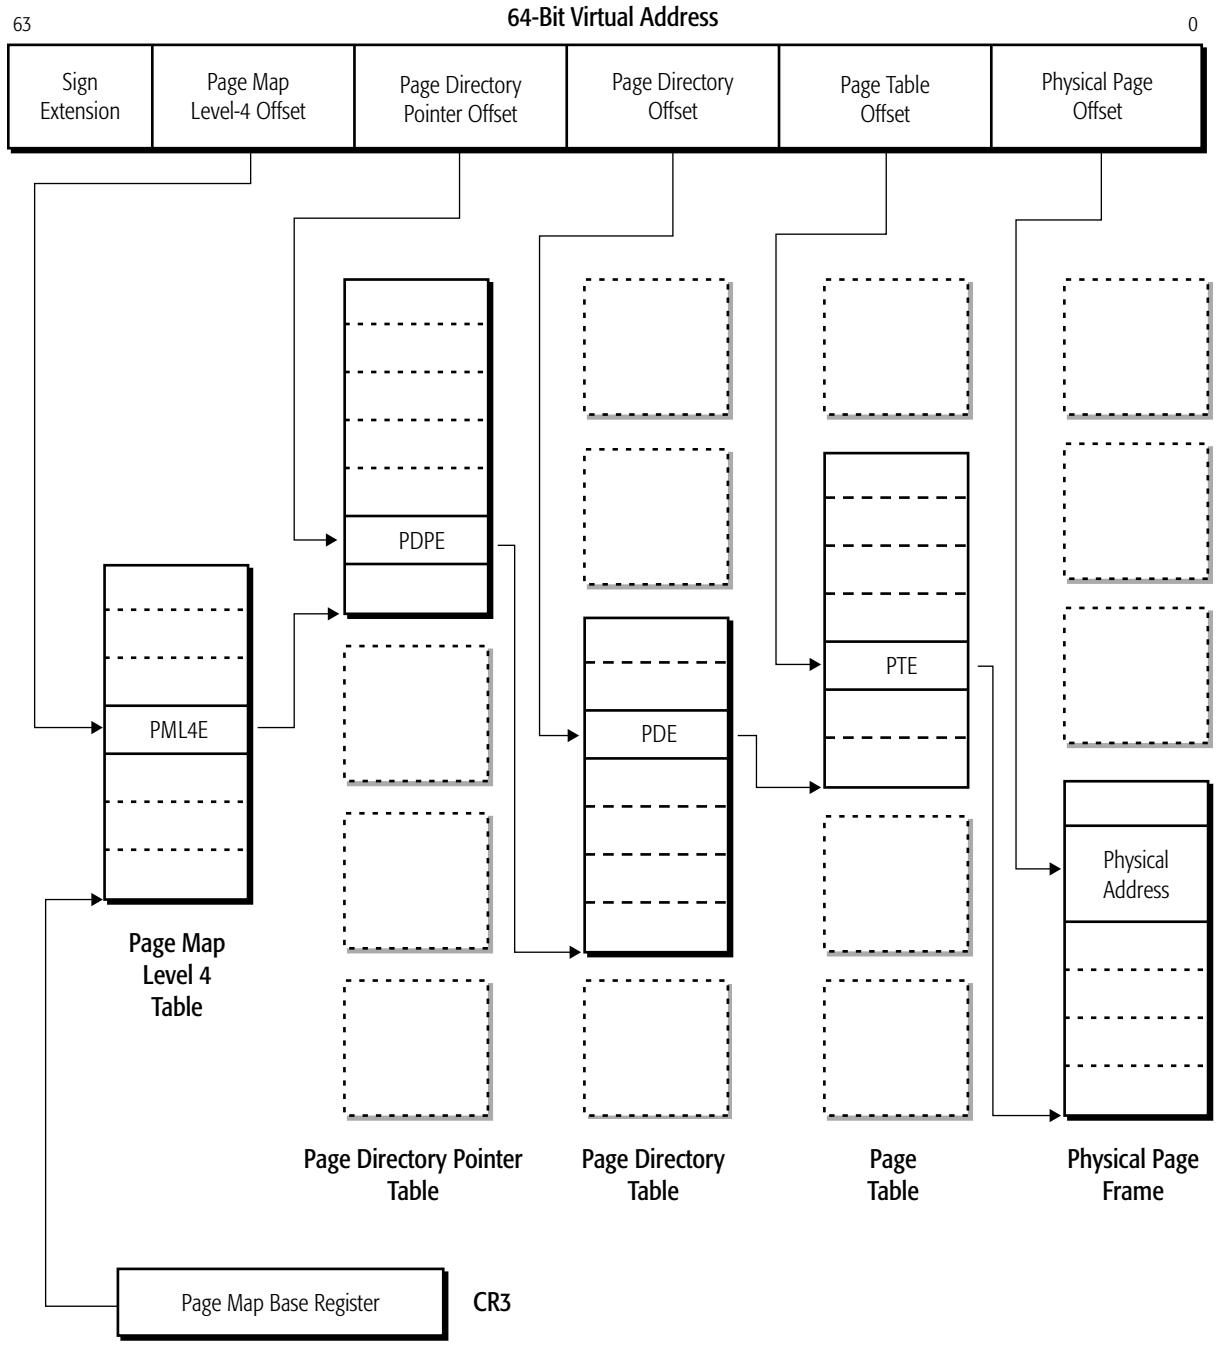

Figure 5-1. Virtual to Physical Address Translation—Long Mode

The following physical-page sizes are supported: 4 Kbytes, 2 Mbytes, 4 Mbytes, and 1 Gbytes. In long mode 4-Kbyte, 2-MByte, and 1-GByte sizes are available. In legacy mode 4-Kbyte, 2-MByte, and 4-MByte sizes are available.

Virtual addresses are 32 bits long, and physical addresses up to the supported physical-address size can be used. The AMD64 architecture enhances the legacy translation support by allowing virtual addresses of up to 64 bits long to be translated into physical addresses of up to 52 bits long.

Currently, the AMD64 architecture defines a mechanism for translating 48-bit virtual addresses to 52-bit physical addresses. The mechanism used to translate a full 64-bit virtual address is reserved and will be described in a future AMD64 architectural specification.

5.1.1 Page-Translation Options

The form of page-translation support available to software depends on which paging features are enabled. Four controls are available for selecting the various paging alternatives:

- Page-Translation Enable (CR0.PG)
- Physical-Address Extensions (CR4.PAE)
- Page-Size Extensions (CR4.PSE)
- Long-Mode Active (EFER.LMA)

Not all paging alternatives are available in all modes. Table 5-1 summarizes the paging support available in each mode.

Table 5-1. Supported Paging Alternatives (CR0.PG=1)

Mode	Physical-Address Extensions (CR4.PAE)	Page-Size Extensions (CR4.PSE)	Page-Directory Pointer Offset	Page-Directory Page Size	Resulting Physical-Page Size	Maximum Virtual Address	Maximum Physical Address
Long Mode (64-bit and compatability modes)	Enabled	–	PDPE.PS=0	PDE.PS=0	4 Kbyte	64-bit	52-bit
				PDE.PS=1	2 Mbyte		
			PDPE.PS=1	–	1 Gbyte		
Legacy Mode	Enabled	–	PDPE.PS=0	PDE.PS=0	4 Kbyte	32-bit	52-bit
				PDE.PS=1	2 Mbyte		52-bit
	Disabled	Disabled		–	4 Kbyte		32-bit
		Enabled		PDE.PS=0	4 Kbyte		32-bit
				PDE.PS=1	4 Mbyte		40-bit

5.1.2 Page-Translation Enable (PG) Bit

Page translation is controlled by the PG bit in CR0 (bit 31). When CR0.PG is set to 1, page translation is enabled. When CR0.PG is cleared to 0, page translation is disabled.

The AMD64 architecture uses CR0.PG to activate and deactivate long mode when long mode is enabled. See “Enabling and Activating Long Mode” on page 474 for more information.

5.1.3 Physical-Address Extensions (PAE) Bit

Physical-address extensions are controlled by the PAE bit in CR4 (bit 5). When CR4.PAE is set to 1, physical-address extensions are enabled. When CR4.PAE is cleared to 0, physical-address extensions are disabled.

Setting CR4.PAE = 1 enables virtual addresses to be translated into physical addresses up to 52 bits long. This is accomplished by doubling the size of paging data-structure entries from 32 bits to 64 bits to accommodate the larger physical base-addresses for physical-pages.

PAE must be enabled before activating long mode. See “Enabling and Activating Long Mode” on page 474.

5.1.4 Page-Size Extensions (PSE) Bit

Page-size extensions are controlled by the PSE bit in CR4 (bit 4). Setting CR4.PSE to 1 allows operating-system software to use 4-Mbyte physical pages in the translation process. The 4-Mbyte physical pages can be mixed with standard 4-Kbyte physical pages or replace them entirely. The selection of physical-page size is made on a page-directory-entry basis. See “Page Size (PS) Bit” on page 152 for more information on physical-page size selection. When CR4.PSE is cleared to 0, page-size extensions are disabled.

The choice of 2 Mbyte or 4 Mbyte as the large physical-page size depends on the value of CR4.PSE and CR4.PAE, as follows:

- If physical-address extensions are enabled (CR4.PAE=1), the large physical-page size is 2 Mbytes, regardless of the value of CR4.PSE.
- If physical-address extensions are disabled (CR4.PAE=0) *and* CR4.PSE=1, the large physical-page size is 4 Mbytes.
- If both CR4.PAE=0 and CR4.PSE=0, the only available page size is 4 Kbytes.

The value of CR4.PSE is ignored when long mode is active. This is because physical-address extensions must be enabled in long mode, and the only available page sizes are 4 Kbytes and 2 Mbytes.

In legacy mode, physical addresses up to 40 bits long can be translated from 32-bit virtual addresses using 32-bit paging data-structure entries when 4-Mbyte physical-page sizes are selected. In this special case, CR4.PSE=1 and CR4.PAE=0. See “4-Mbyte Page Translation” on page 136 for a description of the 4-Mbyte PDE that supports 40-bit physical-address translation. The 40-bit physical-address capability is an AMD64 architecture enhancement over the similar capability available in the legacy x86 architecture.

5.1.5 Page-Directory Page Size (PS) Bit

The page directory offset entry (PDE) and page directory pointer offset entry (PDPE) are data structures used in page translation (see Figure 5-1 on page 130). The page-size (PS) bit in the PDE (bit 7, referred to as PDE.PS) selects between standard 4-Kbyte physical-page sizes and larger (2-Mbyte or 4-Mbyte) physical-page sizes. The page-size (also PS) bit in the PDPE (bit 7, referred to as PDPE.PS) selects between 2-Mbyte and 1-Gbyte physical-page sizes in long mode.

When PDE.PS is set to 1, large physical pages are used, and the PDE becomes the lowest level of the translation hierarchy. The size of the large page is determined by the values of CR4.PAE and CR4.PSE, as shown in Figure 5-1 on page 131. When PDE.PS is cleared to 0, standard 4-Kbyte physical pages are used, and the PTE is the lowest level of the translation hierarchy.

When PDPE.PS is set to 1, 1-Gbyte physical pages are used, and the PDPE becomes the lowest level of the translation hierarchy. Neither the PDE nor PTE are used for 1-Gbyte paging.

5.2 Legacy-Mode Page Translation

Legacy mode supports two forms of translation:

- *Normal* (non-PAE) *Paging*—This is used when physical-address extensions are disabled (CR4.PAE=0). Entries in the page translation table are 32 bits and are used to translate 32-bit virtual addresses into physical addresses as large as 40 bits.
- *PAE Paging*—This is used when physical-address extensions are enabled (CR4.PAE=1). Entries in the page translation table are 64 bits and are used to translate 32-bit virtual addresses into physical addresses as large as 52 bits.

Legacy paging uses up to three levels of page-translation tables, depending on the paging form used and the physical-page size. Entries within each table are selected using virtual-address bit fields. The legacy page-translation tables are:

- *Page Table*—Each page-table entry (PTE) points to a physical page. If 4-Kbyte pages are used, the page table is the lowest level of the page-translation hierarchy. PTEs are not used when translating 2-Mbyte or 4-Mbyte pages.
- *Page Directory*—If 4-Kbyte pages are used, each page-directory entry (PDE) points to a page table. If 2-Mbyte or 4-Mbyte pages are used, a PDE is the lowest level of the page-translation hierarchy and points to a physical page. In non-PAE paging, the page directory is the highest level of the translation hierarchy.
- *Page-Directory Pointer*—Each page-directory pointer entry (PDPE) points to a page directory. Page-directory pointers are only used in PAE paging (CR4.PAE=1), and are the highest level in the legacy page-translation hierarchy.

The translation-table-entry formats and how they are used in the various forms of legacy page translation are described beginning on page 135.

5.2.1 CR3 Register

The CR3 register is used to point to the base address of the highest-level page-translation table. The base address is either the page-directory pointer table or the page directory table. The CR3 register format depends on the form of paging being used. Figure 5-2 on page 134 shows the CR3 format when normal (non-PAE) paging is used (CR4.PAE=0). Figure 5-3 shows the CR3 format when PAE paging is used (CR4.PAE=1).

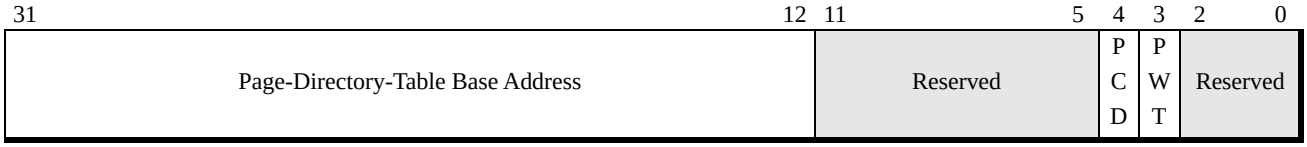

Figure 5-2. Control Register 3 (CR3)—Non-PAE Paging Legacy-Mode

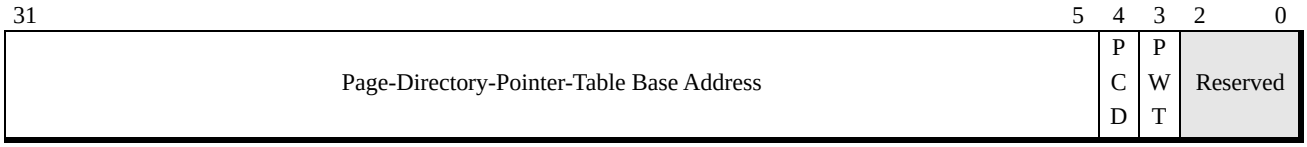

Figure 5-3. Control Register 3 (CR3)—PAE Paging Legacy-Mode

The CR3 register fields for legacy-mode paging are:

Table Base Address Field. This field points to the starting physical address of the highest-level page-translation table. The size of this field depends on the form of paging used:

- *Normal (Non-PAE) Paging (CR4.PAE=0)*—This 20-bit field occupies bits 31:12, and points to the base address of the page-directory table. The page-directory table is aligned on a 4-Kbyte boundary, with the low-order 12 address bits 11:0 assumed to be 0. This yields a total base-address size of 32 bits.
- *PAE Paging (CR4.PAE=1)*—This field is 27 bits and occupies bits 31:5. The CR3 register points to the base address of the page-directory-pointer table. The page-directory-pointer table is aligned on a 32-byte boundary, with the low 5 address bits 4:0 assumed to be 0.

Page-Level Writethrough (PWT) Bit. Bit 3. Page-level writethrough indicates whether the highest-level page-translation table has a writeback or writethrough caching policy. When PWT=0, the table has a writeback caching policy. When PWT=1, the table has a writethrough caching policy.

Page-Level Cache Disable (PCD) Bit. Bit 4. Page-level cache disable indicates whether the highest-level page-translation table is cacheable. When PCD=0, the table is cacheable. When PCD=1, the table is not cacheable.

Reserved Bits. Reserved fields should be cleared to 0 by software when writing CR3.

5.2.2 Normal (Non-PAE) Paging

Non-PAE paging (CR4.PAE=0) supports 4-Kbyte and 4-Mbyte physical pages, as described in the following sections.

4-Kbyte Page Translation. 4-Kbyte physical-page translation is performed by dividing the 32-bit virtual address into three fields. Each of the upper two fields is used as an index into a two-level page-translation hierarchy. The virtual-address fields are used as follows, and are shown in Figure 5-4:

- Bits 31:22 index into the 1024-entry page-directory table.
- Bits 21:12 index into the 1024-entry page table.
- Bits 11:0 provide the byte offset into the physical page.

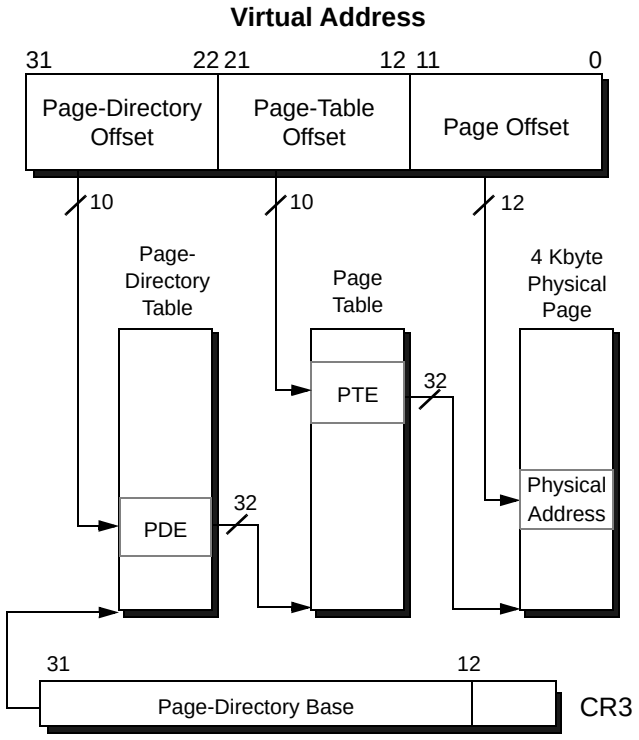

Figure 5-4. 4-Kbyte Non-PAE Page Translation—Legacy Mode

Figure 5-5 on page 136 shows the format of the PDE (page-directory entry), and Figure 5-6 on page 136 shows the format of the PTE (page-table entry). Each table occupies 4 Kbytes and can hold 1024 of the 32-bit table entries. The fields within these table entries are described in "Page-Translation-Table Entry Fields" on page 150.

Figure 5-5 shows bit 7 cleared to 0. This bit is the *page-size* bit (PS), and specifies a 4-Kbyte physical-page translation.

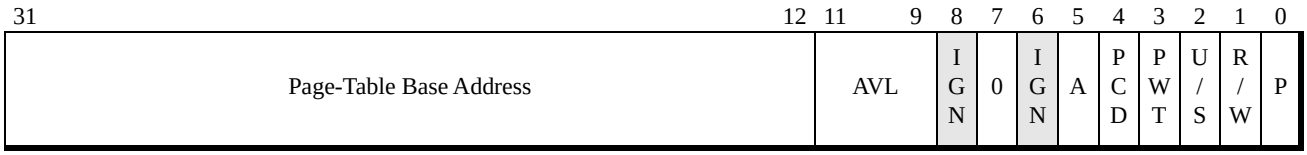

Figure 5-5. 4-Kbyte PDE—Non-PAE Paging Legacy-Mode

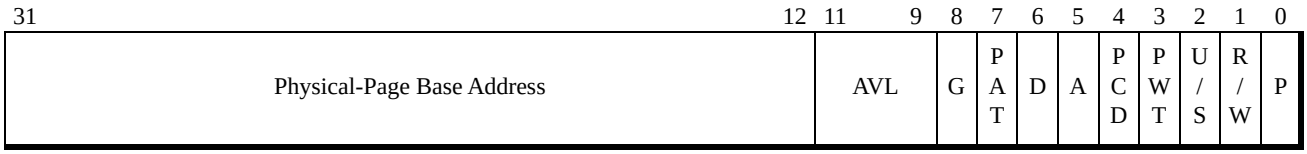

Figure 5-6. 4-Kbyte PTE—Non-PAE Paging Legacy-Mode

4-Mbyte Page Translation. 4-Mbyte page translation is only supported when page-size extensions are enabled (CR4.PSE=1) and physical-address extensions are disabled (CR4.PAE=0).

PSE defines a page-size bit in the 32-bit PDE format (PDE.PS). This bit is used by the processor during page translation to support both 4-Mbyte and 4-Kbyte pages. 4-Mbyte pages are selected when PDE.PS is set to 1, and the PDE points directly to a 4-Mbyte physical page. PTEs are not used in a 4-Mbyte page translation. If PDE.PS is cleared to 0, or if 4-Mbyte page translation is disabled, the PDE points to a PTE.

4-Mbyte page translation is performed by dividing the 32-bit virtual address into two fields. Each field is used as an index into a single-level page-translation hierarchy. The virtual-address fields are used as follows, and are shown in Figure 5-7 on page 137:

- Bits 31:22 index into the 1024-entry page-directory table.
- Bits 21:0 provide the byte offset into the physical page.

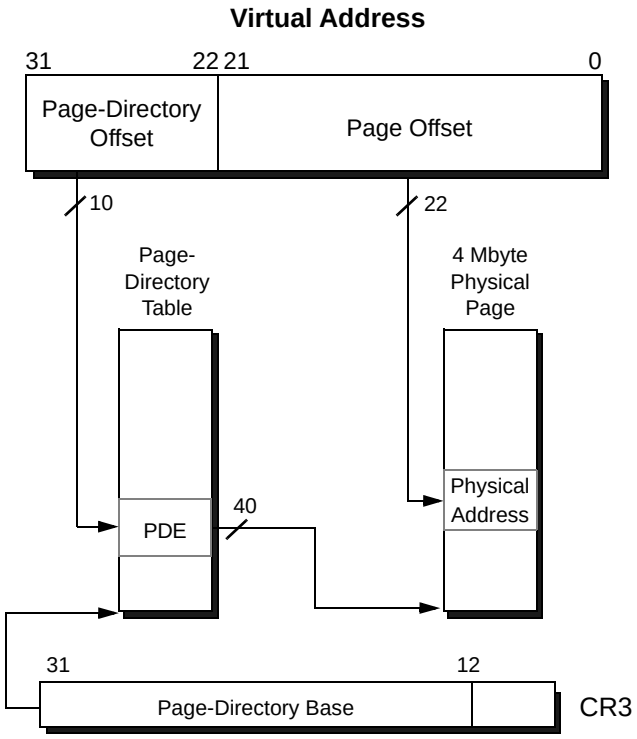

Figure 5-7. 4-Mbyte Page Translation—Non-PAE Paging Legacy-Mode

The AMD64 architecture modifies the legacy 32-bit PDE format in PSE mode to increase physical-address size support to 40 bits. This increase in address size is accomplished by using bits 20:13 to hold eight additional high-order physical-address bits. Bit 21 is reserved and must be cleared to 0.

Figure 5-8 shows the format of the PDE when PSE mode is enabled. The physical-page base-address bits are contained in a split field. The high-order, physical-page base-address bits 39:32 are located in PDE[20:13], and physical-page base-address bits 31:22 are located in PDE[31:22].

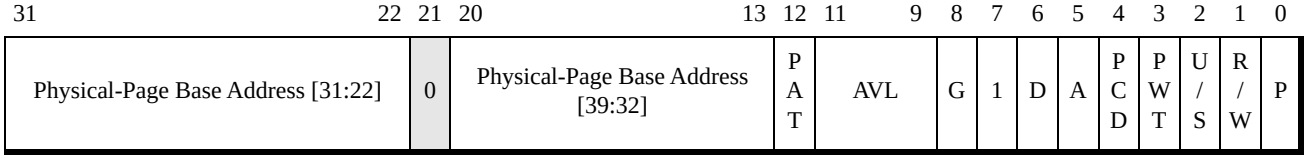

Figure 5-8. 4-Mbyte PDE—Non-PAE Paging Legacy-Mode

5.2.3 PAE Paging

PAE paging is used when physical-address extensions are enabled (CR4.PAE=1). PAE paging doubles the size of page-translation table entries to 64 bits so that the table entries can hold larger physical

addresses (up to 52 bits). The size of each table remains 4 Kbytes, which means each table can hold 512 of the 64-bit entries. PAE paging also introduces a third-level page-translation table, known as the page-directory-pointer table (PDPT).

The size of large pages in PAE-paging mode is 2 Mbytes rather than 4 Mbytes. PAE uses the page-directory page-size bit (PDE.PS) to allow selection between 4-Kbyte and 2-Mbyte page sizes. PAE automatically uses the page-size bit, so the value of CR4.PSE is ignored by PAE paging.

4-Kbyte Page Translation. With PAE paging, 4-Kbyte physical-page translation is performed by dividing the 32-bit virtual address into four fields, each of the upper three fields is used as an index into a 3-level page-translation hierarchy. The virtual-address fields are described as follows and are shown in Figure 5-9:

- Bits 31:30 index into a 4-entry page-directory-pointer table.
- Bits 29:21 index into the 512-entry page-directory table.
- Bits 20:12 index into the 512-entry page table.
- Bits 11:0 provide the byte offset into the physical page.

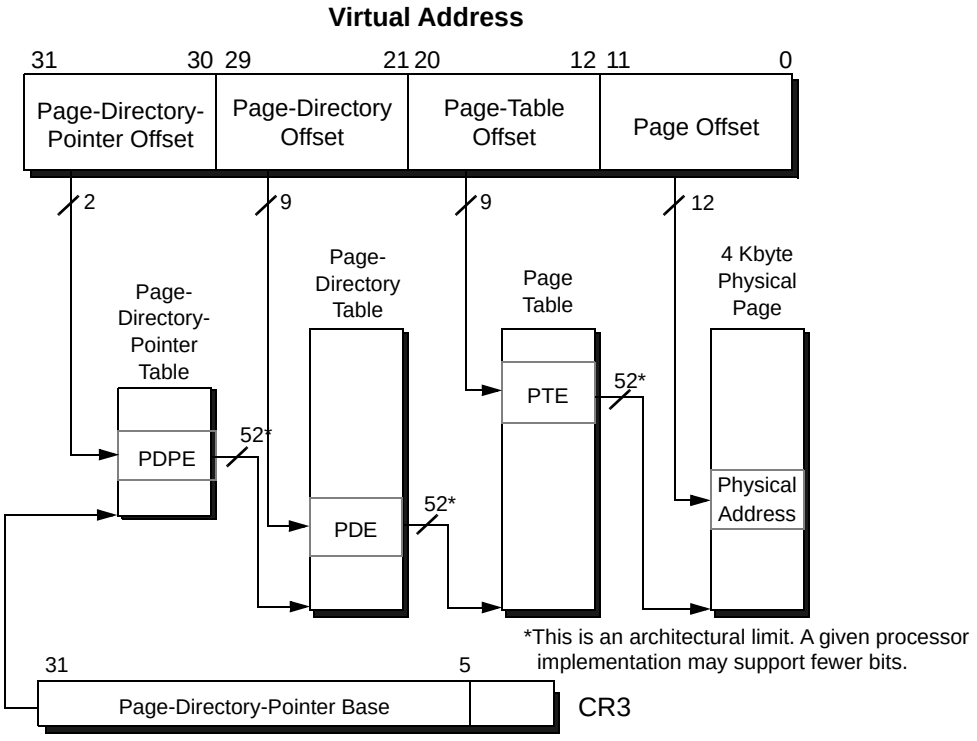

Figure 5-9. 4-Kbyte PAE Page Translation—Legacy Mode

Figures 5-10 through 5-12 show the legacy-mode 4-Kbyte translation-table formats:

- Figure 5-10 shows the PDPE (page-directory-pointer entry) format.
- Figure 5-11 shows the PDE (page-directory entry) format.
- Figure 5-12 shows the PTE (page-table entry) format.

The fields within these table entries are described in “Page-Translation-Table Entry Fields” on page 150.

Figure 5-11 shows the PDE.PS bit cleared to 0 (bit 7), specifying a 4-Kbyte physical-page translation.

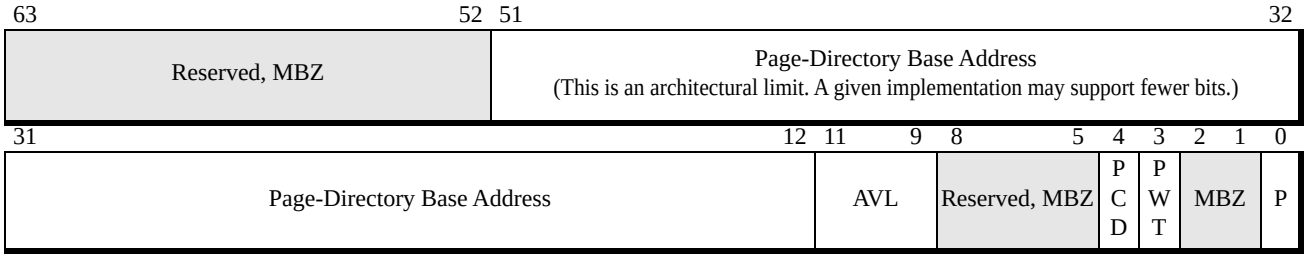

Figure 5-10. 4-Kbyte PDPE—PAE Paging Legacy-Mode

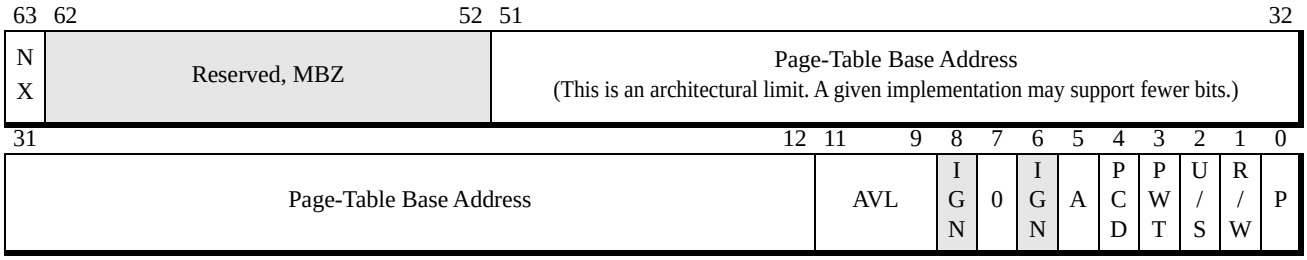

Figure 5-11. 4-Kbyte PDE—PAE Paging Legacy-Mode

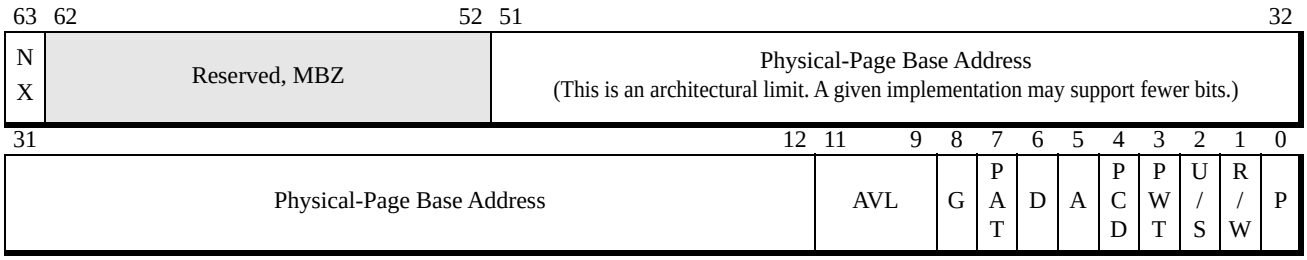

Figure 5-12. 4-Kbyte PTE—PAE Paging Legacy-Mode

2-Mbyte Page Translation. 2-Mbyte page translation is performed by dividing the 32-bit virtual address into three fields. Each field is used as an index into a 2-level page-translation hierarchy. The virtual-address fields are described as follows and are shown in Figure 5-13 on page 140:

- Bits 31:30 index into the 4-entry page-directory-pointer table.

- Bits 29:21 index into the 512-entry page-directory table.
- Bits 20:0 provide the byte offset into the physical page.

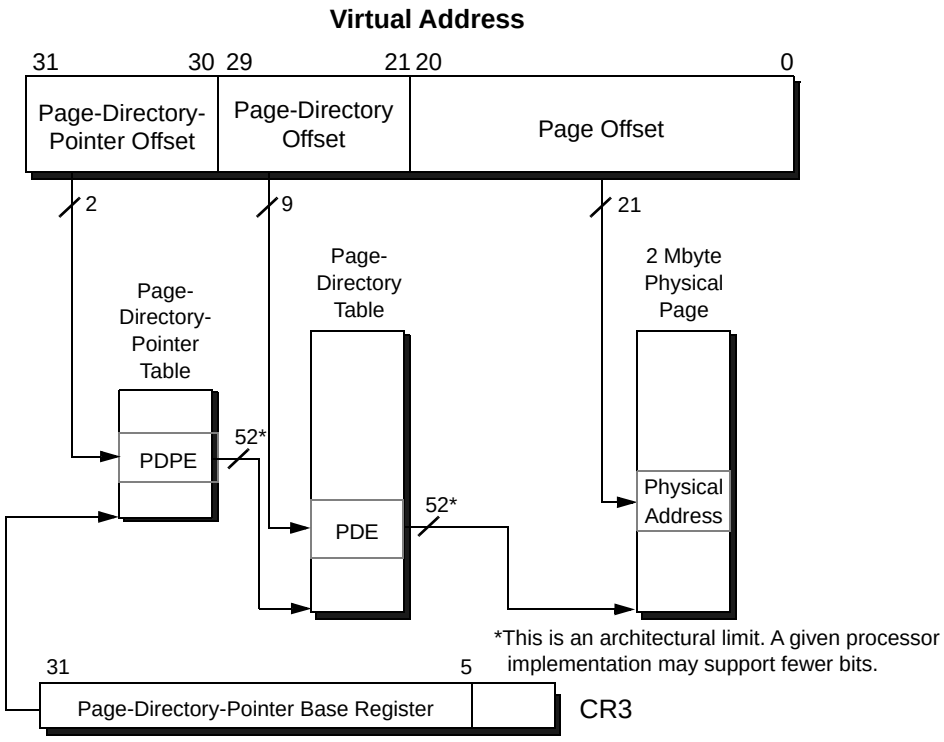

Figure 5-13. 2-Mbyte PAE Page Translation—Legacy Mode

Figure 5-14 shows the format of the PDPE (page-directory-pointer entry) and Figure 5-15 on page 141 shows the format of the PDE (page-directory entry). PTEs are not used in 2-Mbyte page translations.

Figure 5-15 on page 141 shows the PDE.PS bit set to 1 (bit 7), specifying a 2-Mbyte physical-page translation.

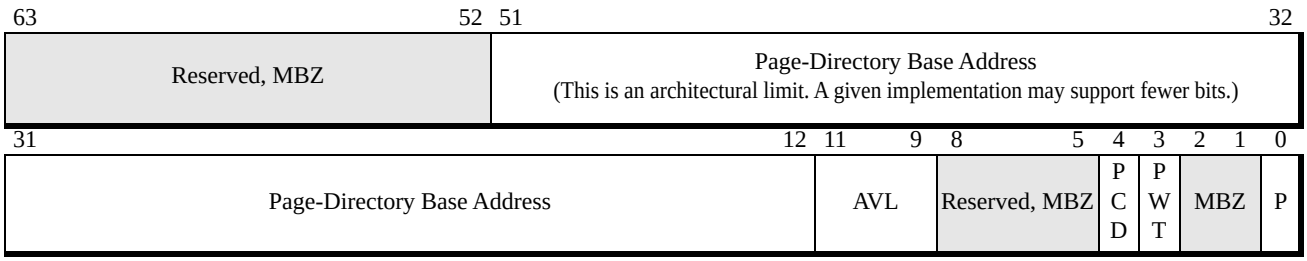

Figure 5-14. 2-Mbyte PDPE—PAE Paging Legacy-Mode

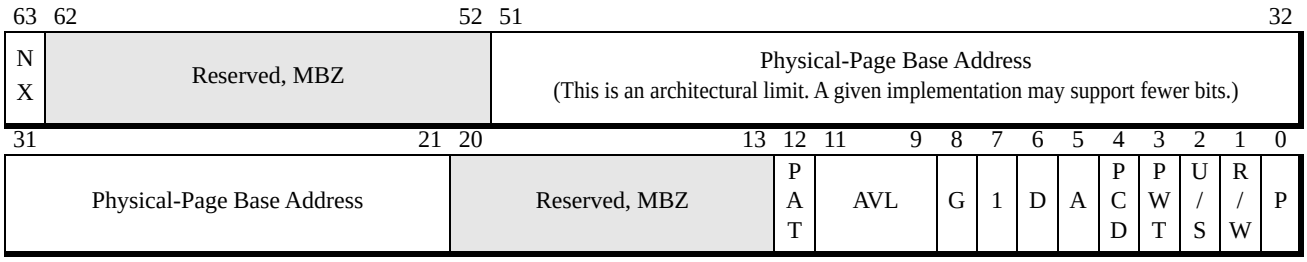

Figure 5-15. 2-Mbyte PDE—PAE Paging Legacy-Mode

5.3 Long-Mode Page Translation

Long-mode page translation requires the use of physical-address extensions (PAE). Before activating long mode, PAE must be enabled by setting CR4.PAE to 1. Activating long mode before enabling PAE causes a general-protection exception (#GP) to occur.

The PAE-paging data structures support mapping of 64-bit virtual addresses into 52-bit physical addresses. PAE expands the size of legacy page-directory entries (PDEs) and page-table entries (PTEs) from 32 bits to 64 bits, allowing physical-address sizes of greater than 32 bits.

The AMD64 architecture enhances the page-directory-pointer entry (PDPE) by defining previously reserved bits for access and protection control. A new translation table is added to PAE paging, called the page-map level-4 (PML4). The PML4 table precedes the PDP table in the page-translation hierarchy.

Because PAE is always enabled in long mode, the PS bit in the page directory entry (PDE.PS) selects between 4-Kbyte and 2-Mbyte page sizes, and the CR4.PSE bit is ignored. When 1-Gbyte pages are supported, the PDPE. PS bit selects the 1-Gbyte page size.

5.3.1 Canonical Address Form

The AMD64 architecture requires implementations supporting fewer than the full 64-bit virtual address to ensure that those addresses are in canonical form. An address is in canonical form if the address bits from the most-significant implemented bit up to bit 63 are all ones or all zeros. If the addresses of all bytes in a virtual-memory reference are not in canonical form, the processor generates a general-protection exception (#GP) or a stack fault (#SS) as appropriate.

5.3.2 CR3

In long mode, the CR3 register is used to point to the PML4 base address. CR3 is expanded to 64 bits in long mode, allowing the PML4 table to be located anywhere in the 52-bit physical-address space. Figure on page 142 shows the long-mode CR3 format.

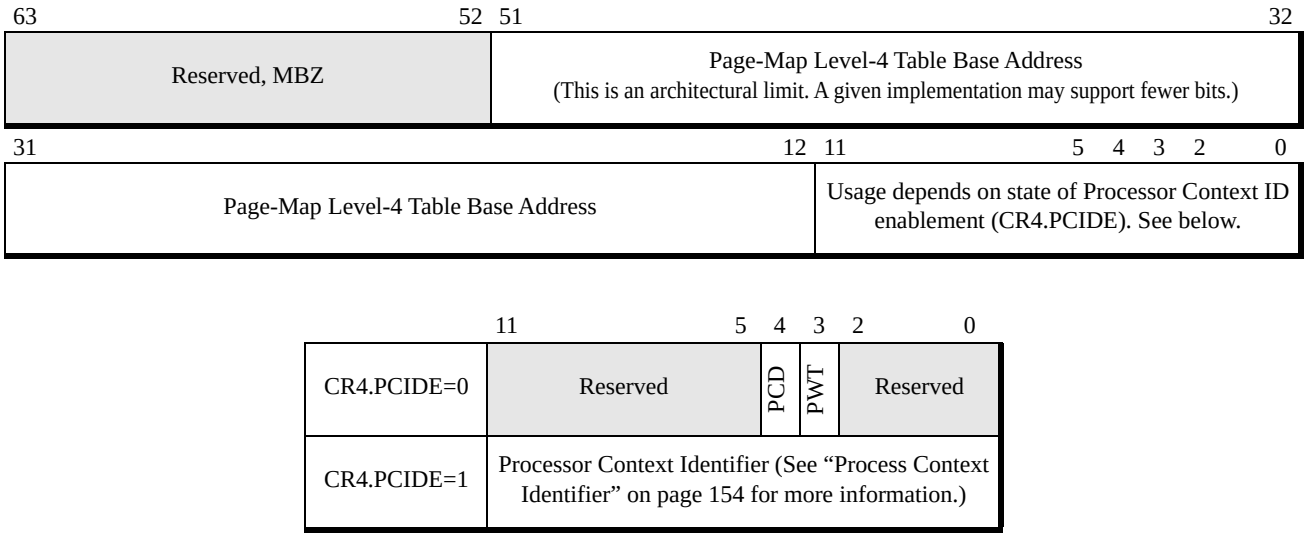

Figure 5-16. Control Register 3 (CR3)—Long Mode

The CR3 register fields for long mode are:

Table Base Address Field. Bits 51:12. This 40-bit field points to the PML4 base address. The PML4 table is aligned on a 4-Kbyte boundary with the low-order 12 address bits (11:0) assumed to be 0. This yields a total base-address size of 52 bits. System software running on processor implementations supporting less than the full 52-bit physical-address space must clear the unimplemented upper base-address bits to 0.

Page-Level Writethrough (PWT) Bit. Bit 3. Page-level writethrough indicates whether the highest-level page-translation table has a writeback or writethrough caching policy. When PWT=0, the table has a writeback caching policy. When PWT=1, the table has a writethrough caching policy.

Page-Level Cache Disable (PCD) Bit. Bit 4. Page-level cache disable indicates whether the highest-level page-translation table is cacheable. When PCD=0, the table is cacheable. When PCD=1, the table is not cacheable.

Process Context Identifier. Bits 11:0. This 12-bit field determines the current Processor Context Identifier (PCID) when CR4.PCIDE=1.

Reserved Bits. Reserved fields should be cleared to 0 by software when writing CR3.

5.3.3 4-Kbyte Page Translation

In long mode, 4-Kbyte physical-page translation is performed by dividing the virtual address into six fields. Four of the fields are used as indices into the level page-translation hierarchy. The virtual-address fields are described as follows, and are shown in Figure 5-17 on page 143:

- Bits 63:48 are a sign extension of bit 47, as required for canonical-address forms.

- Bits 47:39 index into the 512-entry page-map level-4 table.
- Bits 38:30 index into the 512-entry page-directory pointer table.
- Bits 29:21 index into the 512-entry page-directory table.
- Bits 20:12 index into the 512-entry page table.
- Bits 11:0 provide the byte offset into the physical page.

Note: *The sizes of the sign extension and the PML4 fields depend on the number of virtual address bits supported by the implementation.*

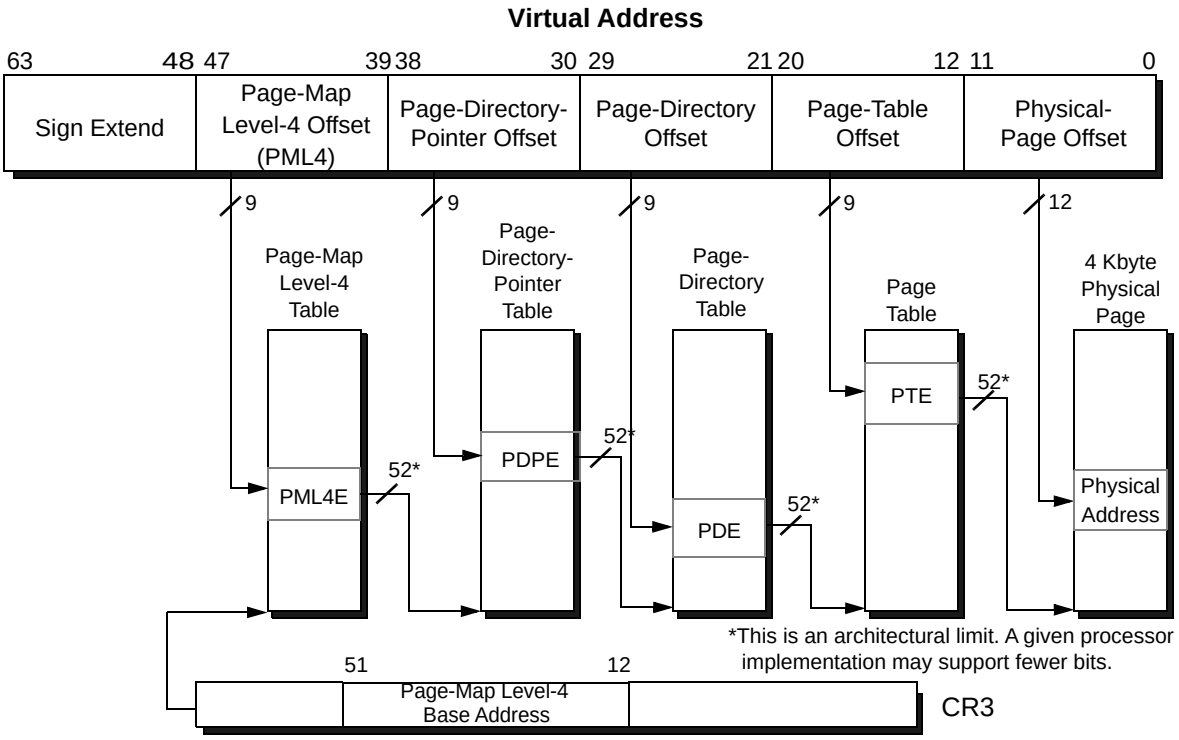

Figure 5-17. 4-Kbyte Page Translation—Long Mode

Figures 5-18 through 5-20 on page 144 and Figure 5-21 on page 145 show the long-mode 4-Kbyte translation-table formats:

- Figure 5-18 on page 144 shows the PML4E (page-map level-4 entry) format.
- Figure 5-19 on page 144 shows the PDPE (page-directory-pointer entry) format.
- Figure 5-20 on page 144 shows the PDE (page-directory entry) format.
- Figure 5-21 on page 145 shows the PTE (page-table entry) format.

The fields within these table entries are described in “Page-Translation-Table Entry Fields” on page 150.

Figure 5-20 on page 144 shows the PDE.PS bit (bit 7) cleared to 0, indicating a 4-Kbyte physical-page translation.

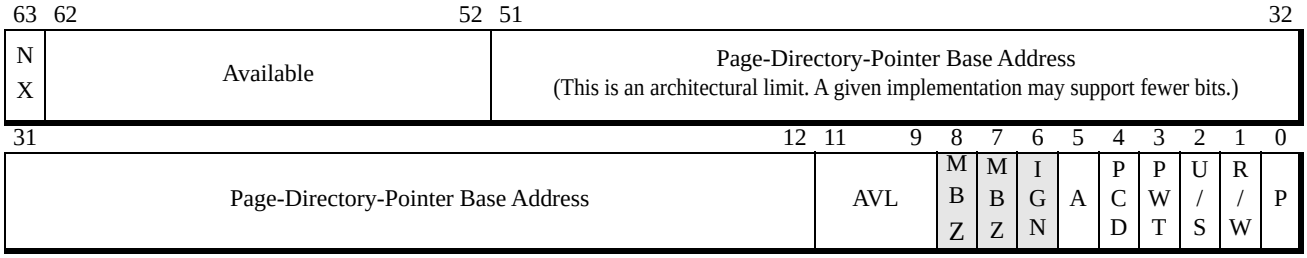

Figure 5-18. 4-Kbyte PML4E—Long Mode

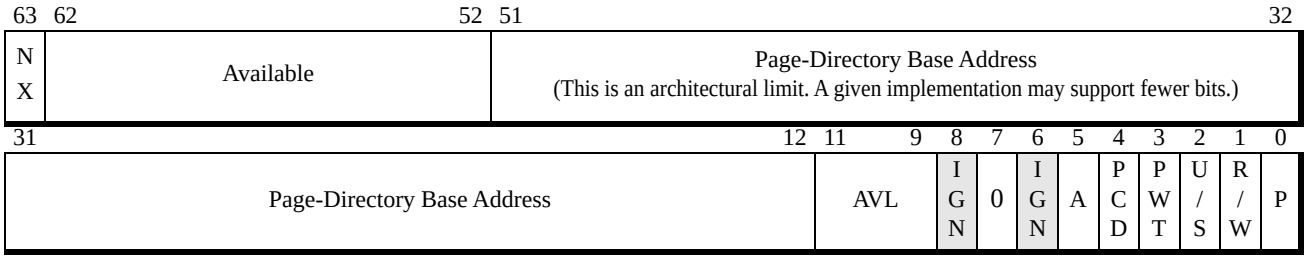

Figure 5-19. 4-Kbyte PDPE—Long Mode

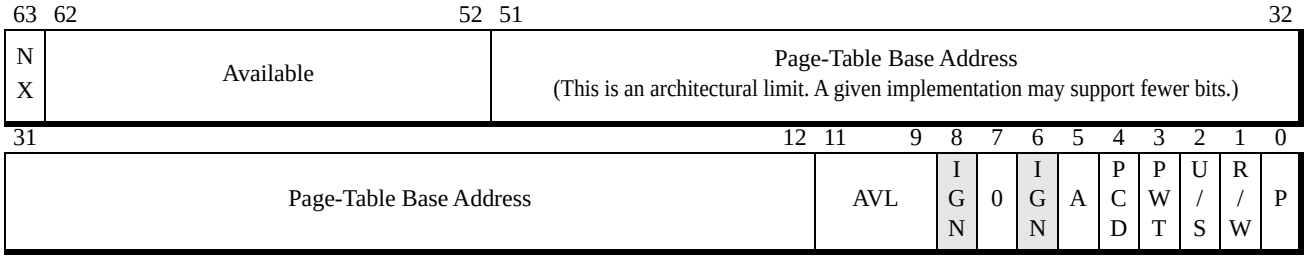

Figure 5-20. 4-Kbyte PDE—Long Mode

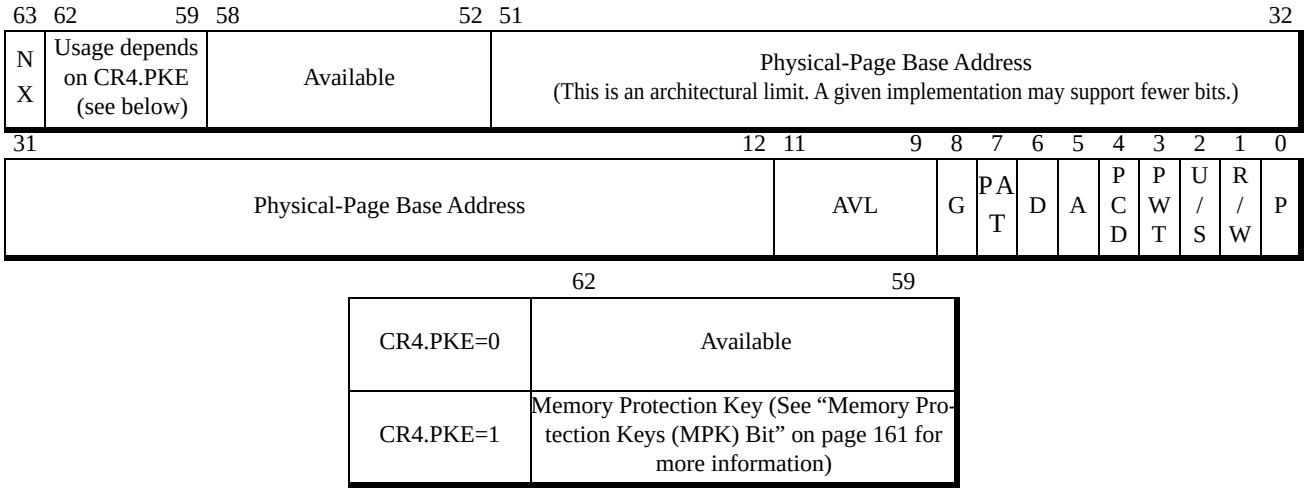

Figure 5-21. 4-Kbyte PTE—Long Mode

5.3.4 2-Mbyte Page Translation

In long mode, 2-Mbyte physical-page translation is performed by dividing the virtual address into five fields. Three of the fields are used as indices into the level page-translation hierarchy. The virtual-address fields are described as follows, and are shown in Figure 5-22:

- Bits 63:48 are a sign extension of bit 47 as required for canonical address forms.
- Bits 47:39 index into the 512-entry page-map level-4 table.
- Bits 38:30 index into the 512-entry page-directory-pointer table.
- Bits 29:21 index into the 512-entry page-directory table.
- Bits 20:0 provide the byte offset into the physical page.

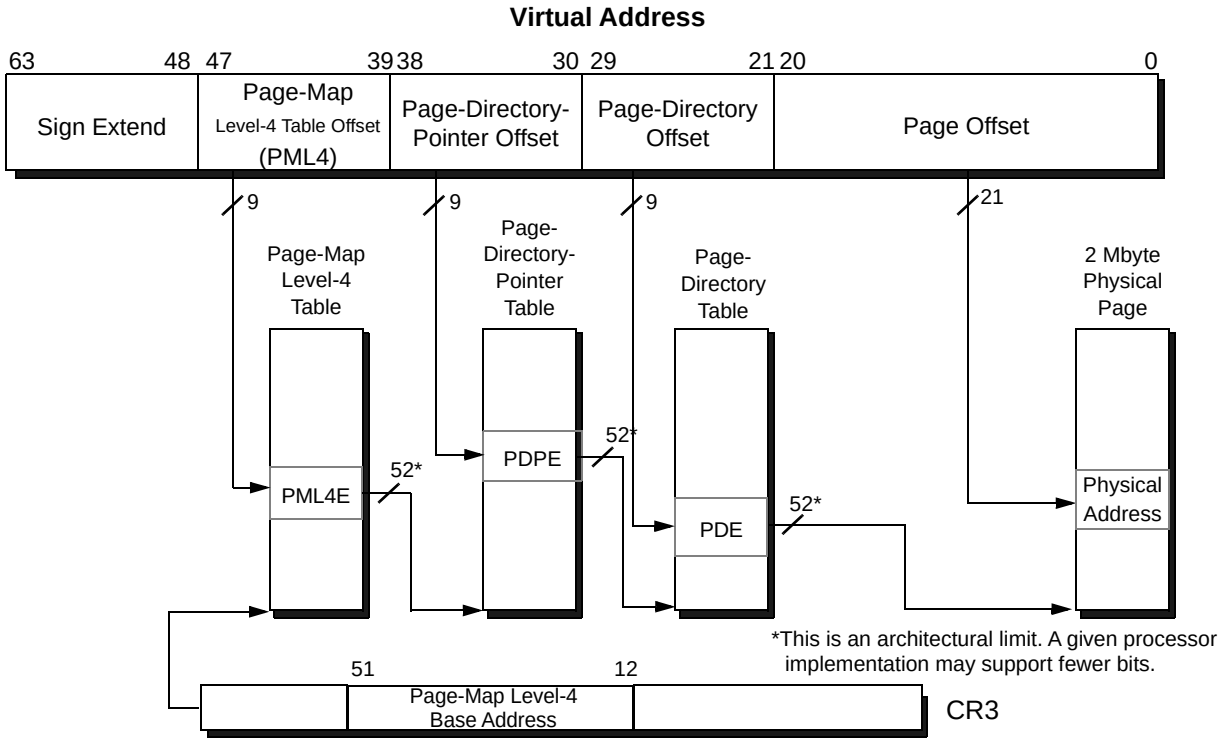

Figure 5-22. 2-Mbyte Page Translation—Long Mode

Figures 5-23 through 5-25 on page 147 show the long-mode 2-Mbyte translation-table formats (the PML4 and PDPT formats are identical to those used for 4-Kbyte page translations and are repeated here for clarity):

- Figure 5-23 on page 147 shows the PML4E (page-map level-4 entry) format.
- Figure 5-24 on page 147 shows the PDPE (page-directory-pointer entry) format.
- Figure 5-25 on page 147 shows the PDE (page-directory entry) format.

The fields within these table entries are described in “Page-Translation-Table Entry Fields” on page 150. PTEs are not used in 2-Mbyte page translations.

Figure 5-25 shows the PDE.PS bit (bit 7) set to 1, indicating a 2-Mbyte physical-page translation.

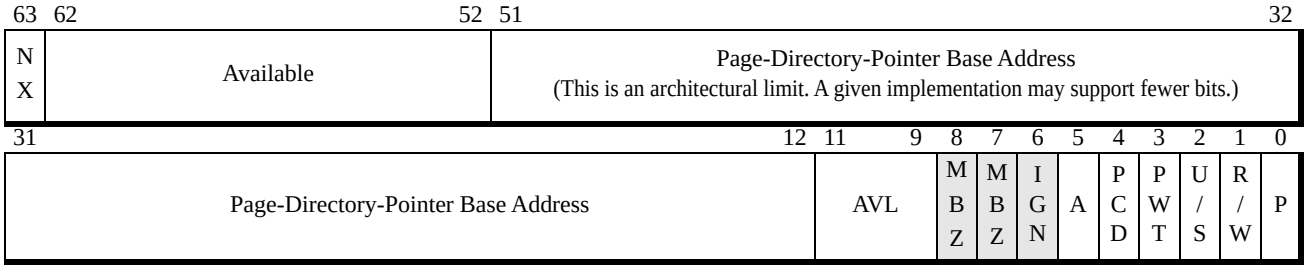

Figure 5-23. 2-Mbyte PML4E—Long Mode

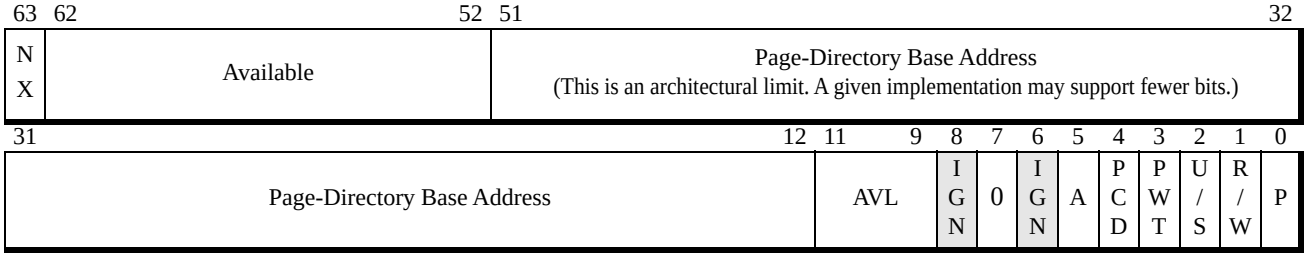

Figure 5-24. 2-Mbyte PDPE—Long Mode

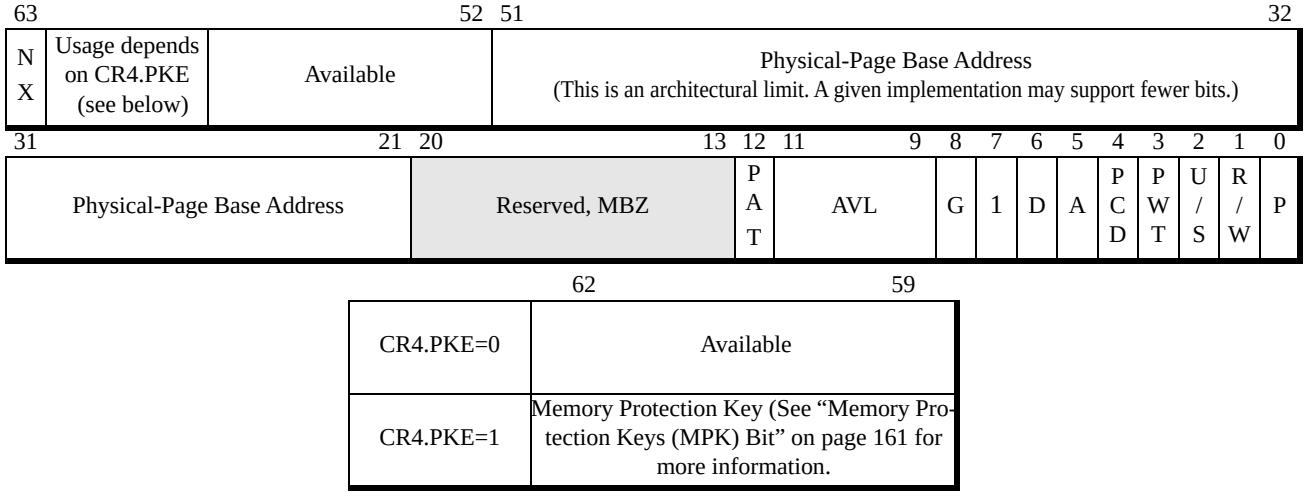

Figure 5-25. 2-Mbyte PDE—Long Mode

5.3.5 1-Gbyte Page Translation

In long mode, 1-Gbyte physical-page translation is performed by dividing the virtual address into four fields. Two of the fields are used as indices into the level page-translation hierarchy. The virtual-address fields are described as follows, and are shown in Figure 5-26 on page 148:

- Bits 63:48 are a sign extension of bit 47 as required for canonical address forms.
- Bits 47:39 index into the 512-entry page-map level-4 table.

- Bits 38:30 index into the 512-entry page-directory-pointer table.
- Bits 29:0 provide the byte offset into the physical page.

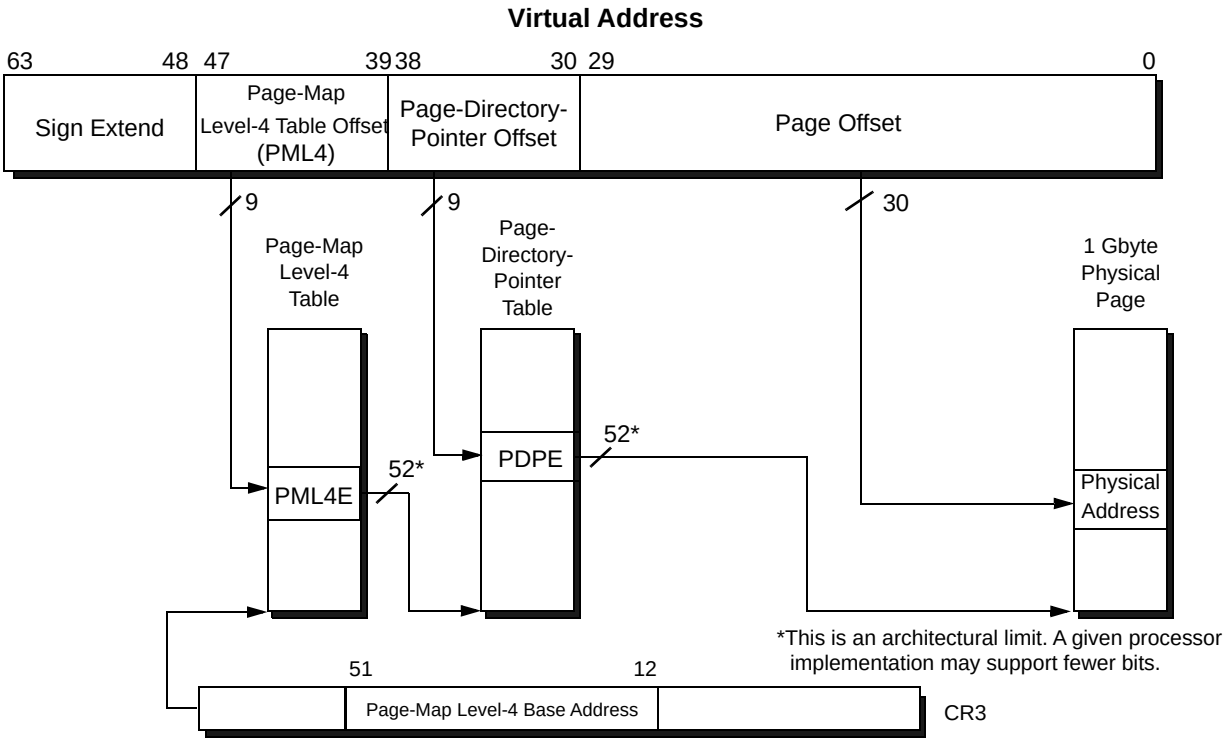

Figure 5-26. 1-Gbyte Page Translation—Long Mode

Figure 5-27 and Figure 5-28 on page 149 show the long mode 1-Gbyte translation-table formats (the PML4 format is identical to the one used for 4-Kbyte page translations and is repeated here for clarity):

- Figure 5-27 shows the PML4E (page-map level-4 entry) format.
- Figure 5-28 shows the PDPE (page-directory-pointer entry) format.

The fields within these table entries are described in “Page-Translation-Table Entry Fields” on page 150 in the current volume. PTEs and PDEs are not used in 1-Gbyte page translations.

Figure 5-28 on page 149 shows the PDPE.PS bit (bit 7) set to 1, indicating a 1-Gbyte physical-page translation.

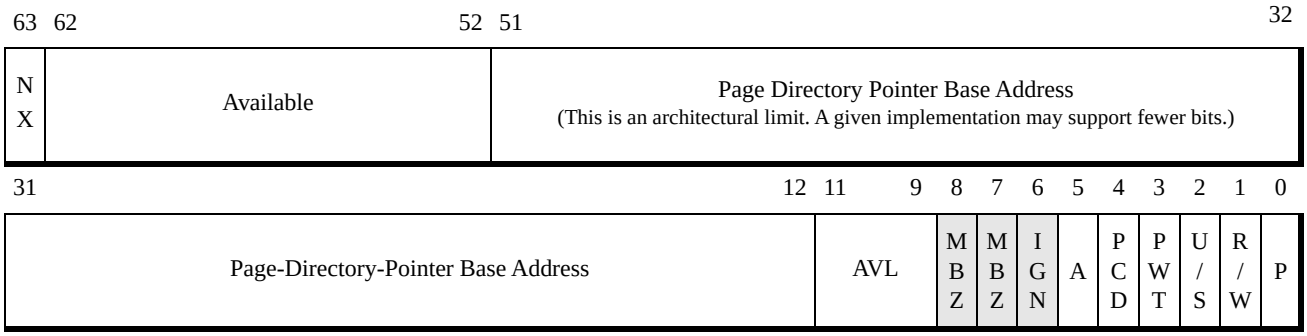

Figure 5-27. 1-Gbyte PML4E—Long Mode

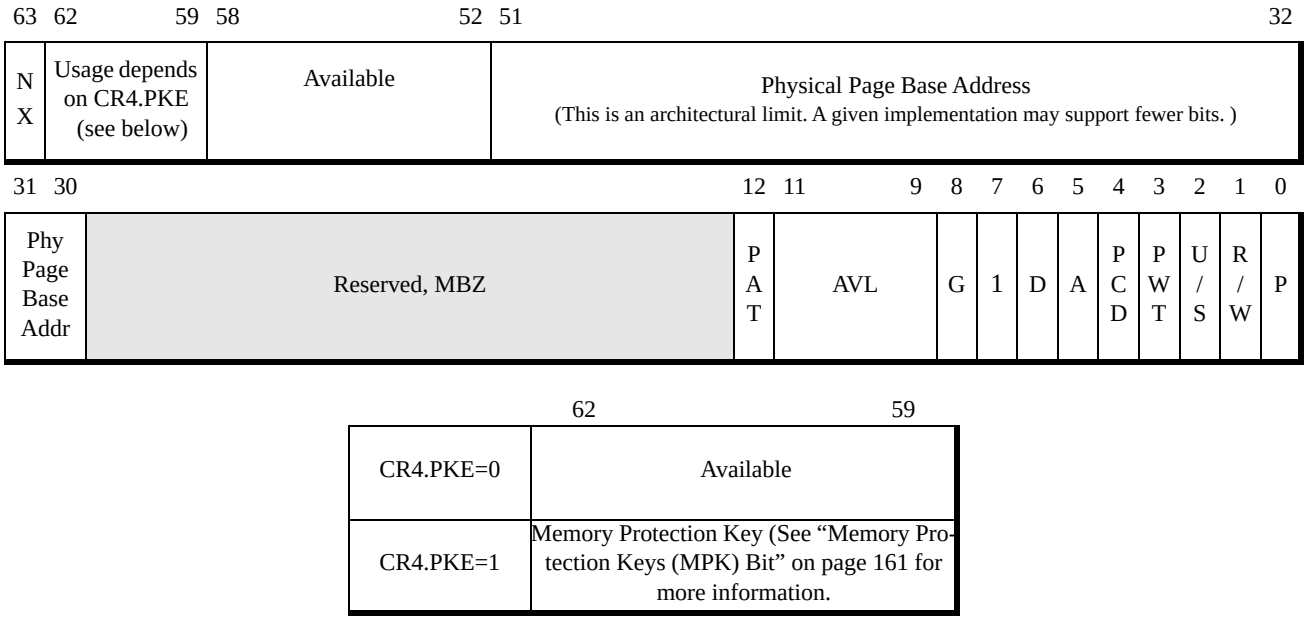

Figure 5-28. 1-Gbyte PDPE—Long Mode

1-Gbyte Paging Feature Identification. EDX bit 26 as returned by CPUID function 8000_0001h indicates 1-Gbyte page support. The EAX register as returned by CPUID function 8000_0019h reports the number of 1-Gbyte L1 TLB entries supported and EBX reports the number of 1-Gbyte L2 TLB entries. For more information using the CPUID instruction see Section 3.3 “Processor Feature Identification” on page 71.

5.4 Page-Translation-Table Entry Fields

The page-translation-table entries contain control and informational fields used in the management of the virtual-memory environment. Most fields are common across all translation table entries and modes and occupy the same bit locations. However, some fields are located in different bit positions depending on the page translation hierarchical level, and other fields have different sizes depending on which physical-page size, physical-address size, and operating mode are selected. Although these fields can differ in bit position or size, their meaning is consistent across all levels of the page translation hierarchy and in all operating modes.

5.4.1 Field Definitions

The following sections describe each field within the page-translation table entries.

Translation-Table Base Address Field. The translation-table base-address field points to the physical base address of the next-lower-level table in the page-translation hierarchy. Page data-structure tables are always aligned on 4-Kbyte boundaries, so only the address bits above bit 11 are stored in the translation-table base-address field. Bits 11:0 are assumed to be 0. The size of the field depends on the mode:

- In normal (non-PAE) paging (CR4.PAE=0), this field specifies a 32-bit physical address.
- In PAE paging (CR4.PAE=1), this field specifies a 52-bit physical address.

52 bits correspond to the maximum physical-address size allowed by the AMD64 architecture. If a processor implementation supports fewer than the full 52-bit physical address, software must clear the unimplemented high-order translation-table base-address bits to 0. For example, if a processor implementation supports a 40-bit physical-address size, software must clear bits 51:40 when writing a translation-table base-address field in a page data-structure entry.

Physical-Page Base Address Field. The physical-page base-address field points to the base address of the translated physical page. This field is found only in the lowest level of the page-translation hierarchy. The size of the field depends on the mode:

- In normal (non-PAE) paging (CR4.PAE=0), this field specifies a 32-bit base address for a physical page.
- In PAE paging (CR4.PAE=1), this field specifies a 52-bit base address for a physical page.

Physical pages can be 4 Kbytes, 2 Mbytes, 4 Mbytes, or 1-Gbyte and they are always aligned on an address boundary corresponding to the physical-page length. For example, a 2-Mbyte physical page is always aligned on a 2-Mbyte address boundary. Because of this alignment, the low-order address bits are assumed to be 0, as follows:

- 4-Kbyte pages, bits 11:0 are assumed 0.
- 2-Mbyte pages, bits 20:0 are assumed 0.
- 4-Mbyte pages, bits 21:0 are assumed 0.
- 1-Gbyte pages, bits 29:0 are assumed 0.

Present (P) Bit. Bit 0. This bit indicates whether the page-translation table or physical page is loaded in physical memory. When the P bit is cleared to 0, the table or physical page is not loaded in physical memory. When the P bit is set to 1, the table or physical page is loaded in physical memory.

Software clears this bit to 0 to indicate a page table or physical page is not loaded in physical memory. A page-fault exception (#PF) occurs if an attempt is made to access a table or page when the P bit is 0. System software is responsible for loading the missing table or page into memory and setting the P bit to 1.

When the P bit is 0, indicating a not-present page, all remaining bits in the page data-structure entry are available to software.

Entries with P cleared to 0 are never cached in TLB nor will the processor set the Accessed or Dirty bit for the table entry.

Read/Write (R/W) Bit. Bit 1. This bit controls read/write access to all physical pages mapped by the table entry. For example, a page-map level-4 R/W bit controls read/write access to all 128M ($512 \times 512 \times 512$) physical pages it maps through the lower-level translation tables. When the R/W bit is cleared to 0, access is restricted to read-only. When the R/W bit is set to 1, both read and write access is allowed. See “Page-Protection Checks” on page 158 for a description of the paging read/write protection mechanism.

User/Supervisor (U/S) Bit. Bit 2. This bit controls user (CPL 3) access to all physical pages mapped by the table entry. For example, a page-map level-4 U/S bit controls the access allowed to all 128M ($512 \times 512 \times 512$) physical pages it maps through the lower-level translation tables. When the U/S bit is cleared to 0, access is restricted to supervisor level (CPL 0, 1, 2). When the U/S bit is set to 1, both user and supervisor access is allowed. See “Page-Protection Checks” on page 158 for a description of the paging user/supervisor protection mechanism.

Page-Level Writethrough (PWT) Bit. Bit 3. This bit indicates whether the page-translation table or physical page to which this entry points has a writeback or writethrough caching policy. When the PWT bit is cleared to 0, the table or physical page has a writeback caching policy. When the PWT bit is set to 1, the table or physical page has a writethrough caching policy. See “Memory Caches” on page 199 for additional information on caching.

Page-Level Cache Disable (PCD) Bit. Bit 4. This bit indicates whether the page-translation table or physical page to which this entry points is cacheable. When the PCD bit is cleared to 0, the table or physical page is cacheable. When the PCD bit is set to 1, the table or physical page is not cacheable. See “Memory Caches” on page 199 for additional information on caching.

Accessed (A) Bit. Bit 5. This bit indicates whether the page-translation table or physical page to which this entry points has been accessed. The A bit is set to 1 by the processor the first time the table or physical page is either read from or written to. The A bit is never cleared by the processor. Instead, software must clear this bit to 0 when it needs to track the frequency of table or physical-page accesses.

Dirty (D) Bit. Bit 6. This bit is only present in the lowest level of the page-translation hierarchy. It indicates whether the physical page to which this entry points has been written. The D bit is set to 1 by

the processor the first time there is a write to the physical page. The D bit is never cleared by the processor. Instead, software must clear this bit to 0 when it needs to track the frequency of physical-page writes.

Page Size (PS) Bit. Bit 7. This bit is present in page-directory entries and long-mode page-directory-pointer entries. When the PS bit is set in the page-directory-pointer entry (PDPE) or page-directory entry (PDE), that entry is the lowest level of the page-translation hierarchy. When the PS bit is cleared to 0 in all levels above PTE, the lowest level of the page-translation hierarchy is the page-table entry (PTE), and the physical-page size is 4 Kbytes. The physical-page size is determined as follows:

- If EFER.LMA=1 and PDPE.PS=1, the physical-page size is 1 Gbyte.
- If CR4.PAE=0 and PDE.PS=1, the physical-page size is 4 Mbytes.
- If CR4.PAE=1 and PDE.PS=1, the physical-page size is 2 Mbytes.

See Table 5-1 on page 131 for a description of the relationship between the PS bit, PAE, physical-page sizes, and page-translation hierarchy.

Global Page (G) Bit. Bit 8. This bit is only present in the lowest level of the page-translation hierarchy. It indicates the physical page is a global page. The TLB entry for a global page (G=1) is not invalidated when CR3 is loaded either explicitly by a MOV CRn instruction or implicitly during a task switch. Use of the G bit requires the page-global enable bit in CR4 to be set to 1 (CR4.PGE=1). See “Global Pages” on page 155 for more information on the global-page mechanism.

Available to Software (AVL) Bit. These bits are not interpreted by the processor and are available for use by system software.

Page-Attribute Table (PAT) Bit. This bit is only present in the lowest level of the page-translation hierarchy, as follows:

- If the lowest level is a PTE (PDE.PS=0), PAT occupies bit 7.
- If the lowest level is a PDE (PDE.PS=1) or PDPE (PDPE.PS=1), PAT occupies bit 12.

The PAT bit is the high-order bit of a 3-bit index into the PAT register (Figure 7-10 on page 218). The other two bits involved in forming the index are the PCD and PWT bits. Not all processors support the PAT bit by implementing the PAT registers. See “Page-Attribute Table Mechanism” on page 218 for a description of the PAT mechanism and how it is used.

Memory Protection Key (MPK) Bits. Bits 62:59. When Memory Protection Keys are enabled (CR4.PKE=1), this 4-bit field selects the memory protection key for the physical page mapped by this entry. Ignored if memory protection keys are disabled (CR4.PKE=0). (See “Memory Protection Keys (MPK) Bit” on page 161 for a description of this mechanism.)

No Execute (NX) Bit. Bit 63. This bit is present in the translation-table entries defined for PAE paging, with the exception that the legacy-mode PDPE does not contain this bit. This bit is not supported by non-PAE paging.

The NX bit can only be set when the no-execute page-protection feature is enabled by setting EFER.NXE to 1 (see “Extended Feature Enable Register (EFER)” on page 56). If EFER.NXE=0, the NX bit is treated as reserved. In this case, a page-fault exception (#PF) occurs if the NX bit is not cleared to 0.

This bit controls the ability to execute code from all physical pages mapped by the table entry. For example, a page-map level-4 NX bit controls the ability to execute code from all 128M ($512 \times 512 \times 512$) physical pages it maps through the lower-level translation tables. When the NX bit is cleared to 0, code can be executed from the mapped physical pages. When the NX bit is set to 1, code cannot be executed from the mapped physical pages. See “No Execute (NX) Bit” on page 152 for a description of the no-execute page-protection mechanism.

Reserved Bits. Software should clear all reserved bits to 0. If the processor is in long mode, or if page-size and physical-address extensions are enabled in legacy mode, a page-fault exception (#PF) occurs if reserved bits are not cleared to 0.

5.4.2 Notes on Accessed and Dirty Bits

The processor never sets the Accessed bit or the Dirty bit for a not present page (P = 0). The ordering of Accessed and Dirty bit updates with respect to surrounding loads and stores is discussed below.

Accessed (A) Bit. The Accessed bit can be set for instructions that are speculatively executed by the processor.

For example, the Accessed bit may be set by instructions in a mispredicted branch path even though those instructions are never retired. Thus, software must not assume that the TLB entry has not been cached in the TLB, just because no instruction that accessed the page was successfully retired. Nevertheless, a table entry is never cached in the TLB without its Accessed bit being set at the same time.

The processor does not order Accessed bit updates with respect to loads done by other instructions.

Dirty (D) Bit. The Dirty bit is not updated speculatively. For instructions with multiple writes, the D bit may be set for any writes completed up to the point of a fault. In rare cases, the Dirty bit may be set even if a write was not actually performed, including MASKMOVQ with a mask of zero and certain x87 floating point instructions that cause an exception. Thus software can not assume that the page has actually been written even where PTE[D] is set to 1.

If PTE[D] is cleared to 0, software can rely on the fact that the page has not been written.

In general, Dirty bit updates are ordered with respect to other loads and stores, although not necessarily with respect to accesses to WC memory; in particular, they may not cause WC buffers to be flushed. However, to ensure compatibility with future processors, a serializing operation should be inserted before reading the D bit.

5.5 Translation-Lookaside Buffer (TLB)

When paging is enabled, every memory access has its virtual address automatically translated into a physical address using the page-translation hierarchy. *Translation-lookaside buffers* (TLBs), also known as *page-translation caches*, nearly eliminate the performance penalty associated with page translation. TLBs are special on-chip caches that hold the most-recently used virtual-to-physical address translations. Each memory reference (instruction and data) is checked by the TLB. If the translation is present in the TLB, it is immediately provided to the processor, thus avoiding external memory references for accessing page tables.

TLBs take advantage of the *principle of locality.* That is, if a memory address is referenced, it is likely that nearby memory addresses will be referenced in the near future. In the context of paging, the proximity of memory addresses required for locality can be broad—it is equal to the page size. Thus, it is possible for a large number of addresses to be translated by a small number of page translations. This high degree of locality means that almost all translations are performed using the on-chip TLBs.

System software is responsible for managing the TLBs when updates are made to the linear-to-physical mapping of addresses. A change to any paging data-structure entry is not automatically reflected in the TLB, and hardware snooping of TLBs during memory-reference cycles is not performed. Software must invalidate the TLB entry of a modified translation-table entry so that the change is reflected in subsequent address translations. TLB invalidation is described in “TLB Management” on page 155. Only privileged software running at CPL=0 can manage the TLBs.

5.5.1 Process Context Identifier

The Process Context Identifier (PCID) feature allows a logical processor to cache TLB mappings concurrently for multiple virtual address spaces. When enabled (by setting CR4.PCIDE=1), the processor associates the current 12-bit PCID with each TLB mapping it creates. Only entries matching the current PCID are used when performing address translations. In this way, the processor may retain cached TLB mappings for multiple contexts.

The current PCID is the value in CR3[11:0]. When PCIDs are enabled the system software can store 12-bit Process Context Identifiers in CR3 for different address spaces. Subsequently, when system software switches address spaces (by writing the page table base pointer in CR3[62:12]), the processor may use TLB mappings previously stored for that address space and PCID, providing that bit 63 of the source operand is set to 1. If bit 63 is set to 0, the legacy behavior of a move to CR3 is maintained, invalidating TLB entries but only non-global entries for the specified PCID. Note that this bit is not stored in the CR3 register itself. PCID-tagged TLB contents may also be managed using the INVPCID instruction; see the INVPCID description in volume 3 for details. A MOV to CR4 that clears CR4.PCIDE causes all cached entries in the TLB for the logical processor to be invalidated. When PCIDs are not enabled (CR4.PCIDE=0) the current PCID is always zero and all TLB mappings are associated with PCID=0.

Attempting to set CR4.PCIDE with a MOV to CR4 if EFER.LMA = 0 or CR3[11:0] <> 0 causes a #GP exception. Attempting to clear CR0.PG with a MOV to CR0 if CR4.PCIDE is set also causes a

#GP exception. The presence of PCID functionality is indicated by CPUID Function 1, ECX[PCID]=1.

5.5.2 Global Pages

The processor invalidates the TLB whenever CR3 is loaded either explicitly or implicitly. After the TLB is invalidated, subsequent address references can consume many clock cycles until their translations are cached as new entries in the TLB. Invalidation of TLB entries for frequently-used or critical pages can be avoided by specifying the translations for those pages as *global*. TLB entries for global pages are not invalidated as a result of a CR3 load. Global pages are invalidated using the INVLPG instruction.

Global-page extensions are controlled by setting and clearing the PGE bit in CR4 (bit 7). When CR4.PGE is set to 1, global-page extensions are enabled. When CR4.PGE is cleared to 0, global-page extensions are disabled. When CR4.PGE=1, setting the global (G) bit in the translation-table entry marks the page as global.

The INVLPG instruction ignores the G bit and can be used to invalidate individual global-page entries in the TLB. To invalidate all entries, including global-page entries, disable global-page extensions (CR4.PGE=0).

5.5.3 TLB Management

Generally, unless system software modifies the linear-to-physical address mapping, the processor manages the TLB transparently to software. This includes allocating entries and replacing old entries with new entries. In general, software changes made to paging-data structures are not automatically reflected in the TLB. In these situations, it is necessary for software to invalidate TLB entries so that these changes will be propagated to the page-translation mechanism.

TLB entries can be explicitly invalidated using operations intended for that purpose or implicitly invalidated as a result of another operation. TLB invalidation has no effect on the associated page-translation tables in memory.

Explicit Invalidations. Several mechanisms are provided to explicitly invalidate the TLB:

- The *Invalidate TLB Entry* instruction (INVLPG) can be used to invalidate a specific entry within the TLB. This instruction invalidates an entry regardless of whether it is marked as global or not.
- The *Invalidate TLB entry in a Specified ASID* instruction (INVLPGA) operates similarly, but operates only on entries associated with the specified ASID. See “Invalidate Page, Alternate ASID” on page 514.
- The *Invalidate TLB with Broadcast* instruction (INVLPGB) can be used to invalidate a specified range of TLB entries on the local processor and broadcast the invalidation operation to remote processors. See INVLPGB in Volume 3.
- The *Invalidate TLB entries in Specified PCID* instruction (INVPCID) can be used to invalidate TLB entries of the specified Processor Context ID. See INVPCID in Volume 3.

- Updates to the CR3 register cause the entire TLB to be invalidated *except* for global pages. The CR3 register can be updated with the MOV CR3 instruction. CR3 is also updated during a task switch, with the updated CR3 value read from the TSS of the new task. This behavior for CR3 is modified by the PCID extension; See “Process Context Identifier” on page 154 for details.
- The TLB_CONTROL field of a VMCB can request specific flushes of the TLB to occur when the VMRUN instruction is executed on that VMCB. See “TLB Flush” on page 513.

Implicit Invalidations. The following operations cause the entire TLB to be invalidated, including global pages:

- Modifying the CR0.PG bit (paging enable).
- Modifying the CR4.PAE bit (physical-address extensions), the CR4.PSE bit (page-size extensions), or the CR4.PGE bit (page-global enable).
- Entering SMM as a result of an SMI interrupt.
- Executing the RSM instruction to return from SMM.
- Updating a memory-type range register (MTRR) with the WRMSR instruction.
- External initialization of the processor.
- External masking of the A20 address bit (asserting the A20M# input signal).
- Writes to certain model-specific registers with the WRMSR instruction; see the *BIOS and Kernel Developer’s Guide (BKDG)* or *Processor Programming Reference Manual* applicable to your product for more information.
- A MOV to CR4 that changes CR4.PKE from 0 to 1.
- A MOV to CR4 that clears CR4.PCIDE from 1 to 0.

Invalidation of Table Entry Upgrades. If a table entry is updated to remove a page access constraint, such as removing supervisor, read-only, and/or no-execute restrictions, an invalidation is not required because the hardware will automatically detect the changes. If a table entry is updated and does not remove a permission violation, it is unpredictable whether the old or updated entry will be used until an invalidation is performed.

Speculative Caching of Address Translations. For performance reasons, AMD64 processors may speculatively load valid address translations into the TLB on false execution paths. Such translations are not based on references that a program makes from an “architectural state” perspective, but which the processor may make in speculatively following an instruction path which turns out to be mispredicted. In general, the processor may create a TLB entry for any linear address for which valid entries exist in the page table structure currently pointed to by CR3. This may occur for both instruction fetches and data references. Such entries remain cached in the TLBs and may be used in subsequent translations. Loading a translation speculatively will set the Accessed bit, if not already set. A translation will *not* be loaded speculatively if the Dirty bit needs to be set.

Caching of Upper Level Translation Table Entries. Similarly, to improve the performance of table walks on TLB misses, AMD64 processors may save upper level translation table entries in special table walk caching structures which are kept coherent with the tables in memory via the same

mechanisms as the TLBs—by means of the INVLPG instruction, moves to CR3, and modification of paging control bits in CR0 and CR4. Like address translations in the TLB, these upper level entries may also be cached speculatively and by false-path execution. These entries are never cached if their P (present) bits are set to 0.

Under certain circumstances, an upper-level table entry that cannot ultimately lead to a valid translation (because there are no valid entries in the lower level table to which it points) may also be cached. This can happen while executing down a false path, when an in-progress table walk gets cancelled by the branch mispredict before the low level table entry that would cause a fault is encountered. Said another way, the fact that a page table has no valid entries does not guarantee that upper level table entries won't be accessed and cached in the processor, as long as those upper level entries are marked as present. For this reason, it is not safe to modify an upper level entry, even if no valid lower-level entries exist, without first clearing its present bit, followed by an INVLPG instruction.

Use of Cached Entries When Reporting a Page Fault Exception. On current AMD64 processors, when any type of page fault exception is encountered by the MMU, any cached upper-level entries that lead to the faulting entry are flushed (along with the TLB entry, if already cached) and the table walk is repeated to confirm the page fault using the table entries in memory. This is done because a table entry is allowed to be upgraded (by marking it as present, or by removing its write, execute or supervisor restrictions) without explicitly maintaining TLB coherency. Such an upgrade will be found when the table is re-walked, which resolves the fault. If the fault is confirmed on the re-walk however, a page fault exception is reported, and upper level entries that may have been cached on the re-walk are flushed.

Handling of D-Bit Updates. When the processor needs to set the D bit in the PTE for a TLB entry that is already marked as writable at all cached TLB levels, the table walk that is performed to access the PTE in memory may use cached upper level table entries. This differs from the fault situation previously described, in which cached entries aren’t used to confirm the fault during the table walk.

Invalidation of Cached Upper-level Entries by INVLPG. The effect of INVLPG on TLB caching of upper-level page table entries is controlled by EFER[TCE] on processors that support the translation cache extension feature. If EFER[TCE] is 0, or if the processor does not support the translation cache extension feature, an INVLPG will flush all upper-level page table entries in the TLB as well as the target PTE. If EFER[TCE] is 1, INVLPG will flush only those upper-level entries that lead to the target PTE, along with the target PTE itself. INVLPGA may flush all upper-level entries regardless of the state of TCE. For further details, see Section 3.1.7 “Extended Feature Enable Register (EFER)” on page 56.

Handling of PDPT Entries in PAE Mode. When 32-bit PAE mode is enabled on AMD64 processors (CR4.PAE is set to 1) a third level of the address translation table hierarchy, the page directory pointer table (PDPT), is enabled. This table contains four entries. On older AMD64 processors, in native mode, these four entries are unconditionally loaded into the table walk cache whenever CR3 is written with the PDPT base address, and remain locked in. At this point they are also checked for reserved bit violations, and if such violations are present a general-protection exception (#GP) occurs.

Under SVM, however, when the processor is in guest mode with PAE enabled, the guest PDPT entries are not cached or validated at this point, but instead are loaded and checked on demand in the normal course of address translation, just like page directory and page table entries. Any reserved bit violations are detected at the point of use, and result in a page-fault (#PF) exception rather than a general-protection (#GP) exception. The cached PDPT entries are subject to displacement from the table walk cache and reloading from the PDPT, hence software must assume that the PDPT entries may be read by the processor at any point while those tables are active. Modern AMD processors implement this same behavior in native mode as well, rather than pre-loading the PDPT entries.

5.6 Page-Protection Checks

The AMD64 architecture provides the following forms of page-level memory protection:

- Supervisor pages. This form of protection prevents non-privileged (user) code from accessing privileged (supervisor) code and data.
- Read-only pages. This form of protection prevents writes into read-only address spaces.
- Instruction fetch restrictions. Two forms of page-level memory protection prevent the processor from fetching instructions from pages that are either known to contain non-executable data or that are accessible by user-mode code.
- Memory protection keys. This form of protection allows an application to manage page-based data access protections from user mode.
- Shadow stack pages. The processor restricts the types of memory accesses that are allowed to read or write a shadow stack page and prohibits the shadow stack mechanism from accessing non-shadow stack pages. See “Shadow Stack Protection” on page 161.

Access protection checks are performed when a virtual address is translated into a physical address. For those checks, the processor examines the page-level memory-protection bits in the translation tables to determine if the access is allowed. The page table bits involved in these checks are:

- User/Supervisor (U/S)—See “User/Supervisor (U/S) Bit” on page 151.
- Read/Write (R/W)—See “Read/Write (R/W) Bit” on page 151.
- No-Execute (NX)—See “No Execute (NX) Bit” on page 152.
- Memory Protection Key (MPK)—See “Memory Protection Keys (MPK) Bit” on page 161.

Access protection actions taken by the processor are controlled by the following bits:

- Write-Protect enable (CR0.WP)—See “Write Protect (WP) Bit” on page 44.
- No-Execute Enable (EFER.NXE)—See “No-Execute Enable (NXE) Bit” on page 58.
- Supervisor-mode Execution Prevention enable (CR4.SMEP)—See “Supervisor Mode Execution Prevention (SMEP)” on page 51.
- Supervisor-mode Access Prevention enable (CR4.SMAP)—See “Supervisor-Mode Access Prevention(CR4.SMAP) Bit” on page 160.
- Alignment Check Bit (RFLAGS.AC) – See ““Alignment Check (AC) Bit” on page 55.

- Protection Key Enable (CR4.PKE)—See “Protected-Mode Enable (PE) Bit” on page 43.
- Control-flow Enforcement Technology (CR4.CET) - See “CR4 Register” on page 47.

These protection checks are available at all levels of the page-translation hierarchy.

5.6.1 User/Supervisor (U/S) Bit

The U/S bit in the page-translation tables determines the privilege level required to access the page. If U/S=0 in any of the page table entries traversed during a table walk, the page is considered a supervisor page. If U/S=1 in all the page table entries traversed during a table walk, the page is considered a user page. Conceptually, user (non-privileged) pages correspond to a current privilege-level (CPL) of 3, or least-privileged. Supervisor (privileged) pages correspond to a CPL of 0, 1, or 2, all of which are jointly regarded as most-privileged.

When the processor is running at a CPL of 0, 1, or 2, it can access both user and supervisor pages unless restricted by SMEP or SMAP (See sections “Supervisor-Mode Execution Prevention (CR4.SMEP) Bit” on page 160 and “Supervisor-Mode Access Prevention(CR4.SMAP) Bit” on page 160 for further details). However, when the processor is running at a CPL of 3, it can only access user pages. If an attempt is made to access a supervisor page while the processor is running at CPL = 3, a page-fault exception (#PF) occurs.

See “Privilege-Level Concept” on page 105 for more information on processor privilege levels.

5.6.2 Read/Write (R/W) Bit

The R/W bit in the page-translation tables specifies the access type allowed for the page. If R/W=0 in any of the page table entries traversed during a table walk, the page is read-only. If R/W=1 in all the page table entries traversed during a table walk, the page is read/write. A page-fault exception (#PF) occurs if an attempt is made by user software to write to a read-only page. If supervisor software attempts to write a read-only page, the outcome depends on the value of the CR0.WP bit (described below).

5.6.3 No Execute (NX) Bit

The NX bit provides the ability to mark a page as non-executable. If the NX bit is set at any level of the page-table hierarchy in the table entries traversed during a table walk, the page mapped by those entries is a no-execute page. When no-execute protection is enabled, any attempt to fetch an instruction from a no-execute page results in a page-fault exception (#PF).

The no-execute protection check applies to all privilege levels. It does not distinguish between supervisor and user-level accesses.

The no-execute protection feature is supported only in PAE-paging mode. In 32-bit PAE mode, the NX bit is not supported at the Page Directory Pointer table level. In this mode, the value of the NX bit at the PDP level defaults to 0.

No-execute protection is enabled by setting the NXE bit in the EFER register to 1. Before setting this bit, system software must verify the processor supports the no-execute feature by checking the CPUID NX feature flag (CPUID Fn8000_0001_EDX[NX]).

5.6.4 Write Protect (CR0.WP) Bit

The ability to write to read-only pages is governed by the processor mode and whether write protection is enabled. If write protection is *not* enabled, a processor running at CPL 0, 1, or 2 can write to any physical page, even if it is marked as read-only. Enabling write protection by setting the WP bit in CR0 prevents supervisor code from writing into read-only pages, including read-only user-level pages.

A page-fault exception (#PF) occurs if software attempts to write (at any privilege level) into a read-only page while write protection is enabled.

5.6.5 Supervisor-Mode Execution Prevention (CR4.SMEP) Bit

When supported and enabled, a page-fault exception (#PF) is generated if the processor attempts to fetch an instruction from a user page while running at CPL 0, 1, or 2.

Supervisor-mode execution prevention is enabled by setting the SMEP bit (bit 20) in the CR4 register to 1. Before setting this bit, system software must verify the processor supports the SMEP feature by checking the SMEP feature flag (CPUID Fn0000_0007_EBX[SMEP]_x0 = 1).

For more information using the CPUID instruction see Section 3.3 “Processor Feature Identification” on page 71.

5.6.6 Supervisor-Mode Access Prevention(CR4.SMAP) Bit

When SMAP is supported and enabled, a page-fault exception (#PF) is generated if the processor attempts to read or write data from a user page and one of the following is true:

- The access is an implicit supervisor-mode access OR
- The access is made while running at CPL 0,1, or 2 and RFLAGS.AC=0.

Some accesses are considered implicit supervisor-mode accesses. Implicit supervisor-mode accesses are subject to the SMAP check regardless of the value of RFLAGS.AC. An implicit supervisor-mode access is one that is considered a supervisor access regardless of the value of CPL.

Supervisor-mode access prevention is enabled by setting the SMAP bit (bit 21) in the CR4 register to 1. Before setting this bit, system software must verify the processor supports the SMAP feature by checking the SMAP feature flag CPUID Fn0000_0007_EBX[SMAP]_x0 (bit 20) = 1.

Shadow stack accesses are not subject to the SMAP check.

For more information on using the CPUID instruction see “Processor Feature Identification” on page 71.

5.6.7 Memory Protection Keys (MPK) Bit

The Memory Protection Key (MPK) feature provides a way for applications to impose page-based data access protections (read/write, read-only or no access), without requiring modification of page tables and subsequent TLB invalidations when the application changes protection domains.

When MPK is enabled (CR4.PKE=1), a protection key is located in bits 62:59 of final page table entry mapping each virtual address. This 4-bit protection key is used as an index (i) into the user-accessible PKRU register which contains 16 access-disable/write-disable (WDi/ADi) pairs.

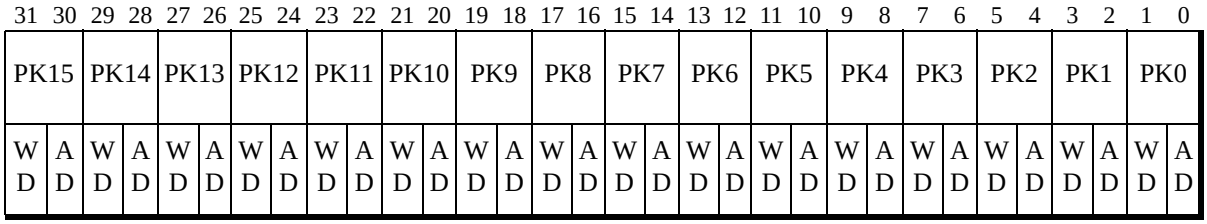

Figure 5-29. PKRU Register

The WDi/ADi pairs operate as follows:

If ADi=0, data access is permitted

- If ADi=1, no data access is permitted (regardless of CPL)
- If WDi == 0, write access is allowed
- If WDi == 1: User-mode write access is not allowed. Supervisor access is controlled by CR0.WP:
  - If CR0.WP=1, supervisor-mode writes are not allowed
  - If CR0.WP=0, supervisor-mode writes are allowed

Software can use the RDPKRU and WRPKRU instructions to read and write the PKRU register. These instructions are not privileged and can be used in user mode or in supervisor mode.

The MPK mechanism is ignored in the following cases:

- if CR4.PKE=0
- if long mode is disabled (EFER.LMA=0)
- for instruction fetches
- for pages marked in the paging structures as supervisor addresses (U/S=0)

5.7 Shadow Stack Protection

When the shadow stack feature is enabled (CR4.CET=1), certain combinations of page-table protection bits are used to distinguish pages containing shadow stacks from ordinary pages. As described in the following sections, the processor restricts the types of memory accesses that can be

made to shadow stack pages and prohibits the shadow stack mechanism from accessing non-shadow stack pages. (See “Shadow Stacks” on page 647 for details on the shadow stack feature).

5.7.1 Shadow Stack Accesses

The processor treats certain memory accesses as shadow stack accesses. Shadow stack accesses are generated only by the shadow stack instructions or by the shadow stack mechanism. As with ordinary data accesses, a shadow stack access can be either a supervisor access or a user access, depending on the CPL when the access is made. Shadow stack accesses made when the processor is at CPL 0, 1, or 2 are supervisor-shadow stack accesses, and accesses made at CPL 3 are user-shadow stack accesses. (An exception is the WRUSS instruction, whose accesses are always treated as user-shadow stack accesses).

5.7.2 Shadow Stack Pages

Shadow stack accesses are allowed only to linear addresses that are mapped to shadow stack pages. A shadow stack is described by the following combination of page-table protection bits:

- R/W(Read/Write)=0 and D(Dirty)=1 in the final page-table entry that maps the linear address.
- R/W(Read/Write)=1 in all other page-mapping structures leading to the final page-table entry.

The U/S (User/Supervisor) bit in the page-translation tables determines the privilege level required to access a given shadow stack page. If U/S=0, the page is considered a supervisor-shadow stack page and if U/S=1 the page is considered a user-shadow stack page.

5.7.3 Shadow Stack Protection Checks

The processor restricts the types of memory accesses that are allowed to read or write a shadow stack page. The page-level protection bits and the type of memory access are examined to determine if the access is allowed. The following section assumes the memory protection key field allows access to the given page, if memory protection keys are enabled, and that CR0.WP=1 (which is prerequisite for enabling the shadow stack feature).

The following memory accesses are allowed to shadow stack pages:

- User-shadow stack accesses can read or write user-shadow stack pages,
- Supervisor-shadow stack accesses can read or write supervisor-shadow stack pages.

*(**Note**: shadow stack write accesses are allowed to complete, even though the R/W bit is 0).*

- Non-shadow stack reads can read any shadow stack page (subject to U/S page protections).

The following memory accesses are not allowed:

- User-shadow stack access to supervisor-shadow stack pages.
- Supervisor-shadow stack access to user-shadow stack pages.
- Any shadow stack access to a non-shadow stack page.
- Non-shadow stack writes to a shadow stack page.

If the memory access is not allowed, a page-fault exception (#PF) is generated with the paging-protection violation bits (user/supervisor, read/write, or both) set in the error code as appropriate. The SS bit is set in the #PF error code if the page-fault was caused by a shadow stack access. (See “Page-Fault Error Code” on page 254).

5.8 Protection Across Paging Hierarchy

The privilege level and access type specified at each level of the page-translation hierarchy have a combined effect on the protection of the translated physical page. Enabling and disabling write protection via CR0.WP further qualifies the protection effect on the physical page.

Table 5-2 shows the overall effect that privilege level and access type have on physical-page protection when write protection is disabled (CR0.WP=0). In this case, when *any* translation-table entry is specified as supervisor level, the physical page is a supervisor page and can only be accessed by software running at CPL 0, 1, or 2. Such a page allows read/write access even if all levels of the page-translation hierarchy specify read-only access.

Table 5-2. Physical-Page Protection, CR0.WP=0

Page-Map Level-4 Entry		Page-Directory-Pointer Entry		Page-Directory Entry		Page-Table Entry		Effective Result on Physical Page	
U/S	R/W	U/S	R/W	U/S	R/W	U/S	R/W	U/S	R/W
S	—	—	—	—	—	—	—	S	R/W
—	—	S	—	—	—	—	—		
—	—	—	—	S	—	—	—		
—	—	—	—	—	—	S	—		
U	R	U	—	U	—	U	—	U	R[1]
U	—	U	R	U	—	U	—		
U	—	U	—	U	R	U	—		
U	—	U	—	U	—	U	R		
U	R/W	U	R/W	U	R/W	U	R/W	U	R/W

Note:
S = Supervisor Level (CPL=0, 1, or 2), U = User Level (CPL = 3), R = Read-Only Access, R/W = Read/Write Access, — = Don’t Care.

Note:
1. *Supervisor-level programs can access these pages as R/W.*

If *all* table entries in the translation hierarchy are specified as user level the physical page is a user page, and both supervisor and user software can access it. In this case the physical page is read-only if any table entry in the translation hierarchy specifies read-only access. All table entries in the translation hierarchy must specify read/write access for the physical page to be read/write.

Table 5-3 shows the overall effect that privilege level and access type have on physical-page access when write protection is enabled (CR0.WP=1). When any translation-table entry is specified as

supervisor level, the physical page is a supervisor page and can only be accessed by supervisor software. In this case, the physical page is read-only if any table entry in the translation hierarchy specifies read-only access. All table entries in the translation hierarchy must specify read/write access for the supervisor page to be read/write.

Table 5-3. Effect of CR0.WP=1 on Supervisor Page Access

Page-Map Level-4 Entry	Page Directory-Pointer Entry	Page Directory Entry	Page Table Entry	Physical Page
R/W	R/W	R/W	R/W	R/W
R	—	—	—	R
—	R	—	—	
—	—	R	—	
—	—	—	R	
W	W	W	W	W

Note:
R = Read-Only Access Type, W = Read/Write Access Type, — = Don't Care.
Physical page is in supervisor mode, as determined by U/S settings in Table 5-2.

5.8.1 Access to User Pages when CR0.WP=1

As shown in Table 5-2 on page 163, read/write access to user-level pages behaves the same as when write protection is disabled (CR0.WP=0), with one critical difference. When write protection is enabled, supervisor programs cannot write into read-only user pages.

5.9 Effects of Segment Protection

Segment-protection and page-protection checks are performed serially by the processor, with segment-privilege checks performed first, followed by page-protection checks. Page-protection checks are not performed if a segment-protection violation is found. If a violation is found during either segment-protection or page-protection checking, an exception occurs and no memory access is performed. Segment-protection violations cause either a general-protection exception (#GP) or a stack exception (#SS) to occur. Page-protection violations cause a page-fault exception (#PF) to occur.

5.10 Upper Address Ignore

The Upper Address Ignore feature provides a way for software to use bits [63:57] of an address as an arbitrary software-assigned and software-interpreted tag. When this feature is enabled, these address bits are excluded from the canonicality check that's done when the address is used for certain memory references.

5.10.1 Detecting and Enabling Upper Address Ignore

Support for the Upper Address Ignore feature is indicated by CPUID Fn8000_0021_EAX[UpperAddressIgnore](bit 7)=1. The Upper Address Ignore feature is enabled by setting EFER.UAIE (bit 20) in 64-bit mode (EFER.LMA=CS.L=1). EFER.UAIE is ignored outside of 64-bit mode.

5.10.2 Upper Address Ignore Operation

When Upper Address Ignore is active the processor no longer performs a canonical address check on bits [63:57] of the logical address for memory references that use either the DS or ES segment, it checks only bits [56:48] of the logical address.

Any memory reference made using the segment registers CS, SS, FS or GS still performs the normal canonical address check. This includes indirect jump, call, and return target addresses since they are CS based. Canonical checks for implicit references to IDT, GDT, LDT and TSS are not suppressed when Upper Address Ignore is active.

5.10.3 Address Tag Storage

The following registers, which hold virtual addresses for communication to software, are not guaranteed to hold the address tag in the upper 7 bits:

- CR2
- x87 DP
- IBS Data Cache Linear Address Register

5.10.4 Debug Breakpoint behavior with Upper Address Ignore

The Debug Breakpoint Address Registers (DR0-3) hold full 64-bit addresses and Upper Address Ignore changes how the address match is performed for data address breakpoints. When Upper Address Ignore is active the value in DR0-3[63:57] is ignored and the linear address of the memory access is only compared against DR0-3[56:0].

6 System Instructions

System instructions provide control over the resources used to manage the processor operating environment. This includes memory management, memory protection, task management, interrupt and exception handling, system-management mode, software debug and performance analysis, and model-specific features. Most instructions used to access these resources are privileged and can only be executed while the processor is running at CPL=0, although some instructions can be executed at any privilege level.

Table 6-1 summarizes the instructions used for system management. These include all privileged instructions, instructions whose privilege requirement is under the control of system software, non-privileged instructions that are used primarily by system software, and instructions used to transfer control to system software. Most of the instructions listed in Table 6-1 are summarized in this chapter, although a few are introduced elsewhere in this manual, as indicated in the *Reference* column of Table 6-1.

For details on individual system instructions, see “System Instruction Reference” in Volume 3.

Table 6-1. System Management Instructions

Mnemonic	Name	Privilege			Reference
		CPL=0	O/S[1]	Any	
ARPL	Adjust Requestor Privilege Level			X	“Adjusting Access Rights” on page 178
CLAC	Clear Alignment Check Flag	X			“CLAC and STAC Instructions” on page 175
CLGI	Clear Global Interrupt Flag	X			“Global Interrupt Flag, STGI and CLGI Instructions” on page 514
CLI	Clear Interrupt Flag		X		“CLI and STI Instructions” on page 175
CLRSSBSY	Clear Shadow Stack Busy	X			“CLRSSBSY” on page 179
CLTS	Clear Task-Switched Flag in CR0	X			“CLTS Instruction” on page 175
HLT	Halt	X			“Processor Halt” on page 178
INCSSP	Increment SSP			X	“INCSSP” on page 179
INT3	Interrupt to Debug Vector			X	“Breakpoint Instruction (INT3)” on page 398
INVD	Invalidate Caches	X			“Cache Management” on page 178
INVLPG	Invalidate TLB Entry	X			“INVLPG Instruction” on page 179
INVLPGA	Invalidate TLB Entry in a Specified ASID	X			“Invalidate Page, Alternate ASID” on page 514

Note:
1. *The operating system controls the privilege required to use the instruction.*

Table 6-1. System Management Instructions (continued)

Mnemonic	Name	Privilege			Reference
		CPL=0	O/S[1]	Any	
INVLPGB	Invalidate TLB Entries with Broadcast	X			"INVLPGB Instruction" on page 179
INVPCID	Invalidate TLB Entries in Specified Processor Context	X			"INVPCID Instruction" on page 179
IRET*x*	Interrupt Return (all forms)			X	"Returning From Interrupt Procedures" on page 268
LAR	Load Access-Rights Byte			X	"Checking Access Rights" on page 177
LGDT	Load Global-Descriptor-Table Register	X			"LGDT and LIDT Instructions" on page 176
LIDT	Load Interrupt-Descriptor-Table Register	X			
LLDT	Load Local-Descriptor-Table Register	X			"LLDT and LTR Instructions" on page 177
LMSW	Load Machine-Status Word	X			"LMSW and SMSW Instructions" on page 174
LSL	Load Segment Limit			X	"Checking Segment Limits" on page 177
LTR	Load Task Register	X			"LLDT and LTR Instructions" on page 177
MONITOR	Setup Monitor Address		X		--
MOV CR*n*	Move to/from Control Registers	X			"MOV CR*n* Instructions" on page 174
MOV DR*n*	Move to/from Debug Registers	X			"Accessing Debug Registers" on page 175
MWAIT	Monitor Wait		X		--
RDFSBASE	Read FS Base Address			X	"RDFSBASE, RDGSBASE, WRFSBASE, and WRGSBASE Instructions" on page 176
RDGSBASE	Read GS Base Address			X	
RDMSR	Read Model-Specific Register	X			"RDMSR and WRMSR Instructions" on page 175
RDPMC	Read Performance-Monitor Counter		X		"RDPMC Instruction" on page 175
RDSSP	Read SSP			X	"RDSSP" on page 179
RDTSC	Read Time-Stamp Counter		X		"RDTSC Instruction" on page 175
RDTSCP	Read Time-Stamp Counter and Processor ID		X		"RDTSCP Instruction" on page 176
RSM	Return from System-Management Mode			X	"Leaving SMM" on page 333

Note:

1. *The operating system controls the privilege required to use the instruction.*

Table 6-1. System Management Instructions (continued)

Mnemonic	Name	Privilege			Reference
		CPL=0	O/S[1]	Any	
RSTORSSP	Restore SSP			X	"RSTORSSP" on page 179
SAVEPREVSSP	Save Previous SSP			X	"SAVEPREVSSP" on page 179
SETSSBSY	Set Shadow Stack Busy	X			"SETSSBSY" on page 179
SGDT	Store Global-Descriptor-Table Register		X		"SGDT and SIDT Instructions" on page 177
SIDT	Store Interrupt-Descriptor-Table Register		X		
SKINIT	Secure Init and Jump with Attestation	X			"Security" on page 540
SLDT	Store Local-Descriptor-Table Register		X		"SLDT and STR Instructions" on page 177
SMSW	Store Machine-Status Word		X		"LMSW and SMSW Instructions" on page 174
STAC	Set Alignment Check Flag		X		"CLAC and STAC Instructions" on page 175
STI	Set Interrupt Flag		X		"CLI and STI Instructions" on page 175

WRMSR	Write Model-Specific Register	X			"RDMSR and WRMSR Instructions" on page 175
WRSS	Write to Shadow Stack			X	"WRSS" on page 180
WRUSS	Write to User Shadow Stack	X			"WRUSS" on page 180

Note:
1. *The operating system controls the privilege required to use the instruction.*

The following instructions are summarized in this chapter but are not categorized as system instructions, because of their importance to application programming:

- The CPUID instruction returns information critical to system software in initializing the operating environment. It is fully described in Section 3.3, "Processor Feature Identification," on page 71.
- The PUSHF and POPF instructions set and clear certain rFLAGS bits depending on the processor operating mode and privilege level. These dependencies are described in "POPF and PUSHF Instructions" on page 175.

The MOV, PUSH, and POP instructions can be used to load and store segment registers, as described in "MOV, POP, and PUSH Instructions" on page 176.

User Mode Instruction Prevention (UMIP)

This security mode restricts certain instructions so that they do not reveal information about structures that are controlled by the processor when it is at CPL=0. The presence of the UMIP feature is indicated by CPUID Function 0000_0007, ECX[2]=1 . This mode is enabled by setting CR4 bit 11 to a 1. Attempts to set CR4 bit 11 when the UMIP feature is not supported result in a #GP fault. Once CR4[11] is set to 1, the SGDT, SIDT, SLDT, SMSW and STR instructions become available only at CPL=0. Any attempt to execute them with CPL>0 results in a #GP fault with error code 0.

6.1 Fast System Call and Return

Operating systems can use both paging and segmentation to implement protected memory models. Segment descriptors provide the necessary memory protection and privilege checking for segment accesses. By setting segment-descriptor fields appropriately, operating systems can enforce access restrictions as needed.

A disadvantage of segment-based protection and privilege checking is the overhead associated with loading a new segment selector (and its corresponding descriptor) into a segment register. Even when using the flat-memory model, this overhead still occurs when switching between privilege levels because code segments (CS) and stack segments (SS) are reloaded with different segment descriptors.

To initiate a call to the operating system, an application transfers control to the operating system through a gate descriptor (call, interrupt, trap, or task gate). In the past, control was transferred using either a far CALL instruction or a software interrupt. Transferring control through one of these gates is slowed by the segmentation-related overhead, as is the later return using a far RET or IRET instruction. The following checks are performed when control is transferred in this manner:

- Selectors, gate descriptors, and segment descriptors are in the proper form.
- Descriptors lie within the bounds of the descriptor tables.
- Gate descriptors reference the appropriate segment descriptors.
- The caller, gate, and target privileges all allow the control transfer to take place.
- The stack created by the call has sufficient properties to allow the transfer to take place.

In addition to these call-gate checks, other checks are made involving the task-state segment when a task switch occurs.

6.1.1 SYSCALL and SYSRET

SYSCALL and SYSRET Instructions. SYSCALL and SYSRET are low-latency system call and return instructions. These instructions assume the operating system implements a flat-memory model, which greatly simplifies calls to and returns from the operating system. This simplification comes from eliminating unneeded checks, and by loading pre-determined values into the CS and SS segment registers (both visible and hidden portions). As a result, SYSCALL and SYSRET can take fewer than one-fourth the number of internal clock cycles to complete than the legacy CALL and RET instructions. SYSCALL and SYSRET are particularly well-suited for use in 64-bit mode, which requires implementation of a paged, flat-memory model.

SYSCALL and SYSRET require that the code-segment base, limit, and attributes (except for DPL) are consistent for all application and system processes. Only the DPL is allowed to vary. The processor assumes (but does not check) that the SYSCALL target CS segment descriptor entry has DPL=0 and the SYSRET target CS segment descriptor entry has DPL=3.

For details on the SYSCALL and SYSRET instructions, see “System Instruction Reference” in Volume 3.

Because SYSCALL and SYSRET do not use the program stack to store return addresses, the shadow stack mechanism is not used to validate their return addresses. However, when shadow stacks are enabled, SYSCALL and SYSRET save and restore the current SSP as follows:

- If the shadow stack feature is enabled at the current CPL (typically CPL=3), SYSCALL saves the current SSP to the PL3_SSP MSR
- If shadow stacks are enabled at the target CPL (CPL=0), SYSCALL clears the SSP to 0.

- If shadow stacks are enabled at CPL=3, SYSRET restores SSP from PL3_SSP.

SYSCALL and SYSRET MSRs. The STAR, LSTAR, and CSTAR registers are model-specific registers (MSRs) used to specify the target address of a SYSCALL instruction as well as the CS and SS selectors of the called and returned procedures. The SFMASK register is used in long mode to specify how rFLAGS is handled by these instructions. Figure 6-1 shows the STAR, LSTAR, CSTAR, and SFMASK register formats.

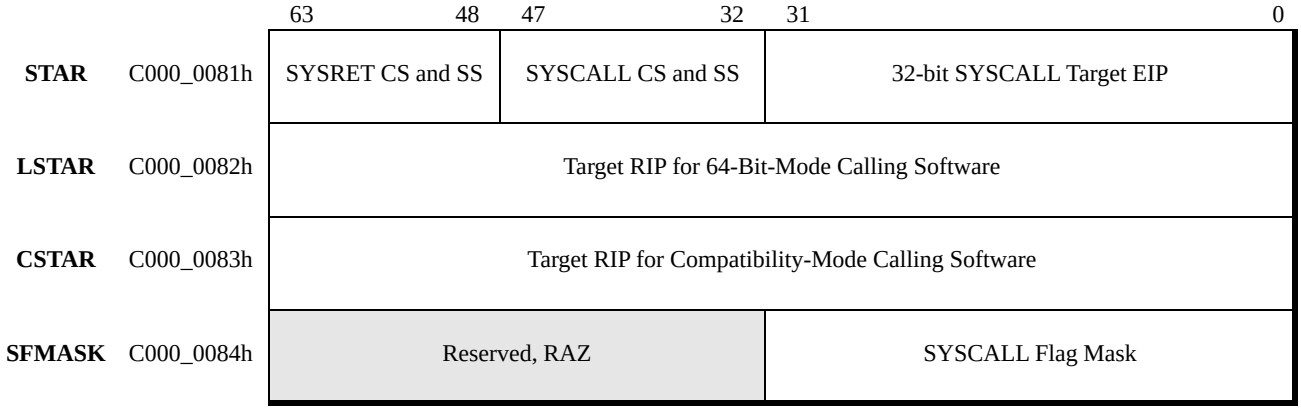

Figure 6-1. STAR, LSTAR, CSTAR, and MASK MSRs

- *STAR*—The STAR register has the following fields (unless otherwise noted, all bits are read/write):
  - *SYSRET CS and SS Selectors*—Bits 63:48. This field is used to specify both the CS and SS selectors loaded into CS and SS during SYSRET. If SYSRET is returning to 32-bit mode (either legacy or compatibility), this field is copied directly into the CS selector field. If SYSRET is returning to 64-bit mode, the CS selector is set to this field + 16. SS.Sel is set to this field + 8, regardless of the target mode. Because SYSRET always returns to CPL 3, the RPL bits 49:48 should be initialized to 11b.
  - *SYSCALL CS and SS Selectors*—Bits 47:32. This field is used to specify both the CS and SS selectors loaded into CS and SS during SYSCALL. This field is copied directly into CS.Sel. SS.Sel is set to this field + 8. Because SYSCALL always switches to CPL 0, the RPL bits 33:32 should be initialized to 00b.
  - *32-bit SYSCALL Target EIP*—Bits 31:0. This is the target EIP of the called procedure.

  The legacy STAR register is not expanded in long mode to provide a 64-bit target RIP address. Instead, long mode provides two new STAR registers—long STAR (LSTAR) and compatibility STAR (CSTAR)—that hold a 64-bit target RIP.
- *LSTAR and CSTAR*—The LSTAR register holds the target RIP of the called procedure in long mode when the calling software is in 64-bit mode. The CSTAR register holds the target RIP of the called procedure in long mode when the calling software is in compatibility mode. The WRMSR instruction is used to load the target RIP into the LSTAR and CSTAR registers. If the RIP written

to either of the MSRs is not in canonical form, a #GP fault is generated on the WRMSR instruction.

- *SFMASK*—The SFMASK register is used to specify which RFLAGS bits are cleared during a SYSCALL. In long mode, SFMASK is used to specify which RFLAGS bits are cleared when SYSCALL is executed. If a bit in SFMASK is *set to 1*, the corresponding bit in RFLAGS is *cleared to 0*. If a bit in SFMASK is cleared to 0, the corresponding RFLAGS bit is not modified.

6.1.2 SYSENTER and SYSEXIT (Legacy Mode Only)

SYSENTER and SYSEXIT Instructions. Like SYSCALL and SYSRET, SYSENTER and SYSEXIT are low-latency system call and return instructions designed for use by system and application software implementing a flat-memory model. However, *these instructions are illegal in long mode and result in an undefined opcode exception (#UD) if software attempts to use them*. Software should use the SYSCALL and SYSRET instructions when running in long mode.

SYSENTER and SYSEXIT MSRs. Three model-specific registers (MSRs) are used to specify the target address and stack pointers for the SYSENTER instruction as well as the CS and SS selectors of the called and returned procedures. The register fields are:

- *SYSENTER Target CS*—Holds the CS selector of the called procedure.
- *SYSENTER Target ESP*—Holds the called-procedure stack pointer. The SS selector is updated automatically to point to the next descriptor entry after the SYSENTER Target CS, and ESP is the offset into that stack segment.
- *SYSENTER Target EIP*—Holds the offset into the CS of the called procedure.

Figure 6-2 shows the register formats and their corresponding MSR IDs.

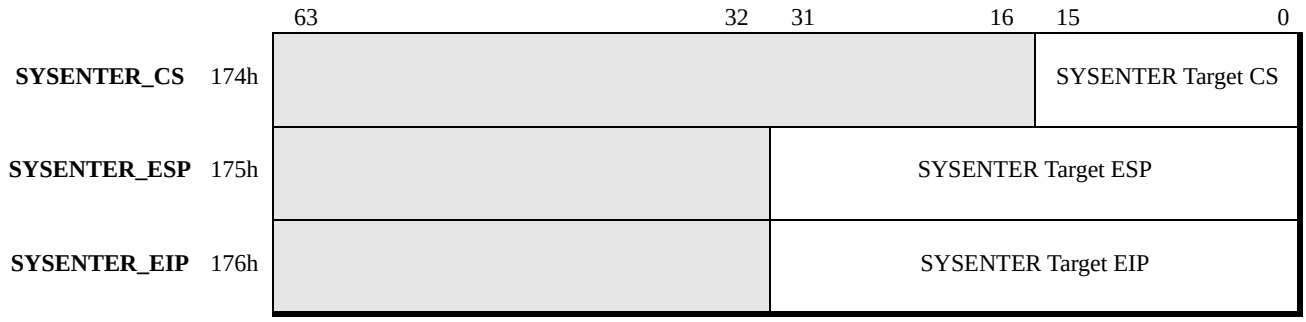

Figure 6-2. SYSENTER_CS, SYSENTER_ESP, SYSENTER_EIP MSRs

6.1.3 SWAPGS Instruction

The SWAPGS instruction provides a fast method for system software to load a pointer to system data structures. SWAPGS can be used upon entering system-software routines as a result of a SYSCALL instruction or as a result of an interrupt or exception. Before returning to application software, SWAPGS can restore an application data-structure pointer that was replaced by the system data-structure pointer.

SWAPGS exchanges the base-address value located in the KernelGSbase model-specific register (MSR address C000_0102h) with the base-address value located in the hidden portion of the GS selector register (GS.base). This exchange allows the system-kernel software to quickly access kernel data structures by using the GS segment-override prefix during memory references.

The need for SwapGS arises from the requirement that, upon entry to the OS kernel, the kernel needs to obtain a 64-bit pointer to its essential data structures. When using SYSCALL to implement system calls, no kernel stack exists at the OS entry point. Neither is there a straightforward method to obtain a pointer to kernel structures, from which the kernel stack pointer could be read. Thus, the kernel cannot save GPRs or reference memory. SwapGS does not require any GPR or memory operands, so no registers need to be saved before using it. Similarly, when the OS kernel is entered via an interrupt or exception (where the kernel stack is already set up), SwapGS can be used to quickly get a pointer to the kernel data structures.

See “FS and GS Registers in 64-Bit Mode” on page 80 for more information on using the GS.base register in 64-bit mode.

6.2 System Status and Control

System-status and system-control instructions are used to determine the features supported by a processor, gather information about the current execution state, and control the processor operating modes.

6.2.1 Processor Feature Identification (CPUID)

CPUID Instruction. The CPUID instruction provides complete information about the processor implementation and its capabilities. Software operating at any privilege level can execute the CPUID instruction to collect this information. System software normally uses the CPUID instruction to determine which optional features are available so the system can be configured appropriately. See Section 3.3, “Processor Feature Identification,” on page 71.

6.2.2 Accessing Control Registers

MOV CR*n* Instructions. The MOV CRn instructions can be used to copy data between the control registers and the general-purpose registers. These instructions are privileged and cause a general-protection exception (#GP) if non-privileged software attempts to execute them.

LMSW and SMSW Instructions. The machine status word is located in CR0 register bits 15:0. The *load machine status word* (LMSW) instruction writes only the least-significant four status-word bits (CR0[3:0]). All remaining status-word bits (CR0[15:4]) are left unmodified by the instruction. The instruction is privileged and causes a #GP to occur if non-privileged software attempts to execute it.

The *store machine status word* (SMSW) instruction stores all 16 status-word bits (CR0[15:0]) into the target GPR or memory location. The instruction is not privileged and can be executed by all software.

CLTS Instruction. The *clear task-switched bit* instruction (CLTS) clears CR0.TS to 0. The CR0.TS bit is set to 1 by the processor every time a task switch takes place. The bit is useful to system software in determining when the x87 and multimedia register state should be saved or restored. See “Task Switched (TS) Bit” on page 44 for more information on using CR0.TS to manage x87-instruction state. The CLTS instruction is privileged and causes a #GP to occur if non-privileged software attempts to execute it.

6.2.3 Accessing the RFLAGS Register

The RFLAGS register contains both application and system bits. This section describes the instructions used to read and write system bits. Descriptions of instruction effects on application flags can be found in “Flags Register” in Volume 1 and “Instruction Effects on rFLAGS” in Volume 3.

POPF and PUSHF Instructions. The *pop and push rFLAGS* instructions are used for moving data between the rFLAGS register and the stack. They are not strictly system instructions, but their behavior is mode-dependent.

CLI and STI Instructions. The *clear interrupt* (CLI) and *set interrupt* (STI) instructions modify only the RFLAGS.IF bit or RFLAGS.VIF bit. Clearing RFLAGS.IF to 0 causes the processor to ignore maskable interrupts. Setting RFLAGS.IF to 1 causes the processor to allow maskable interrupts.

See “Virtual Interrupts” on page 279 for more information on the operation of these instructions when virtual-8086 mode extensions are enabled (CR4.VME=1).

CLAC and STAC Instructions. The *clear alignment check flag (CLAC) and set alignment check flag (STAC)* instructions modify only the RFLAGS.AC bit.

6.2.4 Accessing Debug Registers

The MOV DR*n* instructions are used to copy data between the debug registers and the general-purpose registers. These instructions are privileged and cause a general-protection exception (#GP) if non-privileged software attempts to execute them. See “Debug Registers” on page 386 for a detailed description of the debug registers.

6.2.5 Accessing Model-Specific Registers

RDMSR and WRMSR Instructions. The *read/write model-specific register* instructions (RDMSR and WRMSR) can be used by privileged software to access the 64-bit MSRs. See “Model-Specific Registers (MSRs)” on page 59 for details about the MSRs.

RDPMC Instruction. The *read performance-monitoring counter* instruction, RDPMC, is used to read the model-specific performance-monitoring counter registers.

RDTSC Instruction. The *read time-stamp counter* instruction, RDTSC, is used to read the model-specific time-stamp counter (TSC) register.

RDTSCP Instruction. The *read time-stamp counter and processor ID* instruction, RDTSCP, is used to read the model-specific time-stamp counter (TSC) register. as well as the low 32 bits of the TSC_AUX register (MSR C000_0103h).

6.3 Segment Register and Descriptor Register Access

The AMD64 architecture supports the legacy instructions that load and store segment registers and descriptor registers. In some cases the instruction capabilities are expanded to support long mode.

6.3.1 Accessing Segment Registers

MOV, POP, and PUSH Instructions. The MOV and POP instructions can be used to load a selector into a segment register from a general-purpose register or memory (MOV) or from the stack (POP). Any segment register, except the CS register, can be loaded with the MOV and POP instructions. The CS register must be loaded with a far-transfer instruction.

All segment register selectors can be stored in a general-purpose register or memory using the MOV instruction or pushed onto the stack using the PUSH instruction.

When a selector is loaded into a segment register, the processor automatically loads the corresponding descriptor-table entry into the hidden portion of the selector register. The hidden portion contains the base address, limit, and segment attributes.

Segment-load and segment-store instructions work normally in 64-bit mode. The appropriate entry is read from the system descriptor table (GDT or LDT) and is loaded into the hidden portion of the segment descriptor register. However, the contents of data-segment and stack-segment descriptor registers are ignored, except in the case of the FS and GS segment-register base fields—see “FS and GS Registers in 64-Bit Mode” on page 80 for more information.

The ability to use segment-load instructions allows a 64-bit operating system to set up segment registers for a compatibility-mode application before switching to compatibility mode.

6.3.2 Accessing Segment Register Hidden State

WRMSR and RDMSR Instructions. The base address field of the hidden state of the FS and GS registers are mapped to MSRs and may be read and written by privileged software when running in 64-bit mode.

RDFSBASE, RDGSBASE, WRFSBASE, and WRGSBASE Instructions. When supported and enabled, these instructions allow software running at any privilege level to read and write the base address field of the hidden state of the FS and GS segment registers. These instructions are only defined in 64-bit mode.

6.3.3 Accessing Descriptor-Table Registers

LGDT and LIDT Instructions. The *load GDTR* (LGDT) and *load IDTR* (LIDT) instructions load a *pseudo-descriptor* from memory into the GDTR or IDTR registers, respectively.

LLDT and LTR Instructions. The *load LDTR* (LLDT) and *load TR* (LTR) instructions load a system-segment descriptor from the GDT into the LDTR and TR segment-descriptor registers (hidden portion), respectively.

SGDT and SIDT Instructions. The *store GDTR* (SGDT) and *store IDTR* (SIDT) instructions reverse the operation of the LGDT and LIDT instructions. SGDT and SIDT store a pseudo-descriptor from the GDTR or IDTR register into memory.

SLDT and STR Instructions. In all modes, the *store LDTR* (SLDT) and *store TR* (STR) instructions store the LDT or task selector from the visible portion of the LDTR or TR register into a general-purpose register or memory, respectively. The hidden portion of the LDTR or TR register is not stored.

6.4 Protection Checking

Several instructions are provided to allow software to determine the outcome of a protection check before performing a memory access that could result in a protection violation. By performing the checks before a memory access, software can avoid violations that result in a general-protection exception (#GP).

6.4.1 Checking Access Rights

LAR Instruction. The *load access-rights* (LAR) instruction can be used to determine if access to a segment is allowed, based on privilege checks and type checks. The LAR instruction uses a segment-selector in the source operand to reference a descriptor in the GDT or LDT. LAR performs a set of access-rights checks and, if successful, loads the segment-descriptor access rights into the destination register. Software can further examine the access-rights bits to determine if access into the segment is allowed.

6.4.2 Checking Segment Limits

LSL Instruction. The *load segment-limit* (LSL) instruction uses a segment-selector in the source operand to reference a descriptor in the GDT or LDT. LSL performs a set of preliminary access-rights checks and, if successful, loads the segment-descriptor limit field into the destination register. Software can use the limit value in comparisons with pointer offsets to prevent segment limit violations.

6.4.3 Checking Read/Write Rights

VERR and VERW Instructions. The *verify read-rights* (VERR) and *verify write-rights* (VERW) can be used to determine if a target code or data segment (not a system segment) can be read or written from the current privilege level (CPL). The source operand for these instructions is a pointer to the segment selector to be tested. If the tested segment (code or data) is readable from the current CPL, the VERR instruction sets RFLAGS.ZF to 1; otherwise, it is cleared to zero. Likewise, if the tested data segment is writable, the VERW instruction sets the RFLAGS.ZF to 1. A code segment cannot be tested for writability.

6.4.4 Adjusting Access Rights

ARPL Instruction. The *adjust RPL-field* (ARPL) instruction can be used by system software to prevent access into privileged-data segments by lower-privileged software. This can happen if an application passes a selector to system software and the selector RPL is less than (has greater privilege than) the calling-application CPL. To prevent this surrogate access, system software executes ARPL with the following operands:

- The destination operand is the data-segment selector passed to system software by the application.
- The source operand is the application code-segment selector (available on the system-software stack as a result of the CALL into system software by the application).

ARPL is not supported in 64-bit mode.

6.5 Processor Halt

The *processor halt* instruction (HLT) halts instruction execution, leaving the processor in the halt state. No registers or machine state are modified as a result of executing the HLT instruction. The processor remains in the halt state until one of the following occurs:

- A non-maskable interrupt (NMI).
- An enabled, maskable interrupt (INTR).
- Processor reset (RESET).
- Processor initialization (INIT).
- System-management interrupt (SMI).

6.6 Cache and TLB Management

Cache-management instructions are used by system software to maintain coherency within the memory hierarchy. Memory coherency and caches are discussed in Chapter 7, “Memory System.” Similarly, TLB-management instructions are used to maintain coherency between page translations cached in the TLB and the translation tables maintained by system software in memory. See “Translation-Lookaside Buffer (TLB)” on page 154 for more information.

6.6.1 Cache Management

WBINVD and WBNOINVD Instructions. The *writeback and invalidate* (WBINVD) and *writeback no invalidate* (WBNOINVD) instructions are used to write all modified cache lines to memory so that memory contains the most recent copy of data. After the writes are complete, the WBINVD instruction invalidates all cache lines, whereas the WBNOINVD instruction may leave the lines in the cache hierarchy in a non-modified state. These instructions operate on all caches in the memory hierarchy, including caches that are external to the processor. See the instructions' description in Volume 3 for further operational details.

INVD Instruction. The *invalidate* (INVD) instruction is used to invalidate all cache lines in all caches in the memory hierarchy. Unlike the WBINVD instruction, no modified cache lines are written to memory. The INVD instruction should only be used in situations where memory coherency is not required.

6.6.2 TLB Invalidation

INVLPG Instruction. The *invalidate TLB entry* (INVLPG) instruction can be used to invalidate specific entries within the TLB. The source operand is a virtual-memory address that specifies the TLB entry to be invalidated. Invalidating a TLB entry does not remove the associated page-table entry from the data cache. See “Translation-Lookaside Buffer (TLB)” on page 154 for more information.

INVLPGA Instruction. The *invalidate TLB entry in a Specified ASID* instruction (INVLPGA) can be used to invalidate TLB entries associated with the specified ASID. See “Invalidate Page, Alternate ASID” on page 514.

INVLPGB Instruction. The *invalidate TLB with Broadcast* instruction (INVLPGB) can be used to invalidate a specified range of TLB entries on the local processor and broadcast the invalidation to remote processors. See “INVLPGB” in Volume 3.

INVPCID Instruction. The *invalidate TLB entries in Specified PCID* instruction (INVPCID) can be used to invalidate TLB entries of the specified Processor Context ID. See “INVPCID” in Volume 3.

6.7 Shadow Stack Management

The following instructions are available to software for use in managing shadow stacks if the shadow stack feature is present as indicated by CPUID Fn0000_0007_x0_ECX[CET_SS] (bit 7) =1. Except for RDSSP, attempting to execute these instructions when shadow stacks are disabled results in a #UD exception. For more information refer to the detailed instruction descriptions in APM volume 3.

CLRSSBSY. Validates a shadow stack token and clears the tokens busy bit. This is a privileged instruction.

INCSSP. Increment SSP by ‘n’ stack frames. Used to pop unneeded items from a shadow stack.

RDSSP. Read the SSP into a GPR. Treated as a NOP if shadow stacks are disabled.

RSTORSSP. Used to switch shadow stacks. Expects a ‘shadow stack restore token’ at the top of the new shadow stack. Upon validating this token, sets the token’s busy bit and sets SSP to the top of the new shadow stack.

SAVEPREVSSP. Copies a ‘previous SSP token’ from the current shadow stack back to the previous stack for later use by an RSTORSSP instruction.

SETSSBSY. Validates the shadow stack token pointed to by the PL0_SSP MSR. If valid, sets the busy bit to 1 and sets SSP = PL0_SSP. This is a privileged instruction.

WRSS. Writes the source operand to a shadow stack. This instruction must be enabled in the U_CET and S_CET MSRs, otherwise a #UD is generated.

WRUSS. Writes the source operand to a user shadow stack. This is a privileged instruction.

7 Memory System

This chapter describes:

- Cache coherency mechanisms
- Cache control mechanisms
- Memory typing
- Memory mapped I/O
- Memory ordering rules
- Serializing instructions

Figure 7-1 on page 182 shows a conceptual picture of a processor and memory system, and how data and instructions flow between the various components. This diagram is not intended to represent a specific microarchitectural implementation but instead is used to illustrate the major memory-system components covered by this chapter.

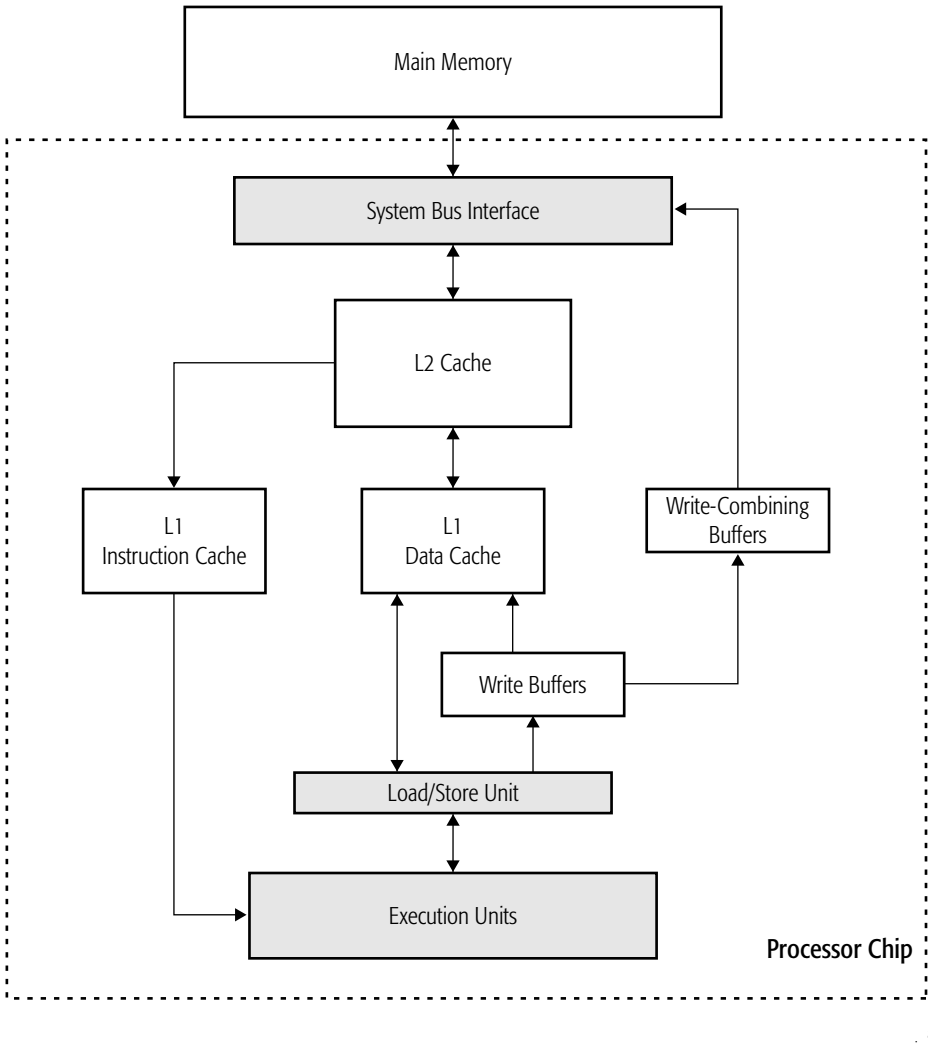

Figure 7-1. Processor and Memory System

The memory-system components described in this chapter are shown as *unshaded* boxes in Figure 7-1. Those items are summarized in the following paragraphs.

Main memory is external to the processor chip and is the memory-hierarchy level farthest from the processor execution units.

Caches are the memory-hierarchy levels closest to the processor execution units. They are much smaller and much faster than main memory, and can be either internal or external to the processor chip. Caches contain copies of the most frequently used instructions and data. By allowing fast access to frequently used data, software can run much faster than if it had to access that data from main memory. Figure 7-1 shows three caches, all internal to the processor:

- *L1 Data Cache*—The L1 (level-1) data cache holds the data most recently read or written by the software running on the processor.
- *L1 Instruction Cache*—The L1 instruction cache is similar to the L1 data cache except that it holds only the instructions executed most frequently. In some processor implementations, the L1 instruction cache can be combined with the L1 data cache to form a unified L1 cache.
- *L2 Cache*—The L2 (level-2) cache is usually several times larger than the L1 caches, but it is also slower. It is common for L2 caches to be implemented as a unified cache containing both instructions and data. Recently used instructions and data that do not fit within the L1 caches can reside in the L2 cache. The L2 cache can be exclusive, meaning it does not cache information contained in the L1 cache. Conversely, inclusive L2 caches contain a copy of the L1-cached information.

Memory-read operations from cacheable memory first check the cache to see if the requested information is available. A *read hit* occurs if the information is available in the cache, and a *read miss* occurs if the information is not available. Likewise, a *write hit* occurs if the memory write can be stored in the cache, and a *write miss* occurs if it cannot be stored in the cache.

Caches are divided into fixed-size blocks called *cache lines*. The cache allocates lines to correspond to regions in memory of the same size as the cache line, aligned on an address boundary equal to the cache-line size. For example, in a cache with 32-byte lines, the cache lines are aligned on 32-byte boundaries and byte addresses 0007h and 001Eh are both located in the same cache line. The size of a cache line is implementation dependent. Most implementations have either 32-byte or 64-byte cache lines. The implemented cache line size is reported by CPUID Fn8000_0005 and Fn8000_0006 for the various caches, as described in Appendix E of Volume 3.

The process of loading data into a cache is a *cache-line fill*. Even if only a single byte is requested, all bytes in a cache line are loaded from memory. Typically, a cache-line fill must remove (evict) an existing cache line to make room for the new line loaded from memory. This process is called *cache-line replacement*. If the existing cache line was modified before the replacement, the processor performs a cache-line *writeback* to main memory when it performs the cache-line fill.

Cache-line writebacks help maintain *coherency* between the caches and main memory. Internally, the processor can also maintain cache coherency by *internally probing* (checking) the other caches and write buffers for a more recent version of the requested data. External devices can also check processor caches for more recent versions of data by *externally probing* the processor. Throughout this document, the term *probe* is used to refer to external probes, while internal probes are always qualified with the word *internal*.

Write buffers temporarily hold data writes when main memory or the caches are busy with other memory accesses. The existence of write buffers is implementation dependent.

Implementations of the architecture can use *write-combining buffers* if the order and size of non-cacheable writes to main memory is not important to the operation of software. These buffers can combine multiple, individual writes to main memory and transfer the data in fewer bus transactions.

7.1 Single-Processor Memory Access Ordering

The flexibility with which memory accesses can be ordered is closely related to the flexibility in which a processor implementation can *execute* and *retire* instructions. Instruction execution *creates* results and status and determines whether or not the instruction causes an exception. Instruction retirement *commits* the results of instruction execution, in program order, to software-visible resources such as memory, caches, write-combining buffers, and registers, or it causes an exception to occur if instruction execution created one.

Implementations of the AMD64 architecture retire instructions in program order, but implementations can execute instructions in any order, subject only to data dependencies. Implementations can also *speculatively execute* instructions—executing instructions before knowing they are needed. Internally, implementations manage data reads and writes so that instructions complete in order. However, because implementations can execute instructions out of order and speculatively, the sequence of memory accesses performed by the hardware can appear to be out of program order. The following sections describe the rules governing memory accesses to which processor implementations adhere. These rules may be further restricted, depending on the memory type being accessed. Further, these rules govern single processor operation; see “Multiprocessor Memory Access Ordering” on page 186 for multiprocessor ordering rules.

7.1.1 Read Ordering

Generally, reads do not affect program order because they do not affect the state of software-visible resources other than register contents. However, some system devices might be sensitive to reads. In such a situation software can map a read-sensitive device to a memory type that enforces strong read-ordering, or use read/write barrier instructions to force strong read-ordering.

For cacheable memory types, the following rules govern read ordering:

- Out-of-order reads are allowed to the extent that they can be performed transparently to software, such that the appearance of in-order execution is maintained. Out-of-order reads can occur as a result of out-of-order instruction execution or speculative execution. The processor can read memory and perform cache refills out-of-order to allow out-of-order execution to proceed.
- Speculative reads are allowed. A speculative read occurs when the processor begins executing a memory-read instruction before it knows the instruction will actually complete. For example, the processor can predict a branch will occur and begin executing instructions following the predicted branch before it knows whether the prediction is valid. When one of the speculative instructions reads data from memory, the read itself is speculative. Cache refills may also be performed speculatively.
- Reads can be reordered ahead of writes. Reads are generally given a higher priority by the processor than writes because instruction execution stalls if the read data required by an instruction is not immediately available. Allowing reads ahead of writes usually maximizes software performance.
- A read *cannot* be reordered ahead of a prior write if the read is from the same location as the prior write. In this case, the read instruction stalls until the write instruction completes execution. The

read instruction requires the result of the write instruction for proper software operation. For cacheable memory types, the write data can be forwarded to the read instruction before it is actually written to memory.

- Instruction fetching constitutes a parallel, asynchronous stream of reads that is independent from and unordered with respect to the read accesses performed by loads in that instruction stream.

7.1.2 Write Ordering

Writes affect program order because they affect the state of software-visible resources. The following rules govern write ordering:

- Generally, out-of-order writes are *not* allowed. Write instructions executed out of order cannot commit (write) their result to memory until all previous instructions have completed in program order. The processor can, however, hold the result of an out-of-order write instruction in a private buffer (not visible to software) until that result can be committed to memory.
- It is possible for writes to *write-combining* memory types to appear to complete out of order, relative to writes into other memory types. See “Memory Types” on page 192 and “Write Combining” on page 198 for additional information.
- Speculative writes are *not* allowed. As with out-of-order writes, speculative write instructions cannot commit their result to memory until all previous instructions have completed in program order. Processors can hold the result in a private buffer (not visible to software) until the result can be committed.
- Write buffering is allowed. When a write instruction completes and commits its result, that result can be buffered until it is actually written to system memory in program order. Although the write buffer itself is not directly accessible by software, the results in the buffer are accessible by subsequent memory accesses to the locations that are buffered, including reads for which only a subset of bytes being accessed are in the buffer. For example, a doubleword read that overlaps a single modified byte in the write buffer can return the buffered value for that byte before that write has been committed to memory.

  In general, any read from cacheable memory returns the net result of all prior globally and locally visible writes to those bytes, as performed in program order. A given implementation may provide bytes from the write buffer to satisfy this, or may stall the read until any overlapping buffered writes have been committed to memory. For cacheable memory types, the write buffer can be read out-of-order and speculatively, just like memory.
- Write combining is allowed. In some situations software can relax the write-ordering rules through the use of a Write Combining memory type or non-temporal store instructions, and allow several writes to be combined into fewer writes to memory. When write-combining is used, it is possible for writes to other memory types to proceed ahead of (out-of-order) memory-combining writes, unless the writes are to the same address. Write-combining should be used only when the order of writes does not affect program order (for example, writes to a graphics frame buffer).

7.1.3 Read/Write Barriers

When the order of memory accesses must be strictly enforced, software can use read/write barrier instructions to force reads and writes to proceed in program order. Read/write barrier instructions force all prior reads or writes to complete before subsequent reads or writes are executed. The LFENCE, SFENCE, and MFENCE instructions are provided as dedicated read, write, and read/write barrier instructions (respectively). Serializing instructions, I/O instructions, and locked instructions (including the implicitly locked XCHG instruction) can also be used as read/write barriers. Barrier instructions are useful for controlling ordering between differing memory types as well as within one memory type; see Section 7.3.1, “Special Coherency Considerations,” on page 191 for details.

Table 7-1 on page 194 summarizes the memory-access ordering possible for each memory type supported by the AMD64 architecture.

7.2 Multiprocessor Memory Access Ordering

The term memory ordering refers to the sequence in which memory accesses are performed by the memory system, as observed by all processors or programs.

To improve performance of applications, AMD64 processors can speculatively execute instructions out of program order and temporarily hold out-of-order results. However, certain rules are followed with regard to normal cacheable accesses on naturally aligned boundaries to WB memory.

In the examples below, all memory values are initialized to zero.

From the point of view of a program, in ascending order of priority:

- All loads, stores and I/O operations from a single processor appear to occur in program order to the code running on that processor and all instructions appear to execute in program order.
- Successive stores from a single processor are committed to system memory and visible to other processors in program order. A store by a processor cannot be committed to memory before a read appearing earlier in the program has captured its targeted data from memory. In other words, stores from a processor cannot be reordered to occur prior to a load preceding it in program order.

  In this context:

  - Loads do not pass previous loads (loads are not reordered). Stores do not pass previous stores (stores are not reordered)

Processor 0	**Processor 1**
Store A ← 1	Load B
Store B ← 1	Load A

    Load A cannot read 0 when Load B reads 1. (This rule may be violated in the case of loads as part of a string operation, in which one iteration of the string reads 0 for Load A while another iteration reads 1 for Load B.)
  - Stores do not pass loads

Processor 0	Processor 1
Load A	Load B
Store B ← 1	Store A ← 1

Load A and Load B cannot both read 1.

- Stores from a processor appear to be committed to the memory system in program order; however, stores can be delayed arbitrarily by store buffering while the processor continues operation. Therefore, stores from a processor may not appear to be sequentially consistent.

Processor 0	Processor 1
Store A ← 1	Store B ← 1
…	…
Store A ← 2	Store B ← 2
…	…
Load B	Load A

Both Load A and Load B may read 1. Also, due to possible write combining one or both processors may not actually store a 1 at the designated location.

- Non-overlapping Loads may pass stores.

Processor 0	Processor 1
Store A ← 1	Store B ← 1
Load B	Load A

All combinations of values (00, 01, 10, and 11) may be observed by Processors 0 and 1.

- Where sequential consistency is needed (for example in Dekker's algorithm for mutual exclusion), an MFENCE instruction should be used between the store and the subsequent load, or a locked access, such as XCHG, should be used for the store.

Processor 0	Processor 1
Store A ← 1	Store B ← 1
MFENCE	MFENCE
Load B	Load A

Load A and Load B cannot both read 0.

- Loads that partially overlap prior stores may return the modified part of the load operand from the store buffer, combining globally visible bytes with bytes that are only locally visible. To ensure that such loads return only a globally visible value, an MFENCE or locked access must be used between the store and the dependent load, or the store or load must be performed with a locked operation such as XCHG.

- Stores to different locations in memory observed from two (or more) other processors will appear in the same order to all observers. Behavior such as that shown in this code example,

Processor 0	Processor 1	Processor X	Processor Y
Store A ← 1	Store B ← 1		
		Load A (1)	Load B (1)
		Load B (0)	Load A (0)

in which processor X sees store A from processor 0 before store B from processor 1, while processor Y sees store B from processor 1 before store A from processor 0, is not allowed.

- Dependent stores between different processors appear to occur in program order, as shown in the code example below.

Processor 0	Processor 1	Processor 2
Store A ← 1		
	Load A (1)	
	Store B ← 1	
		Load B (1)
		Load A (1)

If processor 1 reads a value from A (written by processor 0) before carrying out a store to B, and if processor 2 reads the updated value from B, a subsequent read of A must also be the updated value.

- The local visibility (within a processor) for a memory operation may differ from the global visibility (from another processor). Using a data bypass, a local load can read the result of a local store in a store buffer, before the store becomes globally visible. Program order is still maintained when using such bypasses.

Processor 0	Processor 1
Store A ← 1	Store B ← 1
Load r1 A	Load r3 B
Load r2 B	Load r4 A

Load A in processor 0 can read 1 using the data bypass, while Load A in processor 1 can read 0. Similarly, Load B in processor 1 can read 1 while Load B in processor 0 can read 0. Therefore, the result r1 = 1, r2 = 0, r3 = 1 and r4 = 0 may occur. There are no constraints on the relative order of when the Store A of processor 0 is visible to processor 1 relative to when the Store B of processor 1 is visible to processor 0.

If a very strong memory ordering model is required that does not allow local store-load bypasses, an MFENCE instruction or a synchronizing instruction such as XCHG or a locked Read-modify-write should be used between the store and the subsequent load. This enforces a memory ordering stronger than total store ordering.

Processor 0	Processor 1
Store A ← 1	Store B ← 1
MFENCE	MFENCE

Processor 0	Processor 1
Load r1 A	Load r3 B
Load r2 B	Load r4 A

In this example, the MFENCE instruction ensures that any buffered stores are globally visible before the loads are allowed to execute, so the result r1 = 1, r2 = 0, r3 = 1 and r4 = 0 will not occur.

7.3 Memory Coherency and Protocol

Implementations that support caching support a cache-coherency protocol for maintaining coherency between main memory and the caches. The cache-coherency protocol is also used to maintain coherency between all processors in a multiprocessor system. The cache-coherency protocol supported by the AMD64 architecture is the *MOESI* (modified, owned, exclusive, shared, invalid) protocol. The states of the MOESI protocol are:

- *Invalid*—A cache line in the invalid state does not hold a valid copy of the data. Valid copies of the data can be either in main memory or another processor cache.
- *Exclusive*—A cache line in the exclusive state holds the most recent, correct copy of the data. The copy in main memory is also the most recent, correct copy of the data. No other processor holds a copy of the data.
- *Shared*—A cache line in the shared state holds the most recent, correct copy of the data. Other processors in the system may hold copies of the data in the shared state, as well. If no other processor holds it in the *owned* state, then the copy in main memory is also the most recent.
- *Modified*—A cache line in the modified state holds the most recent, correct copy of the data. The copy in main memory is stale (incorrect), and no other processor holds a copy.
- *Owned*—A cache line in the owned state holds the most recent, correct copy of the data. The owned state is similar to the shared state in that other processors can hold a copy of the most recent, correct data. Unlike the shared state, however, the copy in main memory can be stale (incorrect). Only one processor can hold the data in the owned state—all other processors must hold the data in the shared state.

Figure 7-2 on page 190 shows the general MOESI state transitions possible with various types of memory accesses. This is a logical software view, not a hardware view, of how cache-line state transitions. Instruction-execution activity and external-bus transactions can both be used to modify the cache MOESI state in multiprocessing or multi-mastering systems.

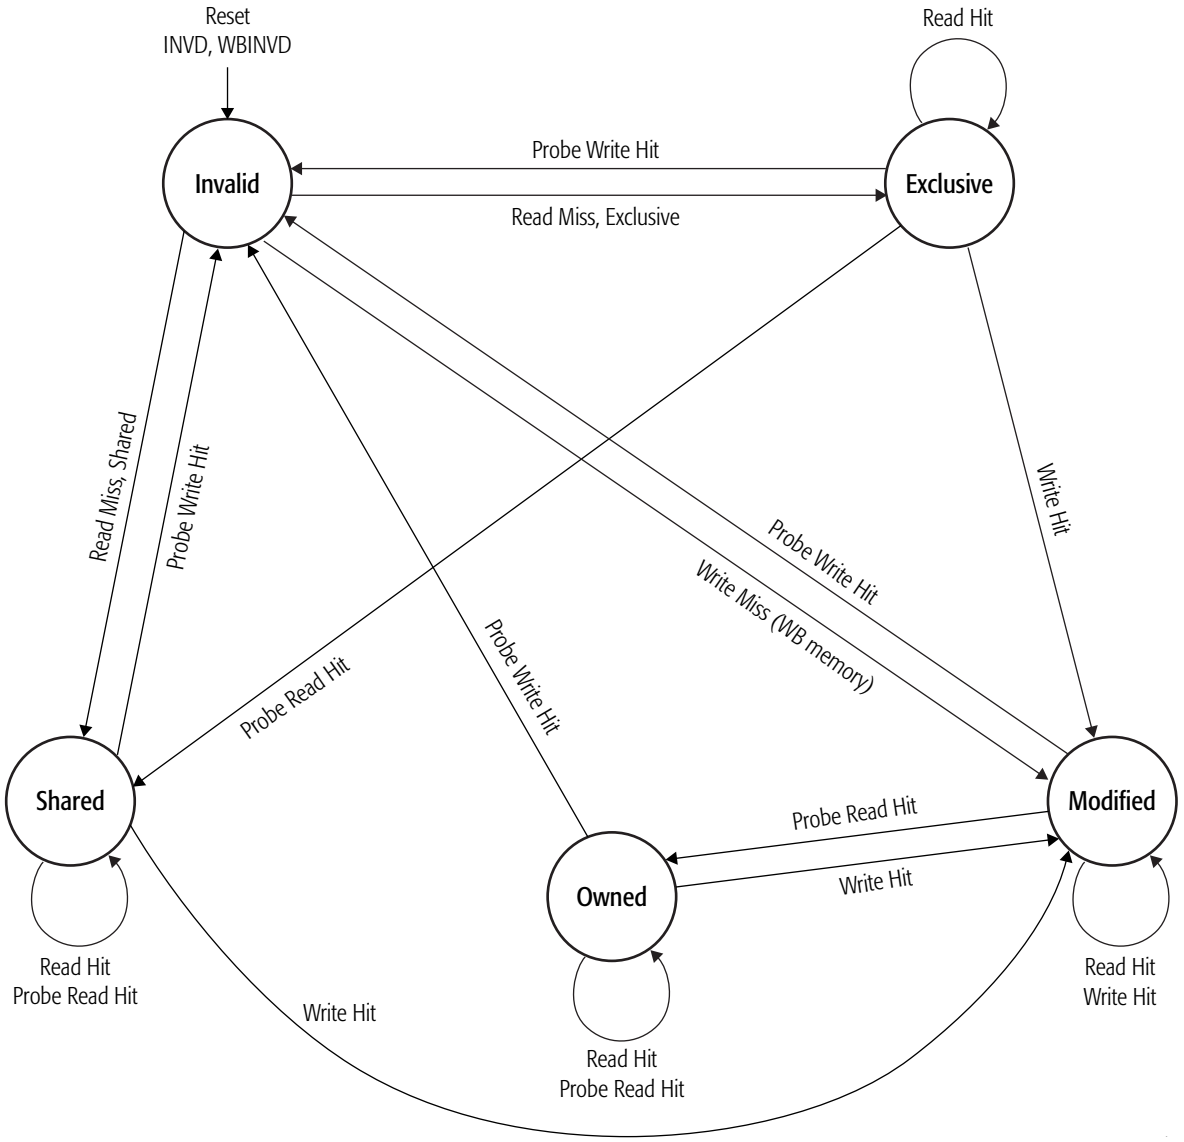

Figure 7-2. MOESI State Transitions

To maintain memory coherency, external bus masters (typically other processors with their own internal caches) need to acquire the most recent copy of data before caching it internally. That copy can be in main memory or in the internal caches of other bus-mastering devices. When an external master has a cache read-miss or write-miss, it *probes* the other mastering devices to determine whether the most recent copy of data is held in any of their caches. If one of the other mastering devices holds the most recent copy, it provides it to the requesting device. Otherwise, the most recent copy is provided by main memory.

There are two general types of bus-master probes:

- Read probes indicate the external master is requesting the data for read purposes.
- Write probes indicate the external master is requesting the data for the purpose of modifying it.

Referring back to Figure 7-2 on page 190, the state transitions involving probes are initiated by other processors and external bus masters into the processor. Some read probes are initiated by devices that intend to cache the data. Others, such as those initiated by I/O devices, do not intend to cache the data. Some processor implementations do not change the data MOESI state if the read probe is initiated by a device that does not intend to cache the data.

State transitions involving read misses and write misses can cause the processor to generate probes into external bus masters and to read main memory.

Read hits do not cause a MOESI-state change. Write hits generally cause a MOESI-state change into the modified state. If the cache line is already in the modified state, a write hit does not change its state.

The specific operation of external-bus signals and transactions and how they influence a cache MOESI state are implementation dependent. For example, an implementation could convert a write miss to a WB memory type into two separate MOESI-state changes. The first would be a read-miss placing the cache line in the exclusive state. This would be followed by a write hit into the exclusive cache line, changing the cache-line state to modified.

7.3.1 Special Coherency Considerations

In some cases, data can be modified in a manner that is impossible for the memory-coherency protocol to handle due to the effects of instruction prefetching. In such situations software must use serializing instructions and/or cache-invalidation instructions to ensure subsequent data accesses are coherent.

An example of this type of a situation is a page-table update followed by accesses to the physical pages referenced by the updated page tables. The following sequence of events shows what can happen when software changes the translation of virtual-page *A* from physical-page *M* to physical-page *N*:

1. Software invalidates the TLB entry. The tables that translate virtual-page *A* to physical-page *M* are now held only in main memory. They are not cached by the TLB.
2. Software changes the page-table entry for virtual-page A in main memory to point to physical-page *N* rather than physical-page *M*.
3. Software accesses data in virtual-page A.

During Step 3, software expects the processor to access the data from physical-page *N*. However, it is possible for the processor to prefetch the data from physical-page *M* before the page table for virtual-page *A* is updated in Step 2. This is because the physical-memory references for the *page tables* are different than the physical-memory references for the *data*. Because the physical-memory references are different, the processor does not recognize them as requiring coherency checking and believes it is safe to prefetch the data from virtual-page A, which is translated into a read from physical page M. Similar behavior can occur when instructions are prefetched from beyond the page table update instruction.

To prevent this problem, software must use an INVLPG or MOV CR3 instruction immediately after the page-table update to ensure that subsequent instruction fetches and data accesses use the correct virtual-page-to-physical-page translation. It is not necessary to perform a TLB invalidation operation preceding the table update.

7.3.2 Access Atomicity

Cacheable, naturally-aligned single loads or stores of up to a quadword are atomic on any processor model, as are misaligned loads or stores of less than a quadword that are contained entirely within a naturally-aligned quadword. Misaligned load or store accesses typically incur a small latency penalty. Model-specific relaxations of this quadword atomicity boundary, with respect to this latency penalty, may be found in a given processor's Software Optimization Guide.

Misaligned accesses can be subject to interleaved accesses from other processors or cache-coherent devices which can result in unintended behavior. Atomicity for misaligned accesses can be achieved where necessary by using the XCHG instruction or any suitable LOCK-prefixed instruction. Note that misaligned locked accesses may incur a significant performance penalty on various processor models.

7.4 Memory Types

Memory type is an attribute that can be associated with a specific region of virtual or physical memory. Memory type designates certain caching and ordering behaviors for loads and stores to addresses in that region. Most memory types are explicitly assigned, although some are inferred by the hardware from current processor state and instruction context.

The AMD64 architecture defines the following memory types:

- *Uncacheable (UC)*—Reads from, and writes to, UC memory are not cacheable. Reads from UC memory cannot be speculative. Write-combining to UC memory is not allowed. Reads from or writes to UC memory cause the write buffers to be written to memory and be invalidated prior to the access to UC memory.

  The UC memory type is useful for memory-mapped I/O devices where strict ordering of reads and writes is important. Note that this strong ordering is with respect to UC accesses only; reads to memory types which support speculative operation may bypass non-conflicting UC accesses.
- *Cache Disable (CD)*—The CD memory type is a form of uncacheable memory type that is inferred when the L1 caches are disabled but not invalidated, or for certain conflicting memory type assignments from the Page Attribute Table (PAT) and Memory Type Range Register (MTRR) mechanisms. The former case occurs when caches are disabled by setting CR0.CD to 1 without invalidating the caches with either the INVD or WBINVD instruction for any reference to a region designated as cacheable. The latter case occurs when a specific type has been assigned to a virtual page via PAT, and a conflicting type has been assigned to the mapped physical page via an MTRR (see “Combined Effect of MTRRs and PAT” on page 221 and “Combining Memory Types, MTRRs” on page 536 for details).

  For the L1 data cache and the L2 cache, reads from, and writes to, CD memory that hit the cache, or any other caches in the system, cause the cache line(s) to be invalidated before accessing main

memory. If a cache line is in the modified state, the line is written to main memory prior to being invalidated. The access is allowed to proceed after any invalidations are complete.

For the L1 instruction cache, instruction fetches from CD memory that hit the cache read the cached instructions rather than access main memory. Instruction fetches that miss the cache access main memory and do not cause cache-line replacement. Writes to CD memory that hit in the instruction cache cause the line to be invalidated.

- *Write-Combining (WC)*—Reads from, and writes to, WC memory are not cacheable. Reads from WC memory can be speculative.

  Writes to this memory type can be combined internally by the processor and written to memory as a single write operation to reduce memory accesses. For example, four word writes to consecutive addresses can be combined by the processor into a single quadword write, resulting in one memory access instead of four.

  The WC memory type is useful for graphics-display memory buffers where the order of writes is not important.

- *Write-Combining Plus (WC+)*—WC+ is an uncacheable memory type, and combines writes in write-combining buffers like WC. Unlike WC (but like the CD memory type), accesses to WC+ memory probe the caches on all processors (including the caches of the processor issuing the request) to maintain coherency. This ensures that cacheable writes are observed by WC+ accesses.

- *Write-Protect (WP)*—Reads from WP memory are cacheable and allocate cache lines on a read miss. Reads from WP memory can be speculative.

  Writes to WP memory that hit in the cache do not update the cache. Instead, all writes update memory (write to memory), and writes that hit in the cache invalidate the cache line. Write buffering of WP memory is allowed.

  The WP memory type is useful for shadowed-ROM memory where updates must be immediately visible to all devices that read the shadow locations.

- *Writethrough (WT)*—Reads from WT memory are cacheable and allocate cache lines on a read miss. Reads from WT memory can be speculative.

  All writes to WT memory update main memory, and writes that hit in the cache update the cache line (cache lines remain in the same state after a write that hits a cache line). Writes that miss the cache do not allocate a cache line. Write buffering of WT memory is allowed.

- *Writeback (WB)*—Reads from WB memory are cacheable and allocate cache lines on a read miss. Cache lines can be allocated in the shared, exclusive, or modified states. Reads from WB memory can be speculative.

  All writes that hit in the cache update the cache line and place the cache line in the modified state. Writes that miss the cache allocate a new cache line and place the cache line in the modified state. Writes to main memory only take place during writeback operations. Write buffering of WB memory is allowed.

  The WB memory type provides the highest-possible performance and is useful for most software and data stored in system memory (DRAM).

Table 7-1 shows the memory access ordering possible for each memory type supported by the AMD64 architecture. Table 7-3 on page 196 shows the ordering behavior of various operations on various memory types in greater detail. Table 7-2 on page 194 shows the caching policy for the same memory types.

Table 7-1. Memory Access by Memory Type

Memory Access Allowed		Memory Type				
		UC/CD	WC	WP	WT	WB
Read	Out-of-Order	no	yes	yes	yes	yes
	Speculative	no	yes	yes	yes	yes
	Reorder Before Write	no	yes	yes	yes	yes
Write	Out-of-Order	no	yes	no	no	no
	Speculative	no	no	no	no	no
	Buffering	no	yes	yes	yes	yes
	Combining[1]	no	yes	no	yes	yes

Note:
1. *Write-combining buffers are separate from write (store) buffers.*

Table 7-2. Caching Policy by Memory Type

Caching Policy	Memory Type					
	UC	CD	WC	WP	WT	WB
Read Cacheable	no	no	no	yes	yes	yes
Write Cacheable	no	no	no	no	yes	yes
Read Allocate	no	no	no	yes	yes	yes
Write Allocate	no	no	no	no	no	yes
Write Hits Update Memory	yes[2]	yes[1]	yes[2]	yes[3]	yes	no

Note:
1. *For the L1 data cache and the L2 cache, if an access hits the cache, the cache line is invalidated. If the cache line is in the modified state, the line is written to main memory and then invalidated. For the L1 instruction cache, read (instruction fetch) hits access the cache rather than main memory.*
2. *The data is not cached, so a cache write hit cannot occur. However, memory is updated.*
3. *Write hits update memory and invalidate the cache line.*

7.4.1 Instruction Fetching from Uncacheable Memory

Instruction fetches from an uncacheable memory type (including those for the CD type which don't hit in the instruction cache) may read a naturally-aligned block of memory no larger than an instruction cache line that contains multiple instructions, and may or may not repeat reads of a given block in the course of extracting instructions from it. In general, the exact sequence of read accesses is not deterministic, regardless of instruction stream contents, aside from the following constraints:

- instruction fetching of branch targets from uncacheable memory will only be done non-speculatively

- sequential instruction fetching will not transition speculatively from a cacheable memory type to an uncacheable memory type
- sequential instruction fetching will not speculatively cross more than one 4KB page boundary

It is recommended that MMIO devices that have read side-effects be separated from memory that's subject to uncacheable instruction fetches by at least one 4KB page.

7.4.2 Memory Barrier Interaction with Memory Types

Memory types other than WB may allow weaker ordering in certain respects. When the ordering of memory accesses to differing memory types must be strictly enforced, software can use the LFENCE, MFENCE or SFENCE barrier instructions to force loads and stores to proceed in program order. Table 7-3 on page 196 summarizes the cases where a memory barrier must be inserted between two memory operations.

The table is read as follows: the ROW is the first memory operation in program order, followed by the COLUMN, which is the second memory operation in program order. Each cell represents the ordered combination of the two memory operations and the letters *a*, *b*, *c*, *d*, *e*, *f*, *g*, *h*, *i*, *j*, *k*, and *l* within the cell represent the applicable memory ordering rule for that combination. These symbols are described in the footnotes below the table. In the table and footnotes, the abbreviation *nt* stands for non-temporal (load or store), *io* stands for input / output, *lf* for LFENCE, *sf* for SFENCE, and *mf* for MFENCE.

Table 7-3. Memory Access Ordering Rules

First Memory Operation	Second Memory Operation								
	Load (wp, wt, wb)	Load (uc)	Load (wc, wc+)	Store (wp, wt, wb)	Store (uc)	Store (wc, wc+, non-temporal)	Load/Store (io)	Lock (atomic)	Serialize instructions/ Interrupts/Exceptions
Load (wp, wt, wb)	a	f	b (lf)	c	c	c	d	d	d
Load (uc)	a	f	b (lf)	c	c	c	d	d	d
Load (wc, wc+)	a	f	b (lf)	c	c	c	d	d	d
Store (wp, wt, wb)	e (mf)	f	e (mf)	g	g	h (sf)	d	d	d
Store (uc)	i	f	i	g	g	h (sf)	d	d	d
Store (wc, wc+, non-temporal)	e (mf)	f	e (mf)	j (sf)	g, m	h (sf)	d	d	d
Load/Store (io)	k	k	k	k	k	l	d, k	d, k	d, k
Lock (atomic)	k	k	k	k	k	k	d, k	d, k	d, k
Serialize instruction/ Interrupts/Exceptions	l	l	l	l	l	l	d, l	d, l	d, l

a — A load (wp, wt, wb) may not pass a previous load (wp, wt, wb, wc, wc+, uc).

b — A load (wc, wc+) may pass a previous load (wp, wt, wb, wc, wc+). To ensure memory order, an LFENCE instruction must be inserted between the two loads.

c — A store (wp, wt, wb, uc, wc, wc+, nt) may not pass a previous load (wp, wt, wb, uc, wc, wc+, nt).

d — All previous loads and stores complete to memory or I/O space before a memory access for an I/O, locked or serializing instruction is issued.

e — A load (wp, wt, wb, wc, wc+) may pass a previous non-conflicting store (wp, wt, wb, wc, wc+, nt). To ensure memory order, an MFENCE instruction must be inserted between the store and the load.

f — A load or store (uc) does not pass a previous load or store (wp, wt, wb, uc, wc, wc+, nt).

g — A store (wp, wt, wb, uc) does not pass a previous store (wp, wt, wb, uc).

h — A store (wc, wc+, nt) may pass a previous store (wp, wt, wb) or non-conflicting store (wc, wc+, nt). To ensure memory order, an SFENCE instruction must be inserted between these two stores. A store (wc, wc+, nt) does not pass a previous conflicting store (wc, wc+, nt, uc).

i — A load (wp, wt, wb, wc, wc+) may pass a previous non-conflicting store (uc). To ensure memory order, an MFENCE instruction must be inserted between the store and the load.

j — A store (wp, wt, wb) may pass a previous store (wc, wc+, nt). To ensure memory order, an SFENCE instruction must be inserted between these two stores.

k — All loads and stores associated with the I/O and locked instructions complete to memory (no buffered stores) before a load or store from a subsequent instruction is issued.

l — All loads and stores complete to memory for the serializing instruction before the subsequent instruction fetch is issued.

m — A store (uc) does not pass a previous store (wc, wc+).

7.5 Buffering and Combining Memory Writes

7.5.1 Write Buffering

Writes to memory (main memory and caches) can be stored internally by the processor in *write buffers* (also known as store buffers) before actually writing the data into a memory location. System performance can be improved by buffering writes, as shown in the following examples:

- When higher-priority memory transactions, such as reads, compete for memory access with writes, writes can be delayed in favor of reads, which minimizes or eliminates an instruction-execution stall due to a memory-operand read.
- When the memory is busy, buffering writes while the memory is busy removes the writes from the instruction-execution pipeline, which frees instruction-execution resources.

The processor manages the write buffer so that it is transparent to software. Memory accesses check the write buffer, and the processor completes writes into memory from the buffer in program order. Also, the processor completely empties the write buffer by writing the contents to memory as a result of performing any of the following operations:

- *SFENCE Instruction*—Executing a store-fence (SFENCE) instruction forces all memory writes before the SFENCE (in program order) to be written into memory (or, for WB type, the cache) before memory writes that follow the SFENCE instruction. The memory-fence (MFENCE) instruction has a similar effect, but it forces the ordering of loads in addition to stores.
- *Serializing Instructions*—Executing a serializing instruction forces the processor to retire the serializing instruction (complete both instruction execution and result writeback) before the next instruction is fetched from memory.
- *I/O instructions*—Before completing an I/O instruction, all previous reads and writes must be written to memory, and the I/O instruction must complete before completing subsequent reads or writes. Writes to I/O-address space (OUT instruction) are never buffered.
- *Locked Instructions*—A locked instruction (an instruction executed using the LOCK prefix) or an XCHG instruction (which is implicitly locked) must complete *after* all previous reads and writes and *before* subsequent reads and writes. Locked writes are never buffered, although locked reads and writes are cacheable.
- *Interrupts and Exceptions*—Interrupts and exceptions, including virtualization intercepts (#VMEXIT), are serializing events that force the processor to write all results from the write buffer to memory before fetching the first instruction from the interrupt or exception service routine.
- *UC Memory Reads*—UC memory reads are not reordered ahead of writes.

Write buffers can behave similarly to *write-combining buffers* because multiple writes may be collected internally before transferring the data to caches or main memory. See the following section for a description of write combining.

7.5.2 Write Combining

Write-combining memory uses a different buffering scheme than write buffering described above. Writes to write-combining (WC) memory can be combined internally by the processor in a buffer for more efficient transfer to main memory at a later time. For example, 16 doubleword writes to consecutive memory addresses can be combined in the WC buffers and transferred to main memory as a single burst operation rather than as individual memory writes.

The following instructions perform writes to WC memory:

- (V)MASKMOVDQU
- MASKMOVQ
- (V)MOVNTDQ
- MOVNTI
- (V)MOVNTPD
- (V)MOVNTPS
- MOVNTQ
- MOVNTSD
- MOVNTSS

WC memory is not cacheable. A WC buffer writes its contents only to main memory.

The size and number of WC buffers available is implementation dependent. The processor assigns an address range to an empty WC buffer when a WC-memory write occurs. The size and alignment of this address range is equal to the buffer size. All subsequent writes to WC memory that fall within this address range can be stored by the processor in the WC-buffer entry until an event occurs that causes the processor to write the WC buffer to main memory. After the WC buffer is written to main memory, the processor can assign a new address range on a subsequent WC-memory write.

Writes to consecutive addresses in WC memory are not required for the processor to combine them. The processor combines any WC memory write that falls within the active-address range for a buffer. Multiple writes to the same address overwrite each other (in program order) until the WC buffer is written to main memory.

It is possible for writes to proceed out of program order when WC memory is used. For example, a write to cacheable memory that follows a write to WC memory can be written into the cache before the WC buffer is written to main memory. For this reason, and the reasons listed in the previous paragraph, software that is sensitive to the order of memory writes should avoid using WC memory.

WC buffers are written to main memory under the same conditions as the write buffers, namely when:

- Executing a store-fence (SFENCE) instruction.

- Executing a serializing instruction.
- Executing an I/O instruction.
  - Executing an MMIO access (load or store to UC memory type)
- Executing a locked instruction (an instruction executed using the LOCK prefix).
- Executing an XCHG instruction
- An interrupt or exception occurs.

WC buffers are also written to main memory when:

- A subsequent non-write-combining operation has a write address that matches the WC-buffer active-address range.
- A write to WC memory falls outside the WC-buffer active-address range. The existing buffer contents are written to main memory, and a new address range is established for the latest WC write.

7.6 Memory Caches

The AMD64 architecture supports the use of internal and external caches. The size, organization, coherency mechanism, and replacement algorithm for each cache is implementation dependent. Generally, the existence of the caches is transparent to both application and system software. In some cases, however, software can use cache-structure information to optimize memory accesses or manage memory coherency. Such software can use the extended-feature functions of the CPUID instruction to gather information on the caching subsystem supported by the processor. For more information, see Section 3.3, “Processor Feature Identification,” on page 71.

7.6.1 Cache Organization and Operation

Although the detailed organization of a processor cache depends on the implementation, the general constructs are similar. L1 caches—data and instruction, or unified—and L2 caches usually are implemented as n-way set-associative caches. Figure 7-3 on page 200 shows a typical *logical* organization of an n-way set-associative cache. The physical implementation of the cache can be quite different.

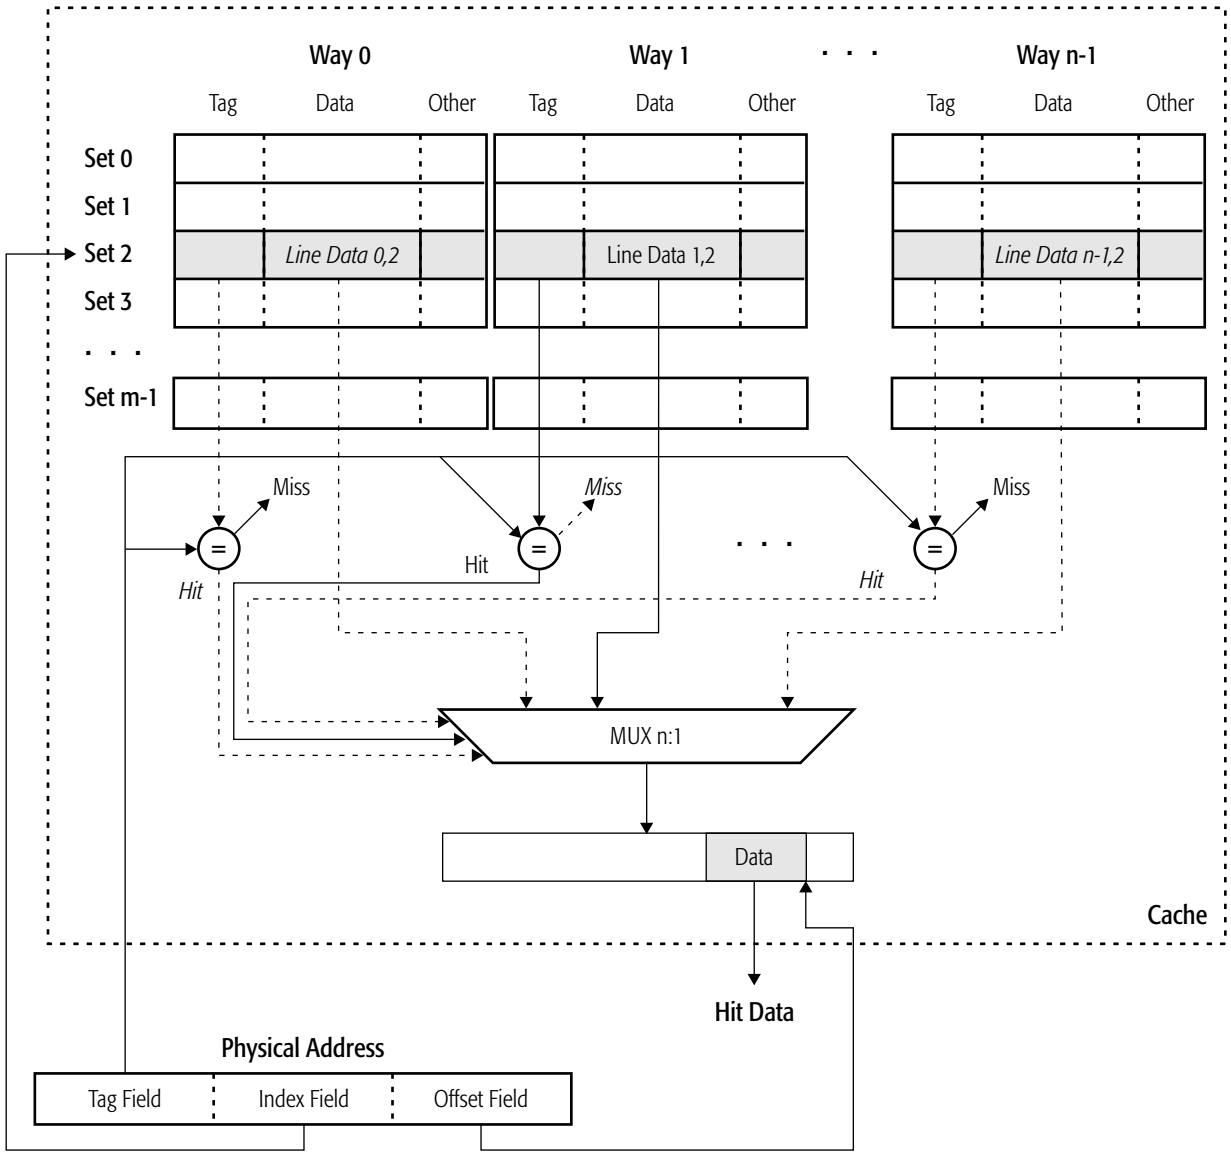

Figure 7-3. Cache Organization Example

As shown in Figure 7-3, the cache is organized as an array of cache lines. Each cache line consists of three parts: a cache-data line (a fixed-size copy of a memory block), a tag, and other information. Rows of cache lines in the cache array are *sets*, and columns of cache lines are *ways*. In an n-way set-associative cache, each set is a collection of n lines. For example, in a four-way set-associative cache, each set is a collection of four cache lines, one from each way.

The cache is accessed using the physical address of the data or instruction being referenced. To access data within a cache line, the physical address is used to select the set, way, and byte from the cache. This is accomplished by dividing the physical address into the following three fields:

- *Index*—The *index field* selects the cache set (row) to be examined for a hit. All cache lines within the set (one from each way) are selected by the index field.
- *Tag*—The *tag field* is used to select a specific cache line from the cache set. The physical-address tag field is compared with each cache-line tag in the set. If a match is found, a cache hit is signalled, and the appropriate cache line is selected from the set. If a match is not found, a cache miss is signalled.
- *Offset*—The *offset field* points to the first byte in the cache line corresponding to the memory reference. The referenced data or instruction value is read from (or written to, in the case of memory writes) the selected cache line starting at the location selected by the offset field.

In Figure 7-3 on page 200, the physical-address index field is shown selecting Set 2 from the cache. The tag entry for each cache line in the set is compared with the physical-address tag field. The tag entry for Way 1 matches the physical-address tag field, so the cache-line data for Set 2, Way 1 is selected using the n:1 multiplexor. Finally, the physical-address offset field is used to point to the first byte of the referenced data (or instruction) in the selected cache line.

Cache lines can contain other information in addition to the data and tags, as shown in Figure 7-3 on page 200. MOESI state and the state bits associated with the cache-replacement algorithm are typical pieces of information kept with the cache line. Instruction caches can also contain pre-decode or branch-prediction information. The type of information stored with the cache line is implementation dependent.

Self-Modifying Code. Software that stores into its own pending instruction stream with the intent of then executing the modified instructions is classified as self-modifying code. To support self-modifying code, AMD64 processors will flush any lines from the instruction cache that such stores hit, and will additionally check whether an instruction being modified is already in decode or execution behind the store instruction. If so, it will flush the pipeline and restart instruction fetch to acquire and re-decode the updated instruction bytes. No special action is needed by software for such updates to be immediately recognized. As with cache coherency, the check for instructions that are in flight is performed using physical addresses to avoid aliasing issues that could arise with virtual (linear) addresses.

When the modified bytes are in cacheable memory, the data cache may retain a copy of the modified cache line in a shared state, and the instruction cache refill may be satisfied from any suitable place in the memory hierarchy in a model-dependent manner that maintains cache coherency.

Cross-Modifying Code. Software that stores into the active instruction stream of another executing thread with the intent that the other thread subsequently execute the modified instruction stream is classified as cross-modifying code. There are two approaches to consider: asynchronous modification and synchronous modification.

Asynchronous modification. This is done with a write to the target instruction stream with no particular coordination being done between the writing and receiving threads. The nature of the code being executed by the target thread is such that it is insensitive to the exact timing of the update, for example executing in a known loop until an update to a branch instruction's offset takes it down a new path (or an update to an immediate operand, or opcode, or other instruction field). Such modifications must be done via a single store to the target thread's instruction stream that is contained entirely within a naturally-aligned quadword, and is subject to the constraints given here. A key aspect is that, although the store is performed atomically, the affected quadword may be read more than once in the process of extracting instruction bytes from it. This can result in the following scenarios resulting from a single store:

1. An update to two successive instructions, A and B, to A' and B' may result in execution of an A-B' sequence rather than A'-B'. However it will not result in an A'-B sequence since stores become visible to instruction fetchers in program order, and instruction fetchers read memory sequentially between taken branches.
2. A modification to one instruction A that changes it to two instructions A'-B will only result in execution of A'-B.
3. A modification to two instructions A-B that combines them into one instruction A' may result in a sequence of A-X, where X starts at the point in A' where B previously started.

Note that since stores to the instruction stream are observed by the instruction fetcher in program order, one can do multiple modifications to an area of the target thread's code that is beyond reach of the thread's current control flow, followed by a final asynchronous update that alters the control flow to expose the modified code to fetching and execution.

If the desired action cannot be achieved within these constraints, a synchronous modification approach must be used for reliable operation.

Synchronous modification. This entails a producer-consumer approach to the modification, where the target thread waits on a signal from the modifying thread, such as changing the state of a shared variable, before executing the modified code. The modifying thread writes to the target instruction bytes in any desired manner, then writes the synchronizing variable to release the target thread. Upon release, the target thread must then execute a serializing instruction such as CPUID or MFENCE (a locked operation is not sufficient) before proceeding to the modified code to avoid executing a stale view of the instructions which may have been speculatively fetched. Note that such speculative fetching is a function of branch predictor operation which is completely beyond the control of software.

See Volume 1, Chapter 3, “Semaphores,” for a discussion of instructions that are useful for interprocessor synchronization.

7.6.2 Cache Control Mechanisms

The AMD64 architecture provides a number of mechanisms for controlling the cacheability of memory. These are described in the following sections.

Cache Disable. Bit 30 of the CR0 register is the cache-disable bit, CR0.CD. Caching is enabled when CR0.CD is cleared to 0, and caching is disabled when CR0.CD is set to 1. When caching is disabled, reads and writes access main memory.

Software can disable the cache while the cache still holds valid data (or instructions). If a read or write hits the L1 data cache or the L2 cache when CR0.CD=1, the processor does the following:

1. Writes the cache line back if it is in the modified or owned state.
2. Invalidates the cache line.
3. Performs a non-cacheable main-memory access to read or write the data.

If an instruction fetch hits the L1 instruction cache when CR0.CD=1, some processor models may read the cached instructions rather than access main memory. When CR0.CD=1, the exact behavior of L2 and L3 caches is model-dependent, and may vary for different types of memory accesses.

The processor also responds to cache probes when CR0.CD=1. Probes that hit the cache cause the processor to perform Step 1. Step 2 (cache-line invalidation) is performed only if the probe is performed on behalf of a memory write or an exclusive read.

Writethrough Disable. Bit 29 of the CR0 register is the *not writethrough* disable bit, CR0.NW. In early x86 processors, CR0.NW is used to control cache writethrough behavior, and the combination of CR0.NW and CR0.CD determines the cache operating mode.

In early x86 processors, clearing CR0.NW to 0 enables writeback caching for main memory, effectively disabling writethrough caching for main memory. When CR0.NW=0, software can disable writeback caching for specific memory pages or regions by using other cache control mechanisms. When software sets CR0.NW to 1, writeback caching is disabled for main memory, while writethrough caching is enabled.

In implementations of the AMD64 architecture, CR0.NW is not used to qualify the cache operating mode established by CR0.CD. Table 7-4 shows the effects of CR0.NW and CR0.CD on the AMD64 architecture cache-operating modes.

Table 7-4. AMD64 Architecture Cache-Operating Modes

CR0.CD	CR0.NW	Cache Operating Mode
0	0	Cache enabled with a writeback-caching policy.
0	1	Invalid setting—causes a general-protection exception (#GP).
1	0	Cache disabled. See “Cache Disable” on page 203.
1	1	

Page-Level Cache Disable. Bit 4 of all paging data-structure entries controls page-level cache disable (PCD). When a data-structure-entry PCD bit is cleared to 0, the page table or physical page pointed to by that entry is cacheable, as determined by the CR0.CD bit. When the PCD bit is set to 1, the page table or physical page is not cacheable. The PCD bit in the paging data-structure base-register

(bit 4 in CR3) controls the cacheability of the highest-level page table in the page-translation hierarchy.

Page-Level Writethrough Enable. Bit 3 of all paging data-structure entries is the page-level writethrough enable control (PWT). When a data-structure-entry PWT bit is cleared to 0, the page table or physical page pointed to by that entry has a writeback caching policy. When the PWT bit is set to 1, the page table or physical page has a writethrough caching policy. The PWT bit in the paging data-structure base-register (bit 3 in CR3) controls the caching policy of the highest-level page table in the page-translation hierarchy.

The corresponding PCD bit must be cleared to 0 (page caching enabled) for the PWT bit to have an effect.

Memory Typing. Two mechanisms are provided for software to control access to and cacheability of specific memory regions:

- The memory-type range registers (MTRRs) control cacheability based on physical addresses. See “MTRRs” on page 209 for more information on the use of MTRRs.
- The page-attribute table (PAT) mechanism controls cacheability based on virtual addresses. PAT extends the capabilities provided by the PCD and PWT page-level cache controls. See “Page-Attribute Table Mechanism” on page 218 for more information on the use of the PAT mechanism.

System software can combine the use of both the MTRRs and PAT mechanisms to maximize control over memory cacheability.

If the MTRRs are disabled in implementations that support the MTRR mechanism, the default memory type is set to uncacheable (UC). Memory accesses are not cached even if the caches are enabled by clearing CR0.CD to 0. Cacheable memory types must be established using the MTRRs in order for memory accesses to be cached.

Cache Control Precedence. The cache-control mechanisms are used to define the memory type and cacheability of main memory and regions of main memory. Taken together, the most restrictive memory type takes precedence in defining the caching policy of memory. The order of precedence is:

1. Uncacheable (UC)
2. Write-combining (WC)
3. Write-protected (WP)
4. Writethrough (WT)
5. Writeback (WB)

For example, assume a large memory region is designated a writethrough type using the MTRRs. Individual pages within that region can have caching disabled by setting the appropriate page-table PCD bits. However, no pages within that region can have a writeback caching policy, regardless of the page-table PWT values.

7.6.3 Cache and Memory Management Instructions

Data Prefetch. The prefetch instructions are used by software as a hint to the processor that the referenced data is likely to be used in the near future. The processor can preload the cache line containing the data in anticipation of its use. PREFETCH provides a hint that the data is to be read. PREFETCHW provides a hint that the data is to be written. The processor can mark the line as modified if it is preloaded using PREFETCHW.

Memory Ordering. Instructions are provided for software to enforce memory ordering (serialization) in weakly-ordered memory types. These instructions are:

- *SFENCE (store fence)*—forces all memory writes (stores) preceding the SFENCE (in program order) to be written into memory before memory writes following the SFENCE.
- *LFENCE (load fence)*—forces all memory reads (loads) preceding the LFENCE (in program order) to be read from memory before memory reads following the LFENCE. In some systems, LFENCE may be configured to be dispatch serializing. In systems where CPUID Fn8000_0021_EAX[LFenceAlwaysSerializing] (bit 2) = 1, LFENCE is always dispatch serializing.
- *MFENCE (memory fence)*—forces all memory accesses (reads and writes) preceding the MFENCE (in program order) to be written into or read from memory before memory accesses following the MFENCE.

Cache Line Writeback and Flush. The CLFLUSH instruction (writeback, if modified, and invalidate) takes the byte memory-address operand (a linear address), and checks to see if the address is cached. If the address is cached, the entire cache line containing the address is invalidated. If any portion of the cache line is dirty (in the modified or owned state), the entire line is written to main memory before it is invalidated. CLFLUSH affects *all caches* in the memory hierarchy—internal and external to the processor, and across all cores. The CLWB instruction operates in the same manner except it does not invalidate the cache line. The checking and invalidation process continues until the address has been updated in memory and, for CLFLUSH, invalidated in all caches.

In most cases, the underlying memory type assigned to the address has no effect on the behavior of this instruction. However, when the underlying memory type for the address is UC or WC (as defined by the MTRRs), the processor does not proceed with checking all caches to see if the address is cached. In both cases, the address is uncacheable, and invalidation is unnecessary. Write-combining buffers are written back to memory if the corresponding physical address falls within the buffer active-address range.

Cache Writeback and Invalidate. Unlike the CLFLUSH and CLWB instructions, the WBINVD and WBNOINVD instructions operate on the entire cache, rather than a single cache line. The WBINVD and WBNOINVD instructions first write back all cache lines that are dirty (in the modified or owned state) to main memory. After writeback is complete, the WBINVD instruction additionally invalidates all cache lines. The checking and invalidation process continues until all internal caches in the executing core's path to system memory are invalidated. In some implementations this may include caches in other branches of the system's cache hierarchy; see the description of these instructions in

volume 3 for more detail. For either instruction, a special bus cycle is transmitted to higher-level external caches directing them to perform a writeback-and-invalidate operation.

Cache Invalidate. The INVD instruction is used to invalidate all cache lines. Unlike the WBINVD instruction, dirty cache lines are not written to main memory. The process continues until all internal caches have been invalidated. A special bus cycle is transmitted to higher-level external caches directing them to perform an invalidation.

The INVD instruction should only be used in situations where memory coherency is not required.

7.6.4 Serializing Instructions

Serializing instructions force the processor to retire the serializing instruction and all previous instructions before the next instruction is fetched. A serializing instruction is retired when the following operations are complete:

- The instruction has executed.
- All registers modified by the instruction are updated.
- All memory updates performed by the instruction are complete.
- All data held in the write buffers have been written to memory.

Serializing instructions can be used as a barrier between memory accesses to force strong ordering of memory operations. Care should be exercised in using serializing instructions because they modify processor state and may affect program flow. The instructions also force execution serialization, which can significantly degrade performance. When strongly-ordered memory accesses are required, but execution serialization is not, it is recommended that software use the memory-ordering instructions described on page 205.

The following are serializing instructions:

- *Non-Privileged Instructions*
  - CPUID
  - IRET
  - RSM
  - MFENCE
- *Privileged Instructions*
  - MOV CRn
  - MOV DRn
  - LGDT, LIDT, LLDT, LTR
  - WRMSR (see note 1)
  - WBINVD, WBNOINVD, INVD
  - INVLPG

Note 1: *Writes to the following MSRs are not serializing:* SPEC_CTRL, PRED_CMD, all x2APIC MSRs.

A dispatch serializing instruction is a lighter form of ordering than a serializing instruction. A dispatch serializing instruction forces the processor to retire the serializing instruction and all previous instructions before the next instruction is executed. In some systems, LFENCE may be configured to be dispatch serializing. In systems where CPUID Fn8000_0021_EAX[LFenceAlwaysSerializing](bit 2) = 1, LFENCE is always dispatch serializing.

7.6.5 Cache and Processor Topology

Cache and processor topology information is useful in the optimal management of system and application resources. Exposing processor and cache topology information to the programmer allows software to make more efficient use of hardware multithreading resources delivering optimal performance. Shared resources in a specific cache and processor topology may require special consideration in the optimization of multiprocessing software performance.

The processor topology allows software to determine which cores or logical processors are siblings in a compute unit, node, and processor package. For example, a scheduler can then choose to either compact or scatter threads (or processes) to cores in compute units, nodes, or across the cores in the entire physical package in order to optimize for a power and performance profile.

Topology extensions define processor topology at both the node, compute unit and cache level. Topology extensions include cache properties with sharing and the processor topology identified. The result is a simplified extension to the CPUID instruction that describes the processors cache topology and leverages existing industry cache properties folded into AMD’s topology extension description.

Topology extensions definition supports existing and future processors with varying degrees of cache level sharing. Topology extensions also support the description of a simple compute unit with one core or packages where the number of cores in a node and/or compute unit are not an even power of two.

CPUID Function 8000_001D: Cache Topology Definition. CPUID Function 8000_001D describes the hierarchical relationships of cache levels relative to the cores which share these resources. Function 8000_001D is defined to be called iteratively with the value 8000001Dh in EAX and an additional parameter in ECX. To gather information for all cache levels, software must call CPUID with 8000001Dh in EAX and ECX set to increasing values beginning with 0 until a value of 0 is returned from EAX[4:0], which indicates no more cache descriptions.

If software dynamically manages cache configuration, it will need to update any stored cache properties for the processor.

CPUID Function 8000_001E: Processor Topology Definition. CPUID Function 8000_001E describes processor topology with component identifiers. To read the processor topology, definition software calls the CPUID instruction with the value 8000001Eh in EAX. After execution the APIC ID is represented in EAX. EBX contains the compute unit description in the processor, while ECX contains system unique node identification. Software may read this information once for each core.

The following CPUID functions provide information about processor topology:

- CPUID Fn8000_0001_ECX
- CPUID Fn8000_0008_ECX
- CPUID Fn8000_001D_EAX, EBX, ECX, EDX
- CPUID Fn8000_001E_EAX, EBX, ECX

For more information using the CPUID instruction, see Section 3.3, “Processor Feature Identification,” on page 71.

7.7 Memory-Type Range Registers

The AMD64 architecture supports three mechanisms for software access-control and cacheability-control over memory regions. These mechanisms can be used in place of similar capabilities provided by external chipsets used with early x86 processors.

This section describes a control mechanism that uses a set of programmable model-specific registers (MSRs) called the *memory-type-range registers* (MTRRs). The MTRR mechanism provides system software with the ability to manage hardware-device memory mapping. System software can characterize physical-memory regions by type (e.g., ROM, flash, memory-mapped I/O) and assign hardware devices to the appropriate physical-memory type.

Another control mechanism is implemented as an extension to the page-translation capability and is called the *page attribute table* (PAT). It is described in “Page-Attribute Table Mechanism” on page 218. Like the MTRRs, PAT provides system software with the ability to manage hardware-device memory mapping. With PAT, however, system software can characterize physical pages and assign virtually-mapped devices to those physical pages using the page-translation mechanism. PAT may be used in conjunction with the MTTR mechanism to maximize flexibility in memory control.

Finally, control mechanisms are provided for managing memory-mapped I/O. These mechanisms employ extensions to the MTRRs and a separate feature called the *top-of-memory registers*. The MTRR extensions include additional MTRR type-field encodings for fixed-range MTRRs and variable-range I/O range registers (IORRs). These mechanisms are described in “Memory-Mapped I/O” on page 222.

7.7.1 MTRR Type Fields

The MTRR mechanism provides a means for associating a physical-address range with a memory type (see “Memory Types” on page 192). The MTRRs contain a type field used to specify the memory type in effect for a given physical-address range.

There are two variants of the memory type-field encodings: standard and extended. Both the standard and extended encodings use type-field bits 2:0 to specify the memory type. For the standard encodings, bits 7:3 are reserved and must be zero. For the extended encodings, bits 7:5 are reserved, but bits 4:3 are defined as the RdMem and WrMem bits. “Extended Fixed-Range MTRR Type-Field Encodings” on page 223 describes the function of these extended bits and how software enables them.

Only the fixed-range MTRRs support the extended type-field encodings. Variable-range MTRRs use the standard encodings.

Table 7-5 on page 209 shows the memory types supported by the MTRR mechanism and their encoding in the MTRR type fields referenced throughout this section. Unless the extended type-field encodings are explicitly enabled, the processor uses the type values shown in Table 7-5.

Table 7-5. MTRR Type Field Encodings

Type Value	Type Name	Type Description
00h	UC—Uncacheable	All accesses are uncacheable. Write combining is not allowed. Speculative accesses are not allowed
01h	WC—Write-Combining	All accesses are uncacheable. Write combining is allowed. Speculative reads are allowed
04h	WT—Writethrough	Reads allocate cache lines on a cache miss. Cache lines are not allocated on a write miss. Write hits update the cache and main memory.
05h	WP—Write-Protect	Reads allocate cache lines on a cache miss. All writes update main memory. Cache lines are not allocated on a write miss. Write hits invalidate the cache line and update main memory.
06h	WB—Writeback	Reads allocate cache lines on a cache miss, and can allocate to either the shared, exclusive, or modified state. Writes allocate to the modified state on a cache miss.

If the MTRRs are disabled in implementations that support the MTRR mechanism, the default memory type is set to uncacheable (UC). *Memory accesses are not cached even if the caches are enabled by clearing CR0.CD to 0.* Cacheable memory types must be established using the MTRRs to enable memory accesses to be cached.

7.7.2 MTRRs

Both fixed-size and variable-size address ranges are supported by the MTRR mechanism. The fixed-size ranges are restricted to the lower 1 Mbyte of physical-address space, while the variable-size ranges can be located anywhere in the physical-address space.

Figure 7-4 on page 210 shows an example mapping of physical memory using the fixed-size and variable-size MTRRs. The areas shaded gray are not mapped by the MTRRs. Unmapped areas are set to the software-selected default memory type.

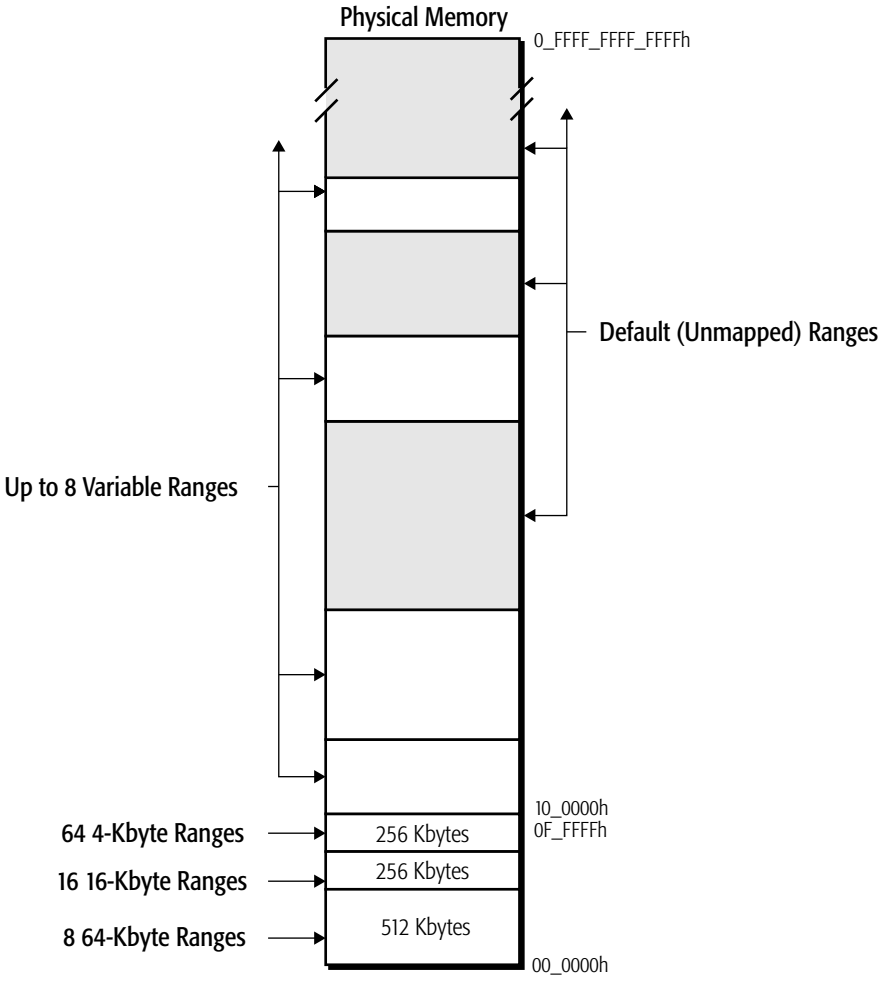

Figure 7-4. MTRR Mapping of Physical Memory

MTRRs are 64-bit model-specific registers (MSRs). They are read using the RDMSR instruction and written using the WRMSR instruction. See “Memory-Typing MSRs” on page 669 for a listing of the MTRR MSR numbers. The following sections describe the types of MTRRs and their function.

Fixed-Range MTRRs. The fixed-range MTRRs are used to characterize the first 1 Mbyte of physical memory. Each fixed-range MTRR contains eight type fields for characterizing a total of eight memory ranges. Fixed-range MTRRs support extended type-field encodings as described in “Extended Fixed-Range MTRR Type-Field Encodings” on page 223. The extended type field allows a fixed-range MTRR to be used as a fixed-range IORR. Figure 7-5 on page 211 shows the format of a fixed-range MTRR.

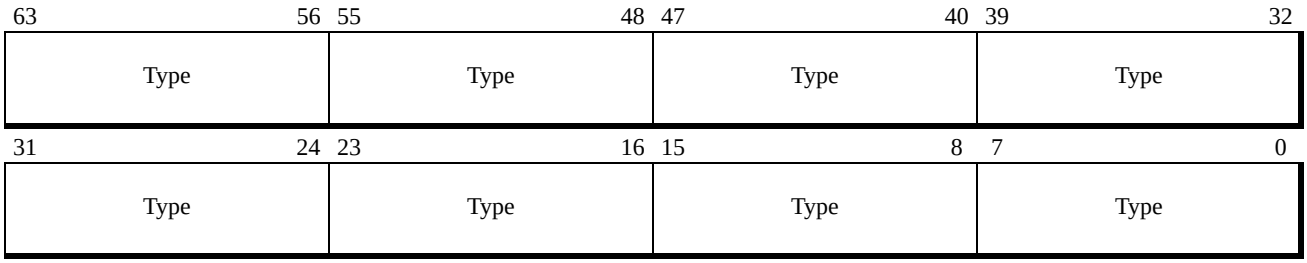

Figure 7-5. Fixed-Range MTRR

For the purposes of memory characterization, the first 1 Mbyte of physical memory is segmented into a total of 88 non-overlapping memory ranges, as follows:

- The 512 Kbytes of memory spanning addresses 00_0000h to 07_FFFFh are segmented into eight 64-Kbyte ranges. A single MTRR is used to characterize this address space.
- The 256 Kbytes of memory spanning addresses 08_0000h to 0B_FFFFh are segmented into 16 16-Kbyte ranges. Two MTRRs are used to characterize this address space.
- The 256 Kbytes of memory spanning addresses 0C_0000h to 0F_FFFFh are segmented into 64 4-Kbyte ranges. Eight MTRRs are used to characterize this address space.

Table 7-6 shows the address ranges corresponding to the type fields within each fixed-range MTRR. The gray-shaded heading boxes represent the bit ranges for each type field in a fixed-range MTTR. See Table 7-5 on page 209 for the type-field encodings.

Table 7-6. Fixed-Range MTRR Address Ranges

Physical Address Range (in hexadecimal)								Register Name
63–56	55–48	47–40	39–32	31–24	23–16	15–8	7–0	
70000–7FFFF	60000–6FFFF	50000–5FFFF	40000–4FFFF	30000–3FFFF	20000–2FFFF	10000–1FFFF	00000–0FFFF	**MTRRfix64K_00000**
9C000–9FFFF	98000–9BFFF	94000–97FFF	90000–93FFF	8C000–8FFFF	88000–8BFFF	84000–87FFF	80000–83FFF	**MTRRfix16K_80000**
BC000–BFFFF	B8000–BBFFF	B4000–B7FFF	B0000–B3FFF	AC000–AFFFF	A8000–ABFFF	A4000–A7FFF	A0000–A3FFF	**MTRRfix16K_A0000**

D7000–D7FFF	D6000–D6FFF	D5000–D5FFF	D4000–D4FFF	D3000–D3FFF	D2000–D2FFF	D1000–D1FFF	D0000–D0FFF	**MTRRfix4K_D0000**
DF000–DFFFF	DE000–DEFFF	DD000–DDFFF	DC000–DCFFF	DB000–DBFFF	DA000–DAFFF	D9000–D9FFF	D8000–D8FFF	**MTRRfix4K_D8000**
E7000–E7FFF	E6000–E6FFF	E5000–E5FFF	E4000–E4FFF	E3000–E3FFF	E2000–E2FFF	E1000–E1FFF	E0000–E0FFF	**MTRRfix4K_E0000**

Table 7-6. Fixed-Range MTRR Address Ranges (continued)

Physical Address Range (in hexadecimal)								Register Name
63–56	55–48	47–40	39–32	31–24	23–16	15–8	7–0	
EF000–EFFFF	EE000–EEFFF	ED000–EDFFF	EC000–ECFFF	EB000–EBFFF	EA000–EAFFF	E9000–E9FFF	E8000–E8FFF	**MTRRfix4K_E8000**
F7000–F7FFF	F6000–F6FFF	F5000–F5FFF	F4000–F4FFF	F3000–F3FFF	F2000–F2FFF	F1000–F1FFF	F0000–F0FFF	**MTRRfix4K_F0000**
FF000–FFFFF	FE000–FEFFF	FD000–FDFFF	FC000–FCFFF	FB000–FBFFF	FA000–FAFFF	F9000–F9FFF	F8000–F8FFF	**MTRRfix4K_F8000**

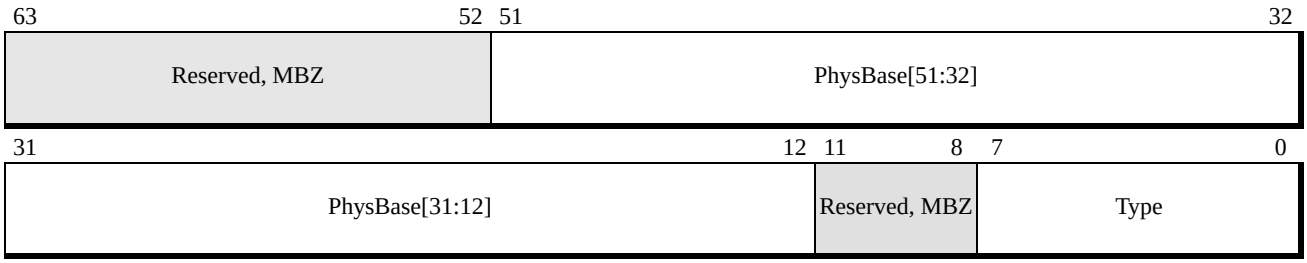
Variable-Range MTRRs. The variable-range MTRRs can be used to characterize any address range within the physical-memory space, including all of physical memory. Up to eight address ranges of varying sizes can be characterized using the MTRR. Two variable-range MTRRs are used to characterize each address range: MTRRphysBase*n* and MTRRphysMask*n* (*n* is the address-range number from 0 to 7). For example, address-range 3 is characterized using the MTRRphysBase3 and MTRRphysMask3 register pair.

Figure 7-6 shows the format of the MTRRphysBase*n* register and Figure 7-7 on page 213 shows the format of the MTRRphysMask*n* register. The fields within the register pair are read/write.

MTRRphysBase*n* Registers. The fields in these variable-range MTRRs, shown in Figure 7-6, are:

- *Type*—Bits 7:0. The memory type used to characterize the memory range. See Table 7-5 on page 209 for the type-field encodings. Variable-range MTRRs do not support the extended type-field encodings.
- *Range Physical Base-Address (PhysBase)*—Bits 51:12. The memory-range base-address in physical-address space. PhysBase is aligned on a 4-Kbyte (or greater) address in the 52-bit physical-address space supported by the AMD64 architecture. PhysBase represents the most-significant 40-address bits of the physical address. Physical-address bits 11:0 are assumed to be 0.

Note that a given processor may implement less than the architecturally-defined physical address size of 52 bits.

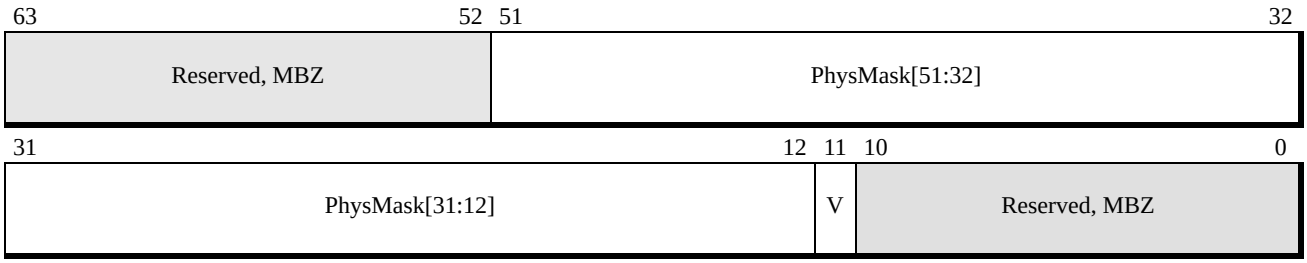


Bits	Mnemonic	Description	Access type
63:52	—	Reserved	MBZ
51:12	PhysBase	Range Physical Base Address	R/W
11:8	—	Reserved	MBZ
7:0	Type	Default Memory Type	R/W

Figure 7-6. MTRRphysBase*n* Register

MTRRphysMask*n* Registers. The fields in these variable-range MTRRs, shown in Figure 7-7, are:

- *Valid (V)*—Bit 11. Indicates that the MTRR pair is valid (enabled) when set to 1. When the valid bit is cleared to 0 the register pair is not used.
- *Range Physical Mask (PhysMask)*—Bits 51:12. The mask value used to specify the memory range. Like PhysBase, PhysMask is aligned on a 4-Kbyte physical-address boundary. Bits 11:0 of PhysMask are assumed to be 0.



Bits	Mnemonic	Description	Access type
63:52	—	Reserved	MBZ
51:12	PhysMask	Range Physical Mask	R/W
11	V	MTRR Pair Enable (Valid)	R/W
10:0	—	Reserved	MBZ

Figure 7-7. MTRRphysMask*n* Register

PhysMask and PhysBase are used together to determine whether a target physical-address falls within the specified address range. PhysMask is logically ANDed with PhysBase and separately ANDed with the upper 40 bits of the target physical-address. If the results of the two operations are identical, the target physical-address falls within the specified memory range. The pseudo-code for the operation is:

```
MaskBase = PhysMask AND PhysBase
MaskTarget = PhysMask AND Target_Address[51:12]
IF MaskBase == MaskTarget
   target address is in range
ELSE
   target address is not in range
```

Variable Range Size and Alignment. The size and alignment of variable memory-ranges (MTRRs) and I/O ranges (IORRs) are restricted as follows:

- The boundary on which a variable range is aligned must be equal to the range size. For example, a memory range of 16 Mbytes must be aligned on a 16-Mbyte boundary.
- The range size must be a power of 2 (2^n, 52 > n > 11), with a minimum allowable size of 4 Kbytes. For example, 4 Mbytes and 8 Mbytes are allowable memory range sizes, but 6 Mbytes is not allowable.

PhysMask and PhysBase Values. Software can calculate the PhysMask value using the following procedure:

1. Subtract the memory-range physical base-address from the upper physical-address of the memory range.
2. Subtract the value calculated in Step 1 from the physical memory size.
3. Truncate the lower 12 bits of the result in Step 2 to create the PhysMask value to be loaded into the MTRRphysMask*n* register. Truncation is performed by right-shifting the value 12 bits.

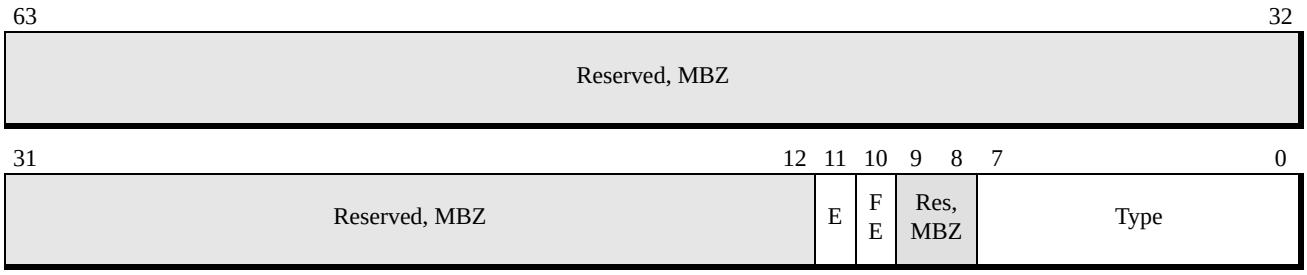
For example, assume a 32-Mbyte memory range is specified within the 52-bit physical address space, starting at address 200_0000h. The upper address of the range is 3FF_FFFFh. Following the process outlined above yields:

1. 3FF_FFFFh–200_0000h = 1FF_FFFFh
2. F_FFFF_FFFF_FFFF–1FF_FFFFh = F_FFFF_FE00_0000h
3. Right shift (F_FFFF_FE00_0000h) by 12 = FF_FFFF_E000h

In this example, the 40-bit value loaded into the PhysMask field is FF_FFFF_E000h.

Software must also truncate the lower 12 bits of the physical base-address before loading it into the PhysBase field. In the example above, the 40-bit PhysBase field is 00_0000_2000h.

Default-Range MTRRs. Physical addresses that are not within ranges established by fixed-range and variable-range MTRRs are set to a default memory-type using the MTRRdefType register. The format of this register is shown in Figure 7-8.



Bits	Mnemonic	Description	Access type
63:12	—	Reserved	MBZ
11	E	MTRR Enable	R/W
10	FE	Fixed Range Enable	R/W
9:8	—	Reserved	MBZ
7:0	Type	Default Memory Type	R/W

Figure 7-8. MTRRdefType Register Format

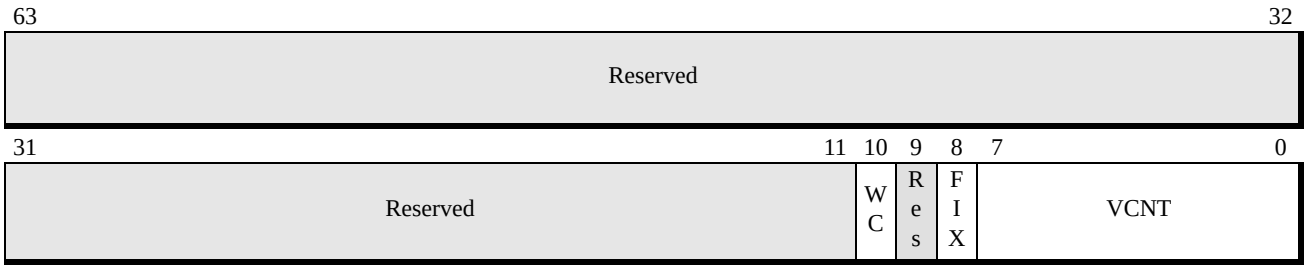
The fields within the MTRRdefType register are read/write. These fields are:

- *Type*—Bits 7:0. The default memory-type used to characterize physical-memory space. See Table 7-5 on page 209 for the type-field encodings. The extended type-field encodings are not supported by this register.
- *Fixed-Range Enable (FE)*—Bit 10. All fixed-range MTRRs are enabled when FE is set to 1. Clearing FE to 0 disables all fixed-range MTRRs. Setting and clearing FE has no effect on the variable-range MTRRs. The FE bit has no effect unless the E bit is set to 1 (see below).
- *MTRR Enable (E)*—Bit 11. This is the MTRR memory typing enable bit. The memory typing capabilities of all fixed-range and variable-range MTRRs are enabled when E is set to 1. Clearing E to 0 disables the memory typing capabilities of all fixed-range and variable-range MTRRs and sets the default memory-type to uncacheable (UC) regardless of the value of the Type field. This bit does not affect the operation of the RdMem and WrMem fields.

7.7.3 Using MTRRs

Identifying MTRR Features. Software determines whether a processor supports the MTRR mechanism by executing the CPUID instruction with either function 0000_0001h or function 8000_0001h. If MTRRs are supported, bit 12 in the EDX register is set to 1 by CPUID. See “Processor Feature Identification” on page 71 for more information on the CPUID instruction.

The MTRR capability register (MTRRcap) is a read-only register containing information describing the level of MTRR support provided by the processor. Figure 7-9 shows the format of this register. If MTRRs are supported, software can read MTRRcap using the RDMSR instruction. Attempting to write to the MTRRcap register causes a general-protection exception (#GP).



Bits	Mnemonic	Description	Access type
63:11	—	Reserved	R
10	WC	Write Combining	R
9	—	Reserved	R
8	FIX	Fixed-Range Registers	R
7:0	VCNT	Variable-Range Register Count	R

Figure 7-9. MTRR Capability Register Format

The MTRRcap register field are:

- *Variable-Range Register Count (VCNT)*—Bits 7:0. The VCNT field contains the number of variable-range register pairs supported by the processor. For example, a processor supporting eight register pairs returns a 08h in this field.
- *Fixed-Range Registers (FIX)*—Bit 8. The FIX bit indicates whether or not the fixed-range registers are supported. If the processor returns a 1 in this bit, *all* fixed-range registers are supported. If the processor returns a 0 in this bit, *no* fixed-range registers are supported.
- *Write-Combining (WC)*—Bit 10. The WC bit indicates whether or not the write-combining memory type is supported. If the processor returns a 1 in this bit, WC memory is supported, otherwise it is not supported.

7.7.4 MTRRs and Page Cache Controls

When paging and the MTRRs are both enabled, the address ranges defined by the MTRR registers can span multiple pages, each of which can characterize memory with different types (using the PCD and PWT page bits). When caching is enabled (CR0.CD=0 and CR0.NW=0), the *effective memory type* is determined as follows:

1. If the page is defined as cacheable and writeback (PCD=0 and PWT=0), then the MTRR defines the effective memory-type.
2. If the page is defined as not cacheable (PCD=1), then UC is the effective memory-type.
3. If the page is defined as cacheable and writethrough (PCD=0 and PWT=1), then the MTRR defines the effective memory-type *unless* the MTRR specifies WB memory, in which case WT is the effective memory-type.

Table 7-7 lists the MTRR and page-level cache-control combinations and their combined effect on the final memory-type, if the PAT register holds the default settings.

Table 7-7. Combined MTRR and Page-Level Memory Type with Unmodified PAT MSR

MTRR Memory Type	Page PCD Bit	Page PWT Bit	Effective Memory-Type
UC	—	—	UC
WC	0	—	WC
	1	0	WC[1]
	1	1	UC
WP	0	—	WP
	1	—	UC
WT	0	—	WT
	1	—	UC
WB	0	0	WB
	0	1	WT
	1	—	UC

Note:
1. The effective memory-type resulting from the combination of PCD=1, PWT=0, and an MTRR WC memory type is implementation dependent.

Large Page Sizes. When paging is enabled, software can use large page sizes (2 Mbytes and 4 Mbytes) in addition to the more typical 4-Kbyte page size. When large page sizes are used, it is possible for multiple MTRRs to span the memory range within a single large page. Each MTRR can characterize the regions within the page with different memory types. If this occurs, the effective memory-type used by the processor within the large page is undefined.

Software can avoid the undefined behavior in one of the following ways:

- Avoid using multiple MTRRs to characterize a single large page.
- Use multiple 4-Kbyte pages rather than a single large page.
- If multiple MTRRs must be used within a single large page, software can set the MTRR type fields to the same value.
- If the multiple MTRRs must have different type-field values, software can set the large page PCD and PWT bits to the most restrictive memory type defined by the multiple MTRRs.

Overlapping MTRR Registers. If the address ranges of two or more MTRRs overlap, the following rules are applied to determine the memory type used to characterize the overlapping address range:

1. Fixed-range MTRRs, which characterize only the first 1 Mbyte of physical memory, have precedence over variable-range MTRRs.
2. If two or more variable-range MTRRs overlap, the following rules apply:

a. If the memory types are identical, then that memory type is used.

b. If at least one of the memory types is UC, the UC memory type is used.

c. If at least one of the memory types is WT, and the only other memory type is WB, then the WT memory type is used.

d. If the combination of memory types is not listed Steps A through C immediately above, then the memory type used is undefined.

7.7.5 MTRRs in Multi-Processing Environments

In multi-processing environments, the MTRRs located in all processors must characterize memory in the same way. Generally, this means that identical values are written to the MTRRs used by the processors. This also means that values CR0.CD and the PAT must be consistent across processors. Failure to do so may result in coherency violations or loss of atomicity. Processor implementations *do not* check the MTRR settings in other processors to ensure consistency. It is the responsibility of system software to initialize and maintain MTRR consistency across all processors.

7.8 Page-Attribute Table Mechanism

The page-attribute table (PAT) mechanism extends the page-table entry format and enhances the capabilities provided by the PCD and PWT page-level cache controls. PAT (and PCD, PWT) allow memory-type characterization based on the virtual (linear) address. The PAT mechanism provides the same memory-typing capabilities as the MTRRs but with the added flexibility of the paging mechanism. Software can use both the PAT and MTRR mechanisms to maximize flexibility in memory-type control.

7.8.1 PAT Register

Like the MTRRs, the PAT register is a 64-bit model-specific register (MSR). The format of the PAT registers is shown in Figure 7-10. See “Memory-Typing MSRs” on page 669 for more information on the PAT MSR number and reset value.

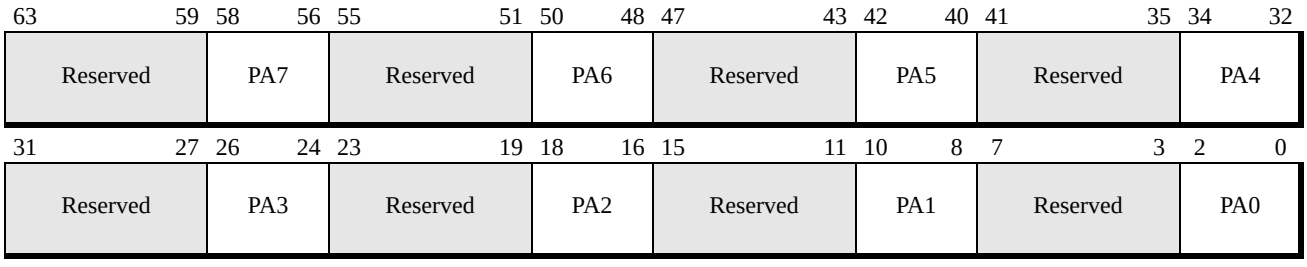


Figure 7-10. PAT Register

The PAT register contains eight page-attribute (PA) fields, numbered from PA0 to PA7. The PA fields hold the encoding of a memory type, as found in Table 7-8 on page 219. The PAT type-encodings

match the MTRR type-encodings, with the exception that PAT adds the 07h encoding. The 07h encoding corresponds to a *UC−* type. The UC− type (07h) is identical to the UC type (00h) except it can be overridden by an MTRR type of WC.

Software can write any supported memory-type encoding into any of the eight PA fields. An attempt to write anything but zeros into the reserved fields causes a general-protection exception (#GP). An attempt to write an unsupported type encoding into a PA field also causes a #GP exception.

The PAT register fields are initiated at processor reset to the default values shown in Table 7-9 on page 220.

Table 7-8. PAT Type Encodings

Type Value	Type Name	Type Description
00h	UC—Uncacheable	All accesses are uncacheable. Write combining is not allowed. Speculative accesses are not allowed.
01h	WC—Write-Combining	All accesses are uncacheable. Write combining is allowed. Speculative reads are allowed.
04h	WT—Writethrough	Reads allocate cache lines on a cache miss, but only to the shared state. Cache lines are not allocated on a write miss. Write hits update the cache and main memory.
05h	WP—Write-Protect	Reads allocate cache lines on a cache miss, but only to the shared state. All writes update main memory. Cache lines are not allocated on a write miss. Write hits invalidate the cache line and update main memory.
06h	WB—Writeback	Reads allocate cache lines on a cache miss, and can allocate to either the shared or exclusive state. Writes allocate to the modified state on a cache miss.
07h	UC– (UC minus)	All accesses are uncacheable. Write combining is not allowed. Speculative accesses are not allowed. Can be overridden by an MTRR with the WC type.

7.8.2 PAT Indexing

PA fields in the PAT register are selected using three bits from the page-table entries. These bits are:

- *PAT (page attribute table)*—The PAT bit is bit 7 in 4-Kbyte PTEs; it is bit 12 in 2-Mbyte and 4-Mbyte PDEs. Page-table entries that don't have a PAT bit (PML4 entries, for example) assume PAT = 0.
- *PCD (page cache disable)*—The PCD bit is bit 4 in all page-table entries. The PCD from the PTE or PDE is selected depending on the paging mode.
- *PWT (page writethrough)*—The PWT bit is bit 3 in all page-table entries. The PWT from the PTE or PDE is selected depending on the paging mode.

Table 7-9 on page 220 shows the various combinations of the PAT, PCD, and PWT bits used to select a PA field within the PAT register. Table 7-9 also shows the default memory-type values established in the PAT register by the processor after a reset. The default values correspond to the memory types

established by the PCD and PWT bits alone in processor implementations that do not support the PAT mechanism. In such implementations, the PAT field in page-table entries is reserved and cleared to 0. See “Page-Translation-Table Entry Fields” on page 150 for more information on the page-table entries.

Table 7-9. PAT-Register PA-Field Indexing

Page Table Entry Bits			PAT Register Field	Default Memory Type
PAT	PCD	PWT		
0	0	0	PA0	WB
0	0	1	PA1	WT
0	1	0	PA2	UC–[1]
0	1	1	PA3	UC
1	0	0	PA4	WB
1	0	1	PA5	WT
1	1	0	PA6	UC–[1]
1	1	1	PA7	UC

Note:
1. Can be overridden by WC memory type set by an MTRR.

7.8.3 Identifying PAT Support

Software determines whether a processor supports the PAT mechanism by executing the CPUID instruction with either function 0000_0001h or function 8000_0001h. If PAT is supported, bit 16 in the EDX register is set to 1 by CPUID. See Section 3.3, “Processor Feature Identification,” on page 71 for more information on the CPUID instruction.

If PAT is supported by a processor implementation, it is *always enabled*. The PAT mechanism cannot be disabled by software. Software can effectively avoid using PAT by:

- Not setting PAT bits in page-table entries to 1.
- Not modifying the reset values of the PA fields in the PAT register.

In this case, memory is characterized using the same types that are used by implementations that do not support PAT.

7.8.4 PAT Accesses

In implementations that support the PAT mechanism, all memory accesses that are translated through the paging mechanism use the PAT index bits to specify a PA field in the PAT register. The memory type stored in the specified PA field is applied to the memory access. The process is summarized as:

1. A virtual address is calculated as a result of a memory access.
2. The virtual address is translated to a physical address using the page-translation mechanism.
3. The PAT, PCD and PWT bits are read from the corresponding page-table entry during the virtual-address to physical-address translation.

4. The PAT, PCD and PWT bits are used to select a PA field from the PAT register.
5. The memory type is read from the appropriate PA field.
6. The memory type is applied to the physical-memory access using the translated physical address.

Page-Translation Table Access. The PAT bit exists only in the PTE (4K paging) or PDEs (2/4 Mbyte paging). In the remaining upper levels (PML4, PDP, and 4KB PDEs), only the PWT and PCD bits are used to index into the first 4 entries in the PAT register. The resulting memory type is used for the next lower paging level.

7.8.5 Combined Effect of MTRRs and PAT

The memory types established by the PAT mechanism can be combined with MTRR-established memory types to form an effective memory-type. The combined effect of MTRR and PAT memory types are shown in Figure 7-10. In the AMD64 architecture, reserved and undefined combinations of MTRR and PAT memory types result in undefined behavior. If the MTRRs are disabled in implementations that support the MTRR mechanism, the default memory type is set to uncacheable (UC).

Table 7-10. Combined Effect of MTRR and PAT Memory Types

PAT Memory Type	MTRR Memory Type	Effective Memory Type
UC	UC	UC
UC	WC, WP, WT, WB	CD
UC−	UC	UC
	WC	WC
	WP, WT, WB	CD
WC	—	WC
WP	UC	UC
	WC	CD
	WP	WP
	WT	CD
	WB	WP
WT	UC	UC
	WC, WP	CD
	WT, WB	WT
WB	UC	UC
	WC	WC
	WP	WP
	WT	WT
	WB	WB

7.8.6 PATs in Multi-Processing Environments

In multi-processing environments, values of CR0.CD and the PAT must be consistent across all processors and the MTRRs in all processors must characterize memory in the same way. In other words, matching address ranges and cachability types are written to the MTRRs for each processor.

Failure to do so may result in coherency violations or loss of atomicity. Processor implementations *do not* check the MTRR, CR0.CD and PAT values in other processors to ensure consistency. It is the responsibility of system software to initialize and maintain consistency across all processors.

7.8.7 Changing Memory Type

A physical page should not have differing cacheability types assigned to it through different virtual mappings; they should be either all of a cacheable type (WB, WT, WP) or all of a non-cacheable type (UC, WC). Otherwise, this may result in a loss of cache coherency, leading to stale data and unpredictable behavior. For this reason, certain precautions must be taken when changing the memory type of a page. In particular, when changing from a cachable memory type to an uncachable type the caches must be flushed, because speculative execution by the processor may have resulted in memory being cached even though it was not programatically referenced. The following table summarizes the serialization requirements for safely changing memory types.

Table 7-11. Serialization Requirements for Changing Memory Types

		New Type				
		WB	**WT**	**WP**	**UC**	**WC**
Old Type	WB	–	a	a	b	b
	WT	a	–	a	b	b
	WP	a	a	–	b	b
	UC	a	a	a	–	a
	WC	a	a	a	a	–

Note:

a. Remove the previous mapping (make it not present in the page tables); Flush the TLBs including the TLBs of other processors that may have used the mapping, even speculatively; Create a new mapping in the page tables using the new type.

b. In addition to the steps described in note a, software should flush the page from the caches of any processor that may have used the previous mapping. This must be done after the TLB flushing in note a has been completed.

7.9 Memory-Mapped I/O

Processor implementations can independently direct reads and writes to either system memory or memory-mapped I/O. The method used for directing those memory accesses is implementation dependent. In some implementations, separate system-memory and memory-mapped I/O buses can be provided at the processor interface. In other implementations, system memory and memory-mapped I/O share common data and address buses, and system logic uses sideband signals from the processor to route accesses appropriately. Refer to AMD data sheets and application notes for more information about particular hardware implementations of the AMD64 architecture.

The I/O range registers (IORRs), and the top-of-memory registers allow system software to specify where memory accesses are directed for a given address range. The MTRR extensions are described in the following section. “IORRs” on page 224 describes the IORRs and “Top of Memory” on page 226 describes the top-of-memory registers. *In implementations that support these features, the default action taken when the features are disabled is to direct memory accesses to memory-mapped I/O.*

7.9.1 Extended Fixed-Range MTRR Type-Field Encodings

The fixed-range MTRRs support extensions to the type-field encodings that allow system software to direct memory accesses to system memory or memory-mapped I/O. The extended MTRR type-field encodings use previously reserved bits 4:3 to specify whether reads and writes to a physical-address range are to system memory or to memory-mapped I/O. The format for this encoding is shown in Figure 7-11 on page 223. The new bits are:

- *WrMem*—Bit 3. When set to 1, the processor directs write requests for this physical address range to system memory. When cleared to 0, writes are directed to memory-mapped I/O.
- *RdMem*—Bit 4. When set to 1, the processor directs read requests for this physical address range to system memory. When cleared to 0, reads are directed to memory-mapped I/O.

The type subfield (bits 2:0) allows the encodings specified in Table 7-5 on page 209 to be used for memory characterization.

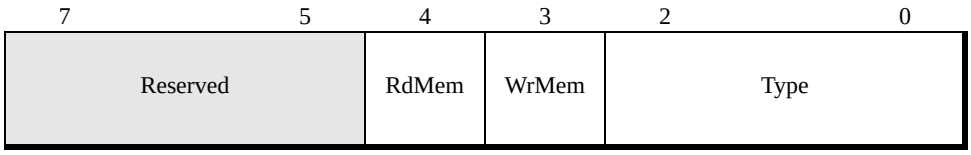

Figure 7-11. Extended MTRR Type-Field Format (Fixed-Range MTRRs)

These extensions are enabled using the following bits in the SYSCFG MSR:

- *MtrrFixDramEn*—Bit 18. When set to 1, RdMem and WrMem attributes are enabled. When cleared to 0, these attributes are disabled. *When disabled, accesses are directed to memory-mapped I/O space.*
- *MtrrFixDramModEn*—Bit 19. When set to 1, software can read and write the RdMem and WrMem bits. When cleared to 0, writes do not modify the RdMem and WrMem bits, and reads return 0.

To use the MTRR extensions, system software must first set MtrrFixDramModEn=1 to allow modification to the RdMem and WrMem bits. After the attribute bits are properly initialized in the fixed-range registers, the extensions can be enabled by setting MtrrFixDramEn=1.

RdMem and WrMem allow the processor to independently direct reads and writes to either system memory or memory-mapped I/O. The RdMem and WrMem controls are particularly useful when shadowing ROM devices located in memory-mapped I/O space. It is often useful to shadow such devices in RAM system memory to improve access performance, but writes into the RAM location can

corrupt the shadowed ROM information. The MTRR extensions solve this problem. System software can create the shadow location by setting WrMem = 1 and RdMem = 0 for the specified memory range and then copy the ROM location into itself. Reads are directed to the memory-mapped ROM, but writes go to the same physical addresses in system memory. After the copy is complete, system software can change the bit values to WrMem = 0 and RdMem = 1. Now reads are directed to the faster copy located in system memory, and writes are directed to memory-mapped ROM. The ROM responds as it would normally to a write, which is to ignore it.

Not all combinations of RdMem and WrMem are supported for each memory type encoded by bits 2:0. Table 7-12 on page 224 shows the allowable combinations. The behavior of reserved encoding combinations (shown as gray-shaded cells) is undefined and results in unpredictable behavior.

Table 7-12. Extended Fixed-Range MTRR Type Encodings

RdMem	WrMem	Type	Implication or Potential Use
0	0	0 (UC)	UC I/O
		1 (WC)	WC I/O
		4 (WT)	WT I/O
		5 (WP)	WP I/O
		6 (WB)	Reserved
0	1	0 (UC)	Used while creating a shadowed ROM
		1 (WC)	
		4 (WT)	Reserved
		5 (WP)	
		6 (WB)	
1	0	0 (UC)	Used to access a shadowed ROM
		1 (WC)	Reserved
		4 (WT)	
		5 (WP)	WP Memory (Can be used to access shadowed ROM)
		6 (WB)	Reserved
1	1	0 (UC)	UC Memory
		1 (WC)	WC Memory
		4 (WT)	WT Memory
		5 (WP)	Reserved
		6 (WB)	WB Memory

7.9.2 IORRs

The IORRs operate similarly to the variable-range MTRRs. The IORRs specify whether reads and writes in any physical-address range map to system memory or memory-mapped I/O. Up to two

address ranges of varying sizes can be controlled using the IORRs. A pair of IORRs are used to control each address range: IORRBase*n* and IORRMask*n* (*n* is the address-range number from 0 to 1).

Figure 7-12 on page 225 shows the format of the IORRBase*n* registers and Figure 7-13 on page 226 shows the format of the IORRMask*n* registers. The fields within the register pair are read/write.

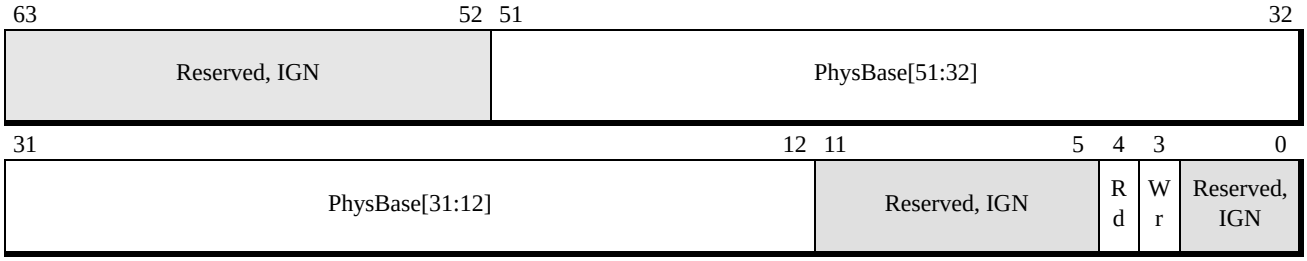
The intersection of the IORR range with the equivalent effective MTRR range follows the same type encoding table (Table 7-12) as the fixed-range MTRR, where the RdMem/WrMem and memory type are directly tied together.

IORRBase*n* Registers. The fields in these IORRs are:

- *WrMem*—Bit 3. When set to 1, the processor directs write requests for this physical address range to system memory. When cleared to 0, writes are directed to memory-mapped I/O.
- *RdMem*—Bit 4. When set to 1, the processor directs read requests for this physical address range to system memory. When cleared to 0, reads are directed to memory-mapped I/O.
- *Range Physical-Base-Address (PhysBase)*—Bits 51:12. The memory-range base-address in physical-address space. PhysBase is aligned on a 4-Kbyte (or greater) address in the 52-bit physical-address space supported by the AMD64 architecture. PhysBase represents the most-significant 40-address bits of the physical address. Physical-address bits 11:0 are assumed to be 0.

Note that a given processor may implement less than the architecturally-defined physical address size of 52 bits.

The format of these registers is shown in Figure 7-12.



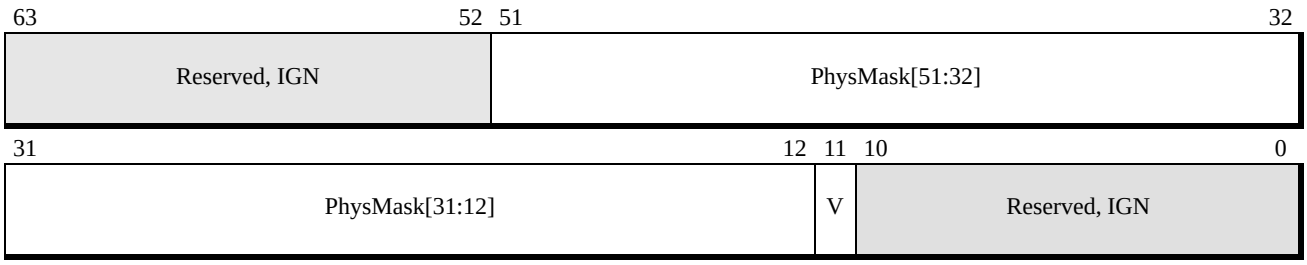
Bits	Mnemonic	Description	Access type
63:52	—	Reserved	Ignored
51:12	PhysBase	Range Physical Base Address	R/W
11:5	—	Reserved	Ignored
4	Rd	RdMem Enable	R/W
3	Wr	WrMem Enable	R/W
2:0	—	Reserved	Ignored

Figure 7-12. IORRBase*n* Register

IORRMask*n* Registers. The fields in these IORRs are:

- *Valid (V)*—Bit 11. Indicates that the IORR pair is valid (enabled) when set to 1. When the valid bit is cleared to 0 the register pair is not used for memory-mapped I/O control (disabled).
- *Range Physical-Mask (PhysMask)*—Bits 51:12. The mask value used to specify the memory range. Like PhysBase, PhysMask is aligned on a 4-Kbyte physical-address boundary. Bits 11:0 of PhysMask are assumed to be 0.

The format of these registers is shown in Figure 7-13 on page 226.



Bits	Mnemonic	Description	Access type
63:52	—	Reserved	Ignored
51:12	PhysMask	Range Physical Mask	R/W
11	V	I/O Register Pair Enable (Valid)	R/W
10:0	—	Reserved	Ignored

Figure 7-13. IORRMask*n* Register

The operation of the PhysMask and PhysBase fields is identical to that of the variable-range MTRRs. See page 213 for a description of this operation.

7.9.3 IORR Overlapping

The use of overlapping IORRs is not recommended. If overlapping IORRs are specified, the resulting behavior is implementation-dependent.

7.9.4 Top of Memory

The *top-of-memory* registers, TOP_MEM and TOP_MEM2, allow system software to specify physical addresses ranges as memory-mapped I/O locations. Processor implementations can direct accesses to memory-mapped I/O differently than system I/O, and the precise method depends on the implementation. System software specifies memory-mapped I/O regions by writing an address into each of the top-of-memory registers. The memory regions specified by the TOP_MEM registers are aligned on 8-Mbyte boundaries as follows:

- Memory accesses from physical address 0 to one less than the value in TOP_MEM are directed to system memory.
- Memory accesses from the physical address specified in TOP_MEM to FFFF_FFFFh are directed to memory-mapped I/O.

- Memory accesses from physical address 1_0000_0000h to one less than the value in TOP_MEM2 are directed to system memory.
- Memory accesses from the physical address specified in TOP_MEM2 to the maximum physical address supported by the system are directed to memory-mapped I/O.

Figure 7-14 on page 227 shows how the top-of-memory registers organize memory into separate system-memory and memory-mapped I/O regions.

The intersection of the top-of-memory range with the equivalent effective MTRR range follows the same type encoding table (Table 7-12 on page 224) as the fixed-range MTRR, where the RdMem/WrMem and memory type are directly tied together.

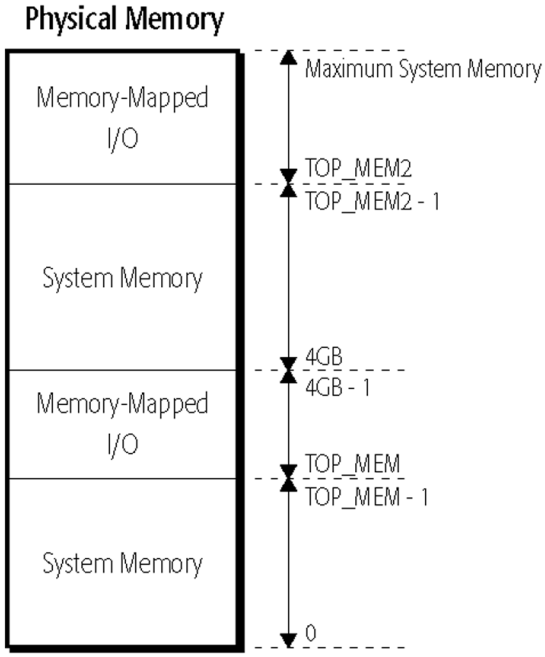


Figure 7-14. Memory Organization Using Top-of-Memory Registers

Figure 7-15 shows the format of the TOP_MEM and TOP_MEM2 registers. Bits 51:23 specify an 8-Mbyte aligned physical address. All remaining bits are reserved and ignored by the processor. System software should clear those bits to zero to maintain compatibility with possible future extensions to the registers. The TOP_MEM registers are model-specific registers. See “Memory-Typing MSRs” on page 669 for information on the MSR address and reset values for these registers.

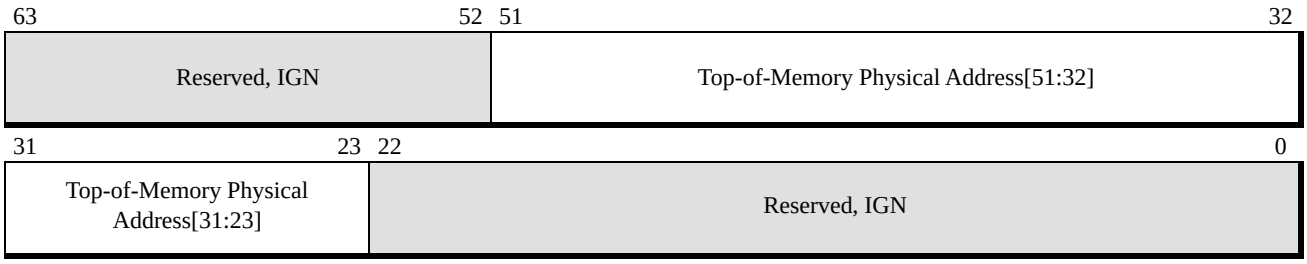

Figure 7-15. Top-of-Memory Registers (TOP_MEM, TOP_MEM2)

The TOP_MEM register is enabled by setting the MtrrVarDramEn bit in the SYSCFG MSR (bit 20) to 1 (one). The TOP_MEM2 register is enabled by setting the MtrrTom2En bit in the SYSCFG MSR (bit 21) to 1 (one). The registers are disabled when their respective enable bits are cleared to 0. When the top-of-memory registers are disabled, memory accesses default to memory-mapped I/O space.

Note that a given processor may implement fewer than the architecturally-defined number of physical address bits.

7.10 Secure Memory Encryption

Software running in non-virtualized (native) mode can utilize the Secure Memory Encryption (SME) feature to mark individual pages of memory as encrypted through the page tables. A page of memory marked encrypted will be automatically decrypted when read by software and automatically encrypted when written to DRAM. SME may therefore be used to protect the contents of DRAM from physical attacks on the system.

All memory encrypted using SME is encrypted with the same AES key which is created randomly each time a system is booted. The memory encryption key cannot be read or modified by software.

For details on using memory encryption in virtualized environments, please see Section 15.34, “Secure Encrypted Virtualization,” on page 571.

7.10.1 Determining Support for Secure Memory Encryption

Support for memory encryption features is reported in CPUID Fn8000_001F[EAX]. Bit 0 indicates support for Secure Memory Encryption. When this feature is present, CPUID Fn8000_001F[EBX] supplies additional information regarding the use of memory encryption such as which page table bit is used to mark pages as encrypted.

Additionally, in some implementations, the physical address size of the processor may be reduced when memory encryption features are enabled, for example from 48 to 43 bits. In this case the upper physical address bits are treated as reserved when the feature is enabled except where otherwise indicated. When memory encryption is supported in an implementation, CPUID Fn8000_001F[EBX] reports any physical address size reduction present. Bits reserved in this mode are treated the same as

other page table reserved bits, and will generate a page fault if found to be non-zero when used for address translation.

Complete CPUID details for encrypted memory features can be found in Volume 3, section E.4.17.

7.10.2 Enabling Memory Encryption Extensions

Prior to using SME, memory encryption features must be enabled by setting SYSCFG MSR bit 23 (MemEncryptionModEn) to 1. In implementations where the physical address size of the processor is reduced when memory encryption features are enabled, software must ensure it is executing from addresses where these upper physical address bits are 0 prior to setting SYSCFG[MemEncryptionModEn]. Memory encryption is then further controlled via the page tables.

Note that software should keep the value of SYSCFG[MemEncryptionModEn] consistent across all CPU cores in the system. Failure to do so may lead to unexpected results.

7.10.3 Supported Operating Modes

SME is supported in all CPU modes when CR4.PAE=1 and paging is enabled. This includes long mode as well as legacy PAE-enabled protected mode.

7.10.4 Page Table Support

Software utilizes the page tables to indicate if a memory page is encrypted or unencrypted. The location of the specific attribute bit (C-bit, or enCrypted bit) used is implementation-specific but may be determined by referencing CPUID Fn8000_001F[EBX] (see Volume 3, section E.4.17 for details) . In some implementations, the bit used may be a physical address bit (e.g., address bit 47), especially in cases where the physical address size is reduced by hardware when memory encryption features are enabled.

To mark a memory page for encryption when stored in DRAM, software sets the C-bit to 1 for the page. If the C-bit is 0, the page is not encrypted when stored in DRAM. The C bit can be applied to translation table entries for any size of page - 4KB, 2MB, or 1GB.

Note that it is possible for the page tables themselves to be located in encrypted memory. For instance, if the C-bit is set in a PML4 entry, the PDP table it points to (and thus all PDPEs in that table) will be loaded from encrypted memory.

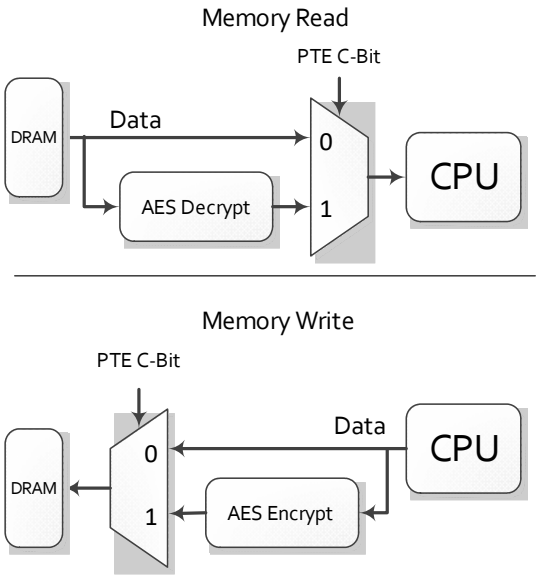

Figure 7-16. Encrypted Memory Accesses

7.10.5 I/O Accesses

In implementations where the physical address size is reduced when memory encryption features are enabled, memory range checks (e.g. MTRR/TOM/IORR/etc.) to determine memory types or DRAM/MMIO are performed using the reduced physical address size. In particular, the C-bit is not considered a physical address bit and is masked by hardware for purposes of these checks.

Additionally, any pages corresponding to MMIO addresses must be configured with the C-bit clear. Encrypted I/O pages are not allowed and accesses with the C-bit set will be ignored.

7.10.6 Restrictions

In some hardware implementations, coherency between the encrypted and unencrypted mappings of the same physical page are not enforced. In such a system, prior to changing the value of the C-bit for a page, software should flush the page from all CPU caches in the system. If a hardware implementation supports coherency across encryption domains as indicated by CPUID Fn8000_001F_EAX[10] then this flush is not required.

Simply changing the value of a C-bit on a page will not automatically encrypt the existing contents of a page, and any data in the page prior to the C-bit modification will become unintelligible. To set the C-bit on a page and cause its contents to become encrypted so the data remains accessible, see Section 7.10.8, “Encrypt-in-Place,” on page 231.

In legacy PAE mode, if the C-bit location is in the upper 32 bits of the page table entry, the first level page table (the PDP table) cannot be located in encrypted memory. This is because when the CPU is in 32-bit PAE mode, the CR3 value is only 32-bits in length.

7.10.7 SMM Interaction

SME is available when the processor is executing in SMM, once it has enabled paging. Any physical address bit restrictions that exist due to memory encryption features being enabled remain in place while in SMM.

7.10.8 Encrypt-in-Place

It is possible to perform an in-place encryption of data in physical memory. This technique is useful for setting the C-bit on a page while maintaining visibility to the page's contents such as during SME initialization. This is accomplished by creating two linear mappings of the same page where one mapping has the C-bit set to 0 and the other has the C-bit set to 1. To avoid possible data corruption, software should use the following algorithm for performing in-place encryption of memory:

1. Create two linear mappings X and Y that map to the same physical page. Mapping X has C-bit=0 and uses the WP (Write Protect) memory type. Mapping Y has C-bit=1 and uses the WB (Write-Back) memory type.
2. Perform a WBINVD on all cores in the system.
3. Copy N bytes from mapping X to a temporary buffer in conventionally-mapped memory (for which the C bit may or may not be set, as desired). N must be equal to the L1 cache line size as specified by CPUID Fn8000_0005[ECX].
4. Write N bytes from the temporary buffer to Y. Note that the initial cache refill of the line for this step will cause it to be decrypted, which corrupts the contents since it is not yet encrypted. This step restores the original contents. (If the line were evicted before this step was completed, the unwritten portion would get corrupted by the outgoing encryption, which is why the line can't be copied in-place, but rather must be copied from the temporary buffer.)
5. Repeat steps 3-4 until the entire page has been copied.

8 Exceptions and Interrupts

Exceptions and interrupts force control transfers from the currently-executing program to a system-software service routine that handles the interrupting event. These routines are referred to as *exception handler*s and *interrupt handlers*, or collectively as *event handlers*. Typically, interrupt events can be handled by the service routine transparently to the interrupted program. During the control transfer to the service routine, the processor stops executing the interrupted program and saves its return pointer. The system-software service routine that handles the exception or interrupt is responsible for saving the state of the interrupted program. This allows the processor to restart the interrupted program after system software has handled the event.

When an exception or interrupt occurs, the processor uses the interrupt vector number as an index into the interrupt-descriptor table (IDT). An IDT is used in all processor operating modes, including real mode (also called real-address mode), protected mode, and long mode.

Exceptions and interrupts come from three general sources:

- *Exceptions* occur as a result of software execution errors or other internal-processor errors. Exceptions also occur during non-error situations, such as program single stepping or address-breakpoint detection. Exceptions are considered *synchronous* events because they are a direct result of executing the interrupted instruction.
- *Software interrupts* occur as a result of executing interrupt instructions. Unlike exceptions and external interrupts, software interrupts allow intentional triggering of the interrupt-handling mechanism. Like exceptions, software interrupts are synchronous events.
- *External interrupts* are generated by system logic in response to an error or some other event outside the processor. They are reported over the processor bus using external signaling. External interrupts are *asynchronous* events that occur independently of the interrupted instruction.

Throughout this section, the term *masking* can refer to either disabling or delaying an interrupt. For example, masking external interrupts *delays* the interrupt, with the processor holding the interrupt as pending until it is unmasked. With floating-point exceptions (SSE and x87), masking *prevents* an interrupt from occurring and causes the processor to perform a default operation on the exception condition.

8.1 General Characteristics

Exceptions and interrupts have several different characteristics that depend on how events are reported and the implications for program restart.

8.1.1 Precision

Precision describes how the exception is related to the interrupted program:

- *Precise* exceptions are reported on a predictable instruction boundary. This boundary is generally the first instruction that has not completed when the event occurs. All previous instructions (in

program order) are allowed to complete before transferring control to the event handler. The pointer to the instruction boundary is saved automatically by the processor. When the event handler completes execution, it returns to the interrupted program and restarts execution at the interrupted-instruction boundary.

- *Imprecise* exceptions are not guaranteed to be reported on a predictable instruction boundary. The boundary can be any instruction that has not completed when the interrupt event occurs. Imprecise events can be considered asynchronous, because the source of the interrupt is not necessarily related to the interrupted instruction. Imprecise exception and interrupt handlers typically collect machine-state information related to the interrupting event for reporting through system-diagnostic software. The interrupted program is not restartable.

8.1.2 Instruction Restart

As mentioned above, precise exceptions are reported on an instruction boundary. The instruction boundary can be reported in one of two locations:

- Most exceptions report the boundary *before* the instruction causing the exception. In this case, all previous instructions (in program order) are allowed to complete, but the interrupted instruction is not. *No program state is updated as a result of partially executing an interrupted instruction.*
- Some exceptions report the boundary *after* the instruction causing the exception. In this case, all previous instructions—including the one executing when the exception occurred—are allowed to complete.

  Program state can be updated when the reported boundary is after the instruction causing the exception. This is particularly true when the event occurs as a result of a task switch. In this case, the general registers, segment-selector registers, page-base address register, and LDTR are all updated by the hardware task-switch mechanism. The event handler cannot rely on the state of those registers when it begins execution and must be careful in validating the state of the segment-selector registers before restarting the interrupted task. This is not an issue in long mode, however, because the hardware task-switch mechanism is disabled in long mode.

8.1.3 Types of Exceptions

There are three types of exceptions, depending on whether they are precise and how they affect program restart:

- *Faults* are precise exceptions reported on the boundary before the instruction causing the exception. Generally, faults are caused by an error condition involving the faulted instruction. Any machine-state changes caused by the faulting instruction are discarded so that the instruction can be restarted. The saved rIP points to the faulting instruction.
- *Traps* are precise exceptions reported on the boundary following the instruction causing the exception. The trapped instruction is completed by the processor and all state changes are saved. The saved rIP points to the instruction following the faulting instruction.
- *Aborts* are imprecise exceptions. Because they are imprecise, aborts typically do not allow reliable program restart.

8.1.4 Masking External Interrupts

General Masking Capabilities. Software can *mask* the occurrence of certain exceptions and interrupts. Masking can delay or even prevent triggering of the exception-handling or interrupt-handling mechanism when an interrupt-event occurs. External interrupts are classified as maskable or nonmaskable:

- *Maskable interrupts* trigger the interrupt-handling mechanism only when RFLAGS.IF=1. Otherwise they are held pending for as long as the RFLAGS.IF bit is cleared to 0.
- *Nonmaskable interrupts* (NMI) are unaffected by the value of the RFLAGS.IF bit. However, the occurrence of an NMI masks further NMIs until an IRET instruction is executed to completion or, in the event of a task switch, to the completion of the outgoing TSS update. An exception raised during execution of the IRET prior to these points will result in NMI continuing to be masked for the duration of the exception handler, until the exception handler completes an IRET.

Masking During Stack Switches. The processor delays recognition of maskable external interrupts and debug exceptions during certain instruction sequences that are often used by software to switch stacks. The typical programming sequence used to switch stacks is:

1. Load a stack selector into the SS register.
2. Load a stack offset into the ESP register.

If an interrupting event occurs after the selector is loaded but before the stack offset is loaded, the interrupted-program stack pointer is invalid during execution of the interrupt handler.

To prevent interrupts from causing stack-pointer problems, the processor does not allow external interrupts or debug exceptions to occur until the instruction immediately following the MOV SS or POP SS instruction completes execution.

The recommended method of performing this sequence is to use the LSS instruction. LSS loads both SS and ESP, and the instruction inhibits interrupts until both registers are updated successfully.

8.1.5 Masking Floating-Point and Media Instructions

Any x87 floating-point exceptions can be masked and reported later using bits in the x87 floating-point status register (FSW) and the x87 floating-point control register (FCW). The floating-point exception-pending exception is used for unmasked x87 floating-point exceptions (see Section “#MF—x87 Floating-Point Exception-Pending (Vector 16)” on page 248).

The SIMD floating-point exception is used for unmasked SSE floating-point exceptions (see Section “#XF—SIMD Floating-Point Exception (Vector 19)” on page 250). SSE floating-point exceptions are masked using the MXCSR register. The exception mechanism is not triggered when these exceptions are masked. Instead, the processor handles the exceptions in a default manner.

8.1.6 Disabling Exceptions

Disabling an exception prevents the exception condition from being recognized, unlike masking an exception which prevents triggering the exception mechanism after the exception is recognized. Some exceptions can be disabled by system software running at CPL=0, using bits in the CR0 register or CR4 register:

- Alignment-check exception (see Section “#AC—Alignment-Check Exception (Vector 17)” on page 249).
- Device-not-available exception (see Section “#NM—Device-Not-Available Exception (Vector 7)” on page 242).
- Machine-check exception (see Section “#MC—Machine-Check Exception (Vector 18)” on page 250).

The debug-exception mechanism provides control over when specific breakpoints are enabled and disabled. See Section “Setting Breakpoints” on page 393 for more information on how breakpoint controls are used for triggering the debug-exception mechanism.

8.2 Vectors

Specific exception and interrupt sources are assigned a fixed vector-identification number (also called an “interrupt vector” or simply “vector”). The interrupt vector is used by the interrupt-handling mechanism to locate the system-software service routine assigned to the exception or interrupt. Up to 256 unique interrupt vectors are available. The first 32 vectors are reserved for predefined exception and interrupt conditions. Software-interrupt sources can trigger an interrupt using any available interrupt vector.

Table 8-1 on page 237 lists the supported interrupt vector numbers, the corresponding exception or interrupt name, the mnemonic, the source of the interrupt event, and a summary of the possible causes.

Table 8-1. Interrupt Vector Source and Cause

Vector	Exception/Interrupt	Mnemonic	Cause
0	Divide-by-Zero-Error	#DE	DIV, IDIV, AAM instructions
1	Debug	#DB	Instruction accesses and data accesses
2	Non-Maskable-Interrupt	#NMI	External NMI signal
3	Breakpoint	#BP	INT3 instruction
4	Overflow	#OF	INTO instruction
5	Bound-Range	#BR	BOUND instruction
6	Invalid-Opcode	#UD	Invalid instructions
7	Device-Not-Available	#NM	x87 instructions
8	Double-Fault	#DF	Exception during the handling of another exception or interrupt
9	Coprocessor-Segment-Overrun	—	Unsupported (Reserved)
10	Invalid-TSS	#TS	Task-state segment access and task switch
11	Segment-Not-Present	#NP	Segment register loads
12	Stack	#SS	SS register loads and stack references
13	General-Protection	#GP	Memory accesses and protection checks
14	Page-Fault	#PF	Memory accesses when paging enabled
15	Reserved	—	
16	x87 Floating-Point Exception-Pending	#MF	x87 floating-point instructions
17	Alignment-Check	#AC	Misaligned memory accesses
18	Machine-Check	#MC	Model specific
19	SIMD Floating-Point	#XF	SSE floating-point instructions
20	Reserved	—	
21	Control-Protection Exception	#CP	RET/IRET or other control transfer
22–27	Reserved	—	
28	Hypervisor Injection Exception	#HV	Event injection
29	VMM Communication Exception	#VC	Virtualization event
30	Security Exception	#SX	Security-sensitive event in host
31	Reserved	—	
0–255	External Interrupts (Maskable)	#INTR	External interrupts
0–255	Software Interrupts	—	INT*n* instruction

Table 8-2 on page 238 shows how each interrupt vector is classified. Reserved interrupt vectors are indicated by the gray-shaded rows.

Table 8-2. Interrupt Vector Classification

Vector	Interrupt (Exception)	Type	Precise	Class[2]
0	Divide-by-Zero-Error	Fault	yes	Contributory
1	Debug	Fault or Trap		Benign
2	Non-Maskable-Interrupt	—	—	
3	Breakpoint	Trap	yes	
4	Overflow			
5	Bound-Range	Fault		
6	Invalid-Opcode			
7	Device-Not-Available			
8	Double-Fault	Abort	no	
9	Coprocessor-Segment-Overrun			
10	Invalid-TSS	Fault	yes	Contributory
11	Segment-Not-Present			
12	Stack			
13	General-Protection			
14	Page-Fault			Benign or Contributory
15	Reserved			
16	x87 Floating-Point Exception-Pending	Fault	no	Benign
17	Alignment-Check		yes	
18	Machine-Check	Abort	no	
19	SIMD Floating-Point	Fault	yes	
20	Reserved			
21	Control Protection	Fault	yes	Contributory
22–27	Reserved			
28	Hypervisor Injection Exception	–	–	Benign
29	VMM Communication Exception	Fault	yes	Contributory
30	Security Exception	–	yes	Contributory
31	Reserved			
0–255	External Interrupts (Maskable)	—[1]	—[1]	Benign
0–255	Software Interrupts			

Note:

1. *External interrupts are not classified by type or whether or not they are precise.*
2. *See Section "#DF—Double-Fault Exception (Vector 8)" on page 242 for a definition of benign and contributory classes.*

The following sections describe each interrupt in detail. The format of the error code reported by each interrupt is described in Section "Error Codes" on page 253.

8.2.1 #DE—Divide-by-Zero-Error Exception (Vector 0)

A #DE exception occurs when the denominator of a DIV instruction or an IDIV instruction is 0. A #DE also occurs if the result is too large to be represented in the destination.

#DE cannot be disabled.

Error Code Returned. None.

Program Restart. #DE is a fault-type exception. The saved instruction pointer points to the instruction that caused the #DE.

8.2.2 #DB—Debug Exception (Vector 1)

When the debug-exception mechanism is enabled, a #DB exception can occur under any of the following circumstances:

- Instruction execution.
- Instruction single stepping.
- Data read.
- Data write.
- I/O read.
- I/O write.
- Task switch.
- Debug-register access, or *general detect fault (debug register access when DR7.GD=1).*
- Executing the INT1 instruction (opcode 0F1h).

#DB conditions are enabled and disabled using the debug-control register, DR7 and RFLAGS.TF. Each #DB condition is described in more detail in Section “Setting Breakpoints” on page 393.

Error Code Returned. None. #DB information is returned in the debug-status register, DR6.

Program Restart. #DB can be either a fault-type or trap-type exception. In the following cases, the saved instruction pointer points to the instruction that caused the #DB:

- Instruction execution.
- Invalid debug-register access, or *general detect.*

In all other cases, the instruction that caused the #DB is completed, and the saved instruction pointer points to the instruction after the one that caused the #DB.

The RFLAGS.RF bit can be used to restart an instruction following an instruction breakpoint resulting in a #DB. In most cases, the processor clears RFLAGS.RF to 0 after every instruction is successfully executed. However, in the case of the IRET, JMP, CALL, and INT*n (*through a task gate) instructions, RFLAGS.RF is not cleared to 0 until the *next* instruction successfully executes.

When a non-debug exception occurs (or when a string instruction is interrupted), the processor normally sets RFLAGS.RF to 1 in the rFLAGS *image* that is pushed on the interrupt stack. A subsequent IRET back to the interrupted program pops the rFLAGS image off the stack and into the RFLAGS register, with RFLAGS.RF=1. The interrupted instruction executes without causing an instruction breakpoint, after which the processor clears RFLAGS.RF to 0.

However, when a #DB exception occurs, the processor clears RFLAGS.RF to 0 in the rFLAGS image that is pushed on the interrupt stack. The #DB handler has two options:

- Disable the instruction breakpoint completely.
- Set RFLAGS.RF to 1 in the interrupt-stack rFLAGS image. The instruction breakpoint condition is ignored immediately after the IRET, but reoccurs if the instruction address is accessed later, as can occur in a program loop.

8.2.3 NMI—Non-Maskable-Interrupt Exception (Vector 2)

An NMI exception occurs as a result of system logic signaling a non-maskable interrupt to the processor.

Error Code Returned. None.

Program Restart. NMI is an interrupt. The processor recognizes an NMI at an instruction boundary. The saved instruction pointer points to the instruction immediately following the boundary where the NMI was recognized.

Masking. NMI cannot be masked. However, when an NMI is recognized by the processor, recognition of subsequent NMIs are disabled until an IRET instruction is executed.

8.2.4 #BP—Breakpoint Exception (Vector 3)

A #BP exception occurs when an INT3 instruction is executed. The INT3 is normally used by debug software to set instruction breakpoints by replacing instruction-opcode bytes with the INT3 opcode.

#BP cannot be disabled.

Error Code Returned. None.

Program Restart. #BP is a trap-type exception. The saved instruction pointer points to the byte after the INT3 instruction. This location can be the start of the next instruction. However, if the INT3 is used to replace the first opcode bytes of an instruction, the restart location is likely to be in the middle of an instruction. In the latter case, the debug software must replace the INT3 byte with the correct instruction byte. The saved RIP instruction pointer must then be decremented by one before returning to the interrupted program. This allows the program to be restarted correctly on the interrupted-instruction boundary.

8.2.5 #OF—Overflow Exception (Vector 4)

An #OF exception occurs as a result of executing an INTO instruction while the overflow bit in RFLAGS is set to 1 (RFLAGS.OF=1).

#OF cannot be disabled.

Error Code Returned. None.

Program Restart. #OF is a trap-type exception. The saved instruction pointer points to the instruction following the INTO instruction that caused the #OF.

8.2.6 #BR—Bound-Range Exception (Vector 5)

A #BR exception can occur as a result of executing the BOUND instruction. The BOUND instruction compares an array index (first operand) with the lower bounds and upper bounds of an array (second operand). If the array index is not within the array boundary, the #BR occurs.

#BR cannot be disabled.

Error Code Returned. None.

Program Restart. #BR is a fault-type exception. The saved instruction pointer points to the BOUND instruction that caused the #BR.

8.2.7 #UD—Invalid-Opcode Exception (Vector 6)

A #UD exception occurs when an attempt is made to execute an invalid or undefined opcode. The validity of an opcode often depends on the processor operating mode. A #UD occurs under the following conditions:

- Execution of any reserved or undefined opcode in any mode.
- Execution of the UD0, UD1 or UD2 instructions.
- Use of the LOCK prefix on an instruction that cannot be locked.
- Use of the LOCK prefix on a lockable instruction with a non-memory target location.
- Execution of an instruction with an invalid-operand type.
- Execution of the SYSENTER or SYSEXIT instructions in long mode.
- Execution of any of the following instructions in 64-bit mode: AAA, AAD, AAM, AAS, BOUND, CALL (opcode 9A), DAA, DAS, DEC, INC, INTO, JMP (opcode EA), LDS, LES, POP (DS, ES, SS), POPA, PUSH (CS, DS, ES, SS), PUSHA, SALC.
- Execution of the ARPL, LAR, LLDT, LSL, LTR, SLDT, STR, VERR, or VERW instructions when protected mode is not enabled, or when virtual-8086 mode is enabled.
- Execution of any legacy SSE instruction when CR4.OSFXSR is cleared to 0. (For further information, see Section “FXSAVE/FXRSTOR Support (OSFXSR)” on page 50.

- Execution of any SSE instruction (uses YMM/XMM registers), or 64-bit media instruction (uses MMX™ registers) when CR0.EM = 1.
- Execution of any SSE floating-point instruction (uses YMM/XMM registers) that causes a numeric exception when CR4.OSXMMEXCPT = 0.
- Use of the DR4 or DR5 debug registers when CR4.DE = 1.
- Execution of RSM when not in SMM mode.

See the specific instruction description (in the other volumes) for additional information on invalid conditions.

#UD cannot be disabled.

Error Code Returned. None.

Program Restart. #UD is a fault-type exception. The saved instruction pointer points to the instruction that caused the #UD.

8.2.8 #NM—Device-Not-Available Exception (Vector 7)

A #NM exception occurs under any of the following conditions:

- An FWAIT/WAIT instruction is executed when CR0.MP=1 and CR0.TS=1.
- Any x87 instruction other than FWAIT is executed when CR0.EM=1.
- Any x87 instruction is executed when CR0.TS=1. The CR0.MP bit controls whether the FWAIT/WAIT instruction causes an #NM exception when TS=1.
- Any 128-bit or 64-bit media instruction when CR0.TS=1.

#NM can be enabled or disabled under the control of the CR0.MP, CR0.EM, and CR0.TS bits as described above. See Section 3.1.1 for more information on the CR0 bits used to control the #NM exception.

Error Code Returned. None.

Program Restart. #NM is a fault-type exception. The saved instruction pointer points to the instruction that caused the #NM.

8.2.9 #DF—Double-Fault Exception (Vector 8)

A #DF exception can occur when a second exception occurs during the handling of a prior (first) exception or interrupt handler.

Usually, the first and second exceptions can be handled sequentially without resulting in a #DF. In this case, the first exception is considered *benign*, as it does not harm the ability of the processor to handle the second exception.

In some cases, however, the first exception adversely affects the ability of the processor to handle the second exception. These exceptions contribute to the occurrence of a #DF, and are called *contributory*

exceptions. If a contributory exception is followed by another contributory exception, a double-fault exception occurs. Likewise, if a page fault is followed by another page fault or a contributory exception, a double-fault exception occurs.

Table 8-3 shows the conditions under which a #DF occurs. Page faults are either benign or contributory, and are listed separately. See the “Class” column in Table 8-2 on page 238 for information on whether an exception is benign or contributory.

Table 8-3. Double-Fault Exception Conditions

First Interrupting Event	Second Interrupting Event
Contributory Exceptions • Divide-by-Zero-Error Exception • Invalid-TSS Exception • Segment-Not-Present Exception • Stack Exception • General-Protection Exception	 Invalid-TSS Exception Segment-Not-Present Exception Stack Exception General-Protection Exception
Page Fault Exception	Page Fault Exception Invalid-TSS Exception Segment-Not-Present Exception Stack Exception General-Protection Exception

If a third interrupting event occurs while transferring control to the #DF handler, the processor shuts down. Only an NMI, RESET, or INIT can restart the processor in this case. However, if the processor shuts down as it is executing an NMI handler, the processor can only be restarted with RESET or INIT.

#DF cannot be disabled.

Error Code Returned. Zero.

Program Restart. #DF is an abort-type exception. The saved instruction pointer is undefined, and the program cannot be restarted.

8.2.10 Coprocessor-Segment-Overrun Exception (Vector 9)

This interrupt vector is reserved. It is for a discontinued exception originally used by processors that supported external x87-instruction coprocessors. On those processors, the exception condition is caused by an invalid-segment or invalid-page access on an x87-instruction coprocessor-instruction operand. On current processors, this condition causes a general-protection exception to occur.

Error Code Returned. Not applicable.

Program Restart. Not applicable.

8.2.11 #TS—Invalid-TSS Exception (Vector 10)

A #TS exception occurs when an invalid reference is made to a segment selector as part of a task switch. A #TS also occurs during a privilege-changing control transfer (through a call gate or an interrupt gate), if a reference is made to an invalid stack-segment selector located in the TSS. Table 8-4 lists the conditions under which a #TS occurs and the error code returned by the exception mechanism.

#TS cannot be disabled.

Error Code Returned. See Table 8-4 for a list of error codes returned by the #TS exception.

Program Restart. #TS is a fault-type exception. If the exception occurs before loading the segment selectors from the TSS, the saved instruction pointer points to the instruction that caused the #TS. However, most #TS conditions occur due to errors with the loaded segment selectors. When an error is found with a segment selector, the hardware task-switch mechanism completes loading the new task state from the TSS, and then triggers the #TS exception mechanism. In this case, the saved instruction pointer points to the first instruction in the new task.

In long mode, a #TS cannot be caused by a task switch, because the hardware task-switch mechanism is disabled. A #TS occurs only as a result of a control transfer through a gate descriptor that results in an invalid stack-segment reference using an SS selector in the TSS. In this case, the saved instruction pointer always points to the control-transfer instruction that caused the #TS.

Table 8-4. Invalid-TSS Exception Conditions

Selector Reference	Error Condition	Error Code
Task-State Segment	TSS limit check on a task switch	TSS Selector Index
	TSS limit check on an inner-level stack pointer	
LDT Segment	LDT does not point to GDT	LDT Selector Index
	LDT reference outside GDT	
	GDT entry is not an LDT descriptor	
	LDT descriptor is not present	
Code Segment	CS reference outside GDT or LDT	CS Selector Index
	Privilege check (conforming DPL > CPL)	
	Privilege check (non-conforming DPL ≠ CPL)	
	Type check (CS not executable)	
Data Segment	Data segment reference outside GDT or LDT	DS, ES, FS or GS Selector Index
	Type check (data segment not readable)	
Stack Segment	SS reference outside GDT or LDT	SS Selector Index
	Privilege check (stack segment descriptor DPL ≠ CPL)	
	Privilege check (stack segment selector RPL ≠ CPL)	
	Type check (stack segment not writable)	

8.2.12 #NP—Segment-Not-Present Exception (Vector 11)

An #NP occurs when an attempt is made to load a segment or gate with a clear present bit, as described in the following situations:

- Using the MOV, POP, LDS, LES, LFS, or LGS instructions to load a segment selector (DS, ES, FS, and GS) that references a segment descriptor containing a clear present bit (descriptor.P=0).
- Far transfer to a CS that is not present.
- Referencing a gate descriptor containing a clear present bit.
- Referencing a TSS descriptor containing a clear present bit. This includes attempts to load the TSS descriptor using the LTR instruction.
- Attempting to load a descriptor containing a clear present bit into the LDTR using the LLDT instruction.
- Loading a segment selector (CS, DS, ES, FS, or GS) as part of a task switch, with the segment descriptor referenced by the segment selector having a clear present bit. In long mode, an #NP cannot be caused by a task switch, because the hardware task-switch mechanism is disabled.

When loading a stack-segment selector (SS) that references a descriptor with a clear present bit, a stack exception (#SS) occurs. For information on the #SS exception, see the next section, "#SS—Stack Exception (Vector 12)."

#NP cannot be disabled.

Error Code Returned. The segment-selector index of the segment descriptor causing the #NP exception.

Program Restart. #NP is a fault-type exception. In most cases, the saved instruction pointer points to the instruction that loaded the segment selector resulting in the #NP. See Section "Exceptions During a Task Switch" on page 253 for a description of the consequences when this exception occurs during a task switch.

8.2.13 #SS—Stack Exception (Vector 12)

An #SS exception can occur in the following situations:

- Implied stack references in which the stack address is not in canonical form. Implied stack references include all push and pop instructions, and any instruction using RSP or RBP as a base register.
- Attempting to load a stack-segment selector that references a segment descriptor containing a clear present bit (descriptor.P=0).
- Any stack access that fails the stack-limit check.

#SS cannot be disabled.

Error Code Returned. The error code depends on the cause of the #SS, as shown in Table 8-5 on page 246:

Table 8-5. Stack Exception Error Codes

Stack Exception Cause	Error Code
Stack-segment descriptor present bit is clear	SS Selector Index
Stack-limit violation	0
Stack reference using a non-canonical address	0

Program Restart. #SS is a fault-type exception. In most cases, the saved instruction pointer points to the instruction that caused the #SS. See Section “Exceptions During a Task Switch” on page 253 for a description of the consequences when this exception occurs during a task switch.

8.2.14 #GP—General-Protection Exception (Vector 13)

Table 8-6 describes the general situations that can cause a #GP exception. The table is not an exhaustive, detailed list of #GP conditions, but rather a guide to the situations that can cause a #GP. If an invalid use of an AMD64 architectural feature results in a #GP, the specific cause of the exception is described in detail in the section describing the architectural feature.

#GP cannot be disabled.

Error Code Returned. As shown in Table 8-6, a selector index is reported as the error code if the #GP is due to a segment-descriptor access. In all other cases, an error code of 0 is returned.

Program Restart. #GP is a fault-type exception. In most cases, the saved instruction pointer points to the instruction that caused the #GP. See Section “Exceptions During a Task Switch” on page 253 for a description of the consequences when this exception occurs during a task switch.

Table 8-6. General-Protection Exception Conditions

Error Condition	Error Code
Any segment privilege-check violation, while loading a segment register.	Selector Index
Any segment type-check violation, while loading a segment register.	
Loading a null selector into the CS, SS, or TR register.	
Accessing a gate-descriptor containing a null segment selector.	
Referencing an LDT descriptor or TSS descriptor located in the LDT.	
Attempting a control transfer to a busy TSS (except IRET).	
In 64-bit mode, loading a non-canonical base address into the GDTR or IDTR.	
In long mode, accessing a system or call-gate descriptor whose extended type field is not 0.	
In long mode, accessing a system descriptor containing a non-canonical base address.	
In long mode, accessing a gate descriptor containing a non-canonical offset.	
In long mode, accessing a gate descriptor that does not point to a 64-bit code segment.	
In long mode, accessing a 16-bit gate descriptor.	
In long mode, attempting a control transfer to a TSS or task gate.	

Table 8-6. General-Protection Exception Conditions (continued)

Error Condition	Error Code
Any segment limit-check or non-canonical address violation (except when using the SS register).	0
Accessing memory using a null segment register.	
Writing memory using a read-only segment register.	
Attempting to execute an SSE instruction specifying an unaligned memory operand.	
Attempting to execute code that is past the CS segment limit or at a non-canonical RIP.	
Executing a privileged instruction while CPL > 0.	
Executing an instruction that is more than 15 bytes long.	
Writing a 1 into any register field that is reserved, must be zero (MBZ).	
Using WRMSR to write a read-only MSR.	
Using WRMSR to write a non-canonical value into an MSR that must be canonical.	
Using WRMSR to set an invalid type encoding in an MTRR or the PAT MSR.	0
Enabling paging while protected mode is disabled.	
Setting CR0.NW=1 while CR0.CD=0.	
Any long-mode consistency-check violation.	

8.2.15 #PF—Page-Fault Exception (Vector 14)

A #PF exception can occur during a memory access in any of the following situations:

- A page-translation-table entry or physical page involved in translating the memory access is not present in physical memory. This is indicated by a cleared present bit (P=0) in the translation-table entry.
- An attempt is made by the processor to load the instruction TLB with a translation for a non-executable page.
- The memory access fails the paging-protection checks (user/supervisor, read/write, or both).
- A reserved bit in one of the page-translation-table entries is set to 1. A #PF occurs for this reason only when CR4.PSE=1 *or* CR4.PAE=1.
- A data access to a user-mode address caused a protection key violation.

#PF cannot be disabled.

CR2 Register. The virtual (linear) address that caused the #PF is stored in the CR2 register. The legacy CR2 register is 32 bits long. The CR2 register in the AMD64 architecture is 64 bits long, as shown in Figure 8-1 on page 248. In AMD64 implementations, when either software or a page fault causes a write to the CR2 register, only the low-order 32 bits of CR2 are used in legacy mode; the processor clears the high-order 32 bits.

Figure 8-1. Control Register 2 (CR2)

Error Code Returned. The page-fault error code is pushed onto the page-fault exception-handler stack. See Section “Page-Fault Error Code” on page 254 for a description of this error code.

Program Restart. #PF is a fault-type exception. In most cases, the saved instruction pointer points to the instruction that caused the #PF. See Section “Exceptions During a Task Switch” on page 253 for a description of what can happen if this exception occurs during a task switch.

8.2.16 #MF—x87 Floating-Point Exception-Pending (Vector 16)

The #MF exception is used to handle unmasked x87 floating-point exceptions. An #MF occurs when *all* of the following conditions are true:

- CR0.NE=1.
- An unmasked x87 floating-point exception is pending. This is indicated by an exception bit in the x87 floating-point status-word register being set to 1
- The corresponding mask bit in the x87 floating-point control-word register is cleared to 0.
- The FWAIT/WAIT instruction or any waiting floating-point instruction is executed.

If there is an exception mask bit (in the FPU control word) set, the exception is not reported. Instead, the x87-instruction unit responds in a default manner and execution proceeds normally.

The x87 floating-point exceptions reported by the #MF exception are (including mnemonics):

- IE—Invalid-operation exception (also called #I), which is either:
  - IE alone—Invalid arithmetic-operand exception (also called #IA), or
  - SF and IE together—x87 Stack-fault exception (also called #IS).
- DE—Denormalized-operand exception (also called #D).
- ZE—Zero-divide exception (also called #Z).
- OE—Overflow exception (also called #O).
- UE—Underflow exception (also called #U).
- PE—Precision exception (also called #P or inexact-result exception).

Error Code Returned. None. Exception information is provided by the x87 status-word register. See “x87 Floating-Point Programming” in Volume 1 for more information on using this register.

Program Restart. #MF is a fault-type exception. The #MF exception is not precise, because multiple instructions and exceptions can occur before the #MF handler is invoked. Also, the saved instruction

pointer does not point to the instruction that caused the exception resulting in the #MF. Instead, the saved instruction pointer points to the x87 floating-point instruction or FWAIT/WAIT instruction that is about to be executed when the #MF occurs. The address of the *last instruction* that caused an x87 floating-point exception is in the x87 instruction-pointer register. See “x87 Floating-Point Programming” in Volume 1 for information on accessing this register.

Masking. Each type of x87 floating-point exception can be masked by setting the appropriate bits in the x87 control-word register. See “x87 Floating-Point Programming” in Volume 1 for more information on using this register.

#MF can also be disabled by clearing the CR0.NE bit to 0. See Section “Numeric Error (NE) Bit” on page 44 for more information on using this bit.

8.2.17 #AC—Alignment-Check Exception (Vector 17)

An #AC exception occurs when an unaligned-memory data reference is performed while alignment checking is enabled.

After a processor reset, #AC exceptions are disabled. Software enables the #AC exception by setting the following register bits:

- CR0.AM=1.
- RFLAGS.AC=1.

When the above register bits are set, an #AC can occur only when CPL=3. #AC never occurs when CPL < 3.

Table 8-7 lists the data types and the alignment boundary required to *avoid* an #AC exception when the mechanism is enabled.

Table 8-7. Data-Type Alignment

Supported Data Type	Required Alignment (Byte Boundary)
Word	2
Doubleword	4
Quadword	8
Bit string	2, 4 or 8 (depends on operand size)
256-bit media	16
128-bit media	16
64-bit media	8
Segment selector	2
32-bit near pointer	4
32-bit far pointer	2
48-bit far pointer	4

Table 8-7. Data-Type Alignment (continued)

Supported Data Type	Required Alignment (Byte Boundary)
x87 Floating-point single-precision	4
x87 Floating-point double-precision	8
x87 Floating-point extended-precision	8
x87 Floating-point save areas	2 or 4 (depends on operand size)

Error Code Returned. Zero.

Program Restart. #AC is a fault-type exception. The saved instruction pointer points to the instruction that caused the #AC.

8.2.18 #MC—Machine-Check Exception (Vector 18)

The #MC exception is model specific. Processor implementations are not required to support the #MC exception, and those implementations that do support #MC can vary in how the #MC exception mechanism works.

The exception is enabled by setting CR4.MCE to 1. The machine-check architecture can include model-specific masking for controlling the reporting of some errors. Refer to Chapter 9, “Machine Check Architecture,” for more information.

Error Code Returned. None. Error information is provided by model-specific registers (MSRs) defined by the machine-check architecture.

Program Restart. #MC is an abort-type exception. If the RIPV flag (RIP valid) is set in the MCG_Status MSR, the saved CS and rIP point to the instruction at which the interrupted process thread can be restarted. If RIPV is clear, there is no reliable way to restart the program. If the EIPV flag (EIP valid) is set in the MCG_Status MSR, the saved CS and rIP point to the process thread that caused the error. If EIPV is clear, the CS:rIP of the instruction causing the failure is not known or the machine check is not related to a specific instruction.

8.2.19 #XF—SIMD Floating-Point Exception (Vector 19)

The #XF exception is used to handle unmasked SSE floating-point exceptions. A #XF exception occurs when all of the following conditions are true:

- A SSE floating-point exception occurs. The exception causes the processor to set the appropriate exception-status bit in the MXCSR register to 1.
- The exception-mask bit in the MXCSR that corresponds to the SSE floating-point exception is clear (=0).
- CR4.OSXMMEXCPT=1, indicating that the operating system supports handling of SSE floating-point exceptions.

The exception-mask bits are used by software to specify the handling of SSE floating-point exceptions. When the corresponding mask bit is cleared to 0, an exception occurs under the control of the CR4.OSXMMEXCPT bit. However, if the mask bit is set to 1, the SSE floating-point unit responds in a default manner and execution proceeds normally.

The CR4.OSXMMEXCPT bit specifies the interrupt vector to be taken when an unmasked SSE floating-point exception occurs. When CR4.OSXMMEXCPT=1, the #XF interrupt vector is taken when an exception occurs. When CR4.OSXMMEXCPT=0, the #UD (undefined opcode) interrupt vector is taken when an exception occurs.

The SSE floating-point exceptions reported by the #XF exception are (including mnemonics):

- IE—Invalid-operation exception (also called #I).
- DE—Denormalized-operand exception (also called #D).
- ZE—Zero-divide exception (also called #Z).
- OE—Overflow exception (also called #O).
- UE—Underflow exception (also called #U).
- PE—Precision exception (also called #P or inexact-result exception).

Each type of SSE floating-point exception can be masked by setting the appropriate bits in the MXCSR register. #XF can also be disabled by clearing the CR4.OSXMMEXCPT bit to 0.

Error Code Returned. None. Exception information is provided by the SSE floating-point MXCSR register. See “Instruction Reference” in Volume 4 for more information on using this register.

Program Restart. #XF is a fault-type exception. Unlike the #MF exception, the #XF exception is precise. The saved instruction pointer points to the instruction that caused the #XF.

8.2.20 #CP—Control-Protection Exception (Vector 21)

A #CP exception is generated when shadow stacks are enabled (CR4.CET=1) and any of the following situations occur:

- For RET or IRET instructions, the return addresses on the shadow stack and the data stack do not match.
- An invalid supervisor shadow stack token is encountered by the CALL, RET, IRET, SETSSBSY or RSTORSSP instructions or during the delivery of an interrupt or exception.
- For inter-privilege RET and IRET instructions, the SSP is not 8-byte aligned, or the previous SSP from shadow stack is not 4-byte aligned or, in legacy or compatibility mode, is not less than 4GB.
- A task switch initiated by IRET where the incoming SSP is not aligned to 4 bytes or is not less than 4GB.

Error Code Returned. The #CP error code is pushed onto the control-protection exception-handler stack. See Section “Control-Protection Error Code” on page 254 for a description of this error code.

Program Restart. #CP is a fault-type exception. In most cases, the saved instruction pointer points to the instruction that caused the #CP. See Section “Exceptions During a Task Switch” on page 253 for a description of what can happen if this exception occurs during a task switch.

8.2.21 #HV—Hypervisor Injection Exception (Vector 28)

The #HV exception may be injected by the hypervisor into a secure guest VM to notify the VM of pending events. See Section 15.36.16 for details.

8.2.22 #VC—VMM Communication Exception (Vector 29)

The #VC exception is generated when certain events occur inside a secure guest VM. See Section 15.35.5 for more details.

8.2.23 #SX—Security Exception (Vector 30)

The #SX exception is generated by security-sensitive events under SVM. See Section 15.28 for details.

8.2.24 User-Defined Interrupts (Vectors 32–255)

User-defined interrupts can be initiated either by system logic or software. They occur when:

- System logic signals an external interrupt request to the processor. The signaling mechanism and the method of communicating the interrupt vector to the processor are implementation dependent.
- Software executes an INT*n* instruction. The INT*n* instruction operand provides the interrupt vector number.

Both methods can be used to initiate an interrupt into vectors 0 through 255. However, because vectors 0 through 31 are defined or reserved by the AMD64 architecture, software should not use vectors in this range for purposes other than their defined use.

Error Code Returned. None.

Program Restart. The saved instruction pointer depends on the interrupt source:

- External interrupts are recognized on instruction boundaries. The saved instruction pointer points to the instruction immediately following the boundary where the external interrupt was recognized.
- If the interrupt occurs as a result of executing the INT*n* instruction, the saved instruction pointer points to the instruction after the INT*n*.

Masking. The ability to mask user-defined interrupts depends on the interrupt source:

- External interrupts can be masked using the RFLAGS.IF bit. Setting RFLAGS.IF to 1 enables external interrupts, while clearing RFLAGS.IF to 0 inhibits them.
- Software interrupts (initiated by the INT*n* instruction) cannot be disabled.

8.3 Exceptions During a Task Switch

An exception can occur during a task switch while loading a segment selector. Page faults can also occur when accessing a TSS. In these cases, the hardware task-switch mechanism completes loading the new task state from the TSS, and then triggers the appropriate exception mechanism. No other checks are performed. When this happens, the saved instruction pointer points to the first instruction in the new task.

In long mode, an exception cannot occur during a task switch, because the hardware task-switch mechanism is disabled.

8.4 Error Codes

The processor exception-handling mechanism reports error and status information for some exceptions using an error code. The error code is pushed onto the stack by the exception mechanism during the control transfer into the exception handler. The error code formats are described in the following sections.

8.4.1 Selector-Error Code

Figure 8-2 shows the format of the selector-error code.

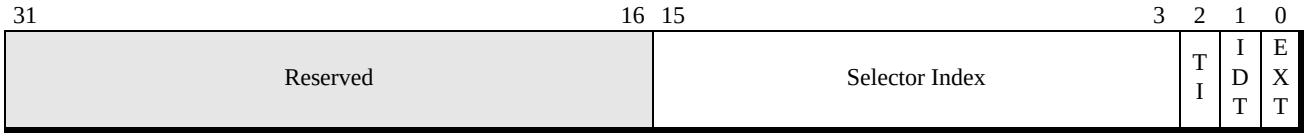

Figure 8-2. Selector Error Code

The information reported by the selector-error code includes:

- *EXT*—Bit 0. If this bit is set to 1, the exception source is external to the processor. If cleared to 0, the exception source is internal to the processor.
- *IDT*—Bit 1. If this bit is set to 1, the error-code selector-index field references a gate descriptor located in the interrupt-descriptor table (IDT). If cleared to 0, the selector-index field references a descriptor in either the global-descriptor table (GDT) or local-descriptor table (LDT), as indicated by the TI bit.
- *TI*—Bit 2. If this bit is set to 1, the error-code selector-index field references a descriptor in the LDT. If cleared to 0, the selector-index field references a descriptor in the GDT. The TI bit is relevant only when the IDT bit is cleared to 0.
- *Selector Index*—Bits 15:3. The selector-index field specifies the index into either the GDT, LDT, or IDT, as specified by the IDT and TI bits.

Some exceptions return a zero in the selector-error code.

8.4.2 Page-Fault Error Code

Figure 8-4 shows the format of the page-fault error code.

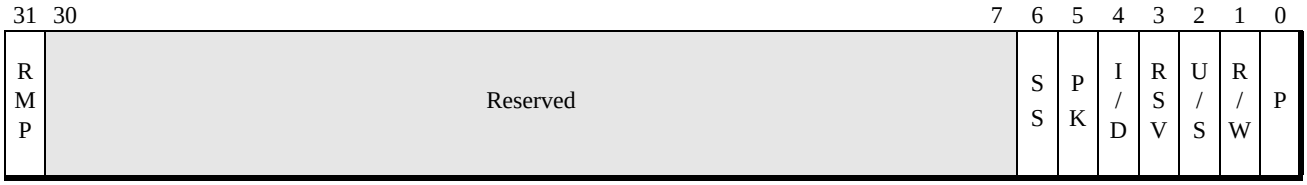

Figure 8-3. Page-Fault Error Code

The information reported by the page-fault error code includes:

- *P*—Bit 0. If this bit is cleared to 0, the page fault was caused by a not-present page. If this bit is set to 1, the page fault was caused by a page-protection violation.
- *R/W*—Bit 1. If this bit is cleared to 0, the access that caused the page fault is a memory read. If this bit is set to 1, the memory access that caused the page fault was a write. This bit does not necessarily indicate the cause of the page fault was a read or write violation.
- *U/S*—Bit 2. If this bit is cleared to 0, an access in supervisor mode (CPL=0, 1, or 2) caused the page fault. If this bit is set to 1, an access in user mode (CPL=3) caused the page fault. This bit does not necessarily indicate the cause of the page fault was a privilege violation.
- *RSV*—Bit 3. If this bit is set to 1, the page fault is a result of the processor reading a 1 from a reserved field within a page-translation-table entry. This type of page fault occurs only when CR4.PSE=1 or CR4.PAE=1. If this bit is cleared to 0, the page fault was not caused by the processor reading a 1 from a reserved field.
- *I/D*—Bit 4. If this bit is set to 1, it indicates that the access that caused the page fault was an instruction fetch. Otherwise, this bit is cleared to 0. This bit is only defined if no-execute feature is enabled (EFER.NXE=1 && CR4.PAE=1).
- *PK*—Bit 5. If this bit is set to 1, it indicates that a data access to a user-mode address caused a protection key violation. This fault only occurs if memory protection keys are enabled (CR4.PKE=1).
- *SS*—Bit 6. If this bit is set to 1, the page fault was caused by a shadow stack access. This bit is only set when the shadow stack feature is enabled (CR4.CET=1).
- *RMP*—Bit 31. If this bit is set to 1, the page fault is a result of the processor encountering an RMP violation. This type of page fault only occurs when SYSCFG[SecureNestedPagingEn]=1. If this bit is cleared to 0, the page fault was not caused by an RMP violation. See section 15.36.10 for additional information.

8.4.3 Control-Protection Error Code

Figure 8-4 shows the format of the #CP error code.

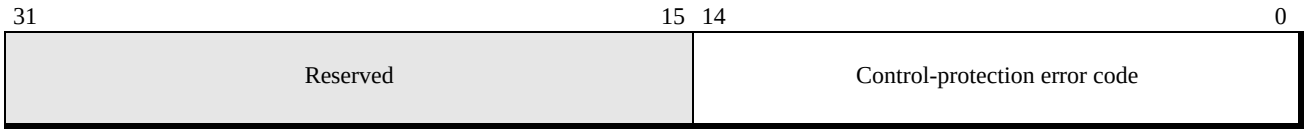

Figure 8-4. Control-Protection Error Code

The control-protection error codes are defined below:

Table 8-8. Control-Protection Error Codes

Error Code Value	Name	Cause
1	NEAR-RET	A RET (near) instruction encountered a return address mismatch.
2	FAR-RET/IRET	A RET (far) or IRET instruction encountered a return address mismatch.
3	RSTORSSP	An RSTORSSP instruction encountered an invalid shadow stack restore token.
4	SETSSBSY	A SETSSBSY instruction encountered an invalid supervisor shadow stack token.

8.5 Priorities

To allow for consistent handling of multiple-interrupt conditions, simultaneous interrupts are prioritized by the processor. The AMD64 architecture defines priorities between groups of interrupts, and interrupt prioritization within a group is implementation dependent. Table 8-9 shows the interrupt priorities defined by the AMD64 architecture.

When simultaneous interrupts occur, the processor transfers control to the highest-priority interrupt handler. Lower-priority interrupts from external sources are held pending by the processor, and they are handled after the higher-priority interrupt is handled. Lower-priority interrupts that result from internal sources are discarded. Those interrupts reoccur when the high-priority interrupt handler completes and transfers control back to the interrupted instruction. Software interrupts are discarded as well, and reoccur when the software-interrupt instruction is restarted.

Table 8-9. Simultaneous Interrupt Priorities

Interrupt Priority	Interrupt Condition	Interrupt Vector
(High) 0	Processor Reset	—
	Machine-Check Exception	18
1	External Processor Initialization (INIT)	—
	SMI Interrupt	
	External Clock Stop (Stpclk)	

Table 8-9. Simultaneous Interrupt Priorities (continued)

Interrupt Priority	Interrupt Condition	Interrupt Vector
2	Data, and I/O Breakpoint (Debug Register)	1
	Single-Step Execution Instruction Trap (RFLAGS.TF=1)	
3	Non-Maskable Interrupt	2
4	Maskable External Interrupt (INTR)	32–255
5	Instruction Breakpoint (Debug Register)	1
	Code-Segment-Limit Violation[1]	13
	Instruction-Fetch Page Fault[1]	14
6	Invalid Opcode Exception[1]	6
	Device-Not-Available Exception	7
	Instruction-Length Violation (> 15 Bytes)	13
7	Divide-by-zero Exception	0
	Invalid-TSS Exception	10
	Segment-Not-Present Exception	11
	Stack Exception	12
	General-Protection Exception	13
	Data-Access Page Fault	14
	Floating-Point Exception-Pending Exception	16
	Alignment-Check Exception	17
	SIMD Floating-Point Exception	19
	Control-Protection Exception	21
	Hypervisor Injection Exception	28
	VMM Communication Exception	29

Note:

1. This reflects the relative priority for faults encountered when fetching the first byte of an instruction. In the fetching and decoding of subsequent bytes of an instruction, if those bytes span the segment limit or cross into a non-executable or not-present page, the fetch will result in a #GP(0) fault or #PF as appropriate, preventing those bytes from being accessed. However, if the instruction can be determined to be invalid based just on the bytes preceding that boundary, a #UD fault may take priority. This behavior is model-dependent.

8.5.1 Floating-Point Exception Priorities

Floating-point exceptions (SSE and x87 floating-point) can be handled in one of two ways:

- Unmasked exceptions are reported in the appropriate floating-point status register, and a software-interrupt handler is invoked. See Section “#MF—x87 Floating-Point Exception-Pending (Vector 16)” on page 248 and Section “#XF—SIMD Floating-Point Exception (Vector 19)” on page 250 for more information on the floating-point interrupts.

- Masked exceptions are also reported in the appropriate floating-point status register. Instead of transferring control to an interrupt handler, however, the processor handles the exception in a default manner and execution proceeds.

If the processor detects more than one exception while executing a single floating-point instruction, it prioritizes the exceptions in a predictable manner. When responding in a default manner to masked exceptions, it is possible that the processor acts only on the high-priority exception and ignores lower-priority exceptions. In the case of vector (SIMD) floating-point instructions, priorities are set on sub-operations, not across all operations. For example, if the processor detects and acts on a QNaN operand in one sub-operation, the processor can still detect and act on a denormal operand in another sub-operation.

When reporting SSE floating-point exceptions before taking an interrupt or handling them in a default manner, the processor first classifies the exceptions as follows:

- *Input exceptions* include SNaN operand (#I), invalid operation (#I), denormal operand (#D), or zero-divide (#Z). Using a NaN operand with a maximum, minimum, compare, or convert instruction is also considered an input exception.
- *Output exceptions* include numeric overflow (#O), numeric underflow (#U), and precision (#P).

Using the above classification, the processor applies the following procedure to report the exceptions:

1. The exceptions for all sub-operations are prioritized.
2. The exception conditions for all sub-operations are logically ORed together to form a single set of exceptions covering all operations. For example, if two sub-operations produce a denormal result, only one denormal exception is reported.
3. If the set of exceptions includes any *unmasked* input exceptions, all input exceptions are reported in MCXSR, and no output exceptions are reported. Otherwise, all input and output exceptions are reported in MCXSR.
4. If any exceptions are unmasked, control is transferred to the appropriate interrupt handler.

Table 8-10 on page 257 lists the priorities for simultaneous floating-point exceptions.

Table 8-10. Simultaneous Floating-Point Exception Priorities

Exception Priority	Exception Condition	
(High) 0	SNaN Operand	#I
	NaN Operand of Maximum, Minimum, Compare, and Convert Instructions (Vector Floating-Point)	
	Stack Overflow (x87 Floating-Point)	
	Stack Underflow (x87 Floating-Point)	
1	QNaN Operand	—

Table 8-10. Simultaneous Floating-Point Exception Priorities (continued)

Exception Priority	Exception Condition	
2	Invalid Operation (Remaining Conditions)	#I
	Zero Divide	#Z
3	Denormal Operand	#D
4	Numeric Overflow	#O
	Numeric Underflow	#U
5 (Low)	Precision	#P

8.5.2 External Interrupt Priorities

The AMD64 architecture allows software to define up to 15 external interrupt-priority classes. Priority classes are numbered from 1 to 15, with priority-class 1 being the lowest and priority-class 15 the highest. The organization of these priority classes is implementation dependent. A typical method is to use the upper four bits of the interrupt vector number to define the priority. Thus, interrupt vector 53h has a priority of 5 and interrupt vector 37h has a priority of 3.

A new control register (CR8) is introduced by the AMD64 architecture for managing priority classes. This register, called the *task-priority register* (TPR), uses its four low-order bits to specify a task priority. The remaining 60 bits are reserved and must be written with zeros. Figure 8-5 shows the format of the TPR.

The TPR is available only in 64-bit mode.

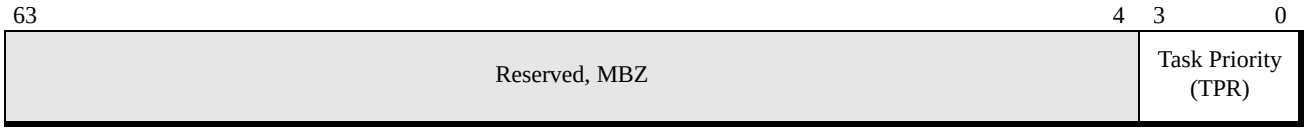

Figure 8-5. Task Priority Register (CR8)

System software can use the TPR register to temporarily block low-priority interrupts from interrupting a high-priority task. This is accomplished by loading TPR with a value corresponding to the highest-priority interrupt that is to be blocked. For example, loading TPR with a value of 9 (1001b) blocks all interrupts with a priority class of 9 or less, while allowing all interrupts with a priority class of 10 or more to be recognized. Loading TPR with 0 enables all external interrupts. Loading TPR with 15 (1111b) disables all external interrupts. The TPR is cleared to 0 on reset.

System software reads and writes the TPR using a MOV CR8 instruction. The MOV CR8 instruction requires a privilege level of 0. Programs running at any other privilege level cannot read or write the TPR, and an attempt to do so results in a general-protection exception (#GP).

A serializing instruction is not required after loading the TPR, because a new priority level is established when the MOV instruction completes execution. For example, assume two sequential TPR loads are performed, in which a low value is first loaded into TPR and immediately followed by a load of a higher value. Any pending, lower-priority interrupt enabled by the first MOV CR8 is recognized between the two MOVs.

The TPR is an architectural abstraction of the interrupt controller (IC), which prioritizes and manages external interrupt delivery to the processor. The IC can be an external system device, or it can be integrated on the chip like the local advanced programmable interrupt controller (APIC). Typically, the IC contains a priority mechanism similar, if not identical to, the TPR. The IC, however, is implementation dependent, and the underlying priority mechanisms are subject to change. The TPR, by contrast, is part of the AMD64 architecture.

Effect of IC on TPR. The features of the implementation-specific IC can impact the operation of the TPR. For example, the TPR might affect interrupt delivery only if the IC is enabled. Also, the mapping of an external interrupt to a specific interrupt priority is an implementation-specific behavior of the IC.

While the CR8 register provides the same functionality as the TPR at offset 80h of the local APIC, software should only use one mechanism to access the TPR. For example, updating the TPR with a write to the local APIC offset 0x80 but then reading it with a MOV CR8 is not guaranteed to return the same value that was written by the local APIC write.

8.6 Real-Mode Interrupt Control Transfers

In real mode, the IDT is a table of 4-byte entries, one entry for each of the 256 possible interrupts implemented by the system. The real mode IDT is often referred to as an *interrupt vector table*, or IVT. Table entries contain a far pointer (CS:IP pair) to an exception or interrupt handler. The base of the IDT is stored in the IDTR register, which is loaded with a value of 00h during a processor reset. Figure 8-6 on page 260 shows how the real-mode interrupt handler is located by the interrupt mechanism.

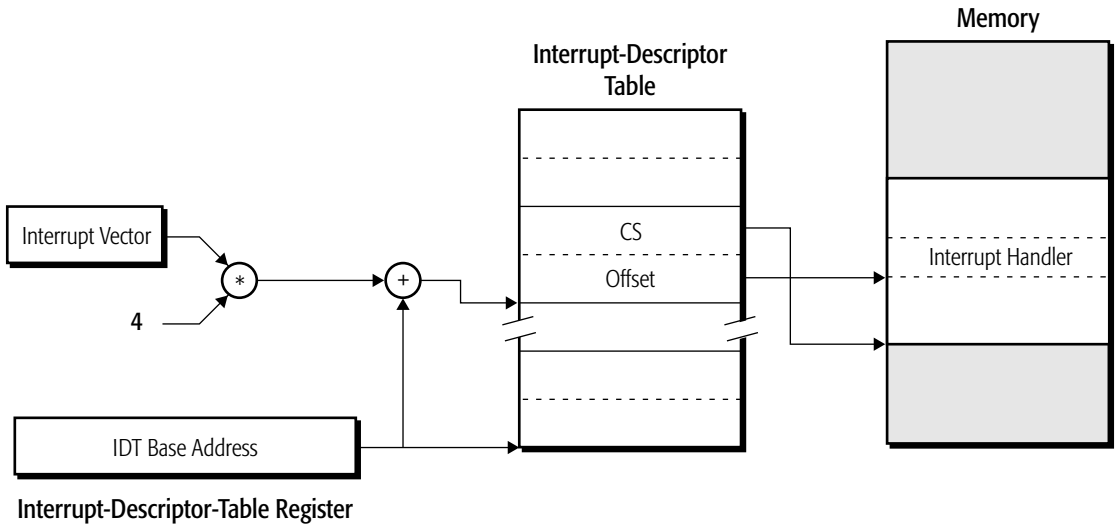

Figure 8-6. Real-Mode Interrupt Control Transfer

When an exception or interrupt occurs in real mode, the processor performs the following:

1. Pushes the FLAGS register (EFLAGS[15:0]) onto the stack.
2. Clears EFLAGS.IF to 0 and EFLAGS.TF to 0.
3. Saves the CS register and IP register (RIP[15:0]) by pushing them onto the stack.
4. Locates the interrupt-handler pointer (CS:IP) in the IDT by scaling the interrupt vector by four and adding the result to the value in the IDTR.
5. Transfers control to the interrupt handler referenced by the CS:IP in the IDT.

Figure 8-7 on page 261 shows the stack after control is transferred to the interrupt handler in real mode.

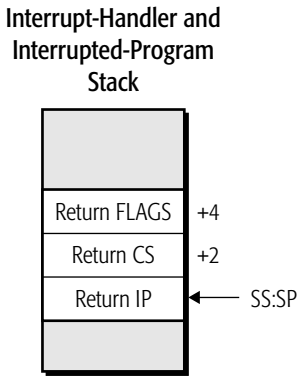

Figure 8-7. Stack After Interrupt in Real Mode

An IRET instruction is used to return to the interrupted program. When an IRET is executed, the processor performs the following:

1. Pops the saved CS value off the stack and into the CS register. The saved IP value is popped into RIP[15:0].
2. Pops the FLAGS value off of the stack and into EFLAGS[15:0].
3. Execution begins at the saved CS.IP location.

8.7 Legacy Protected-Mode Interrupt Control Transfers

In protected mode, the interrupt mechanism transfers control to an exception or interrupt handler through gate descriptors. In protected mode, the IDT is a table of 8-byte gate entries, one for each of the 256 possible interrupt vectors implemented by the system. Three gate types are allowed in the IDT:

- Interrupt gates.
- Trap gates.
- Task gates.

If a reference is made to any other descriptor type in the IDT, a general-protection exception (#GP) occurs.

Interrupt-gate control transfers are similar to CALLs and JMPs through call gates. The interrupt mechanism uses gates (interrupt, trap, and task) to establish protected entry-points into the exception and interrupt handlers.

The remainder of this chapter discusses control transfers through interrupt gates and trap gates. If the gate descriptor in the IDT is a task gate, a TSS-segment selector is referenced, and a task switch

occurs. See Chapter 12, “Task Management,” for more information on the hardware task-switch mechanism.

8.7.1 Locating the Interrupt Handler

When an exception or interrupt occurs, the processor scales the interrupt vector number by eight and uses the result as an offset into the IDT. If the gate descriptor referenced by the IDT offset is an interrupt gate or a trap gate, it contains a segment-selector and segment-offset field (see Section “Legacy Segment Descriptors” on page 88 for a detailed description of the gate-descriptor format and fields). These two fields perform the same function as the pointer operand in a far control-transfer instruction. The gate-descriptor segment-selector field points to the target code-segment descriptor located in either the GDT or LDT. The gate-descriptor segment-offset field is the instruction-pointer offset into the interrupt-handler code segment. The code-segment base taken from the code-segment descriptor is added to the gate-descriptor segment-offset field to create the interrupt-handler virtual address (linear address).

Figure 8-8 on page 263 shows how the protected-mode interrupt handler is located by the interrupt mechanism.

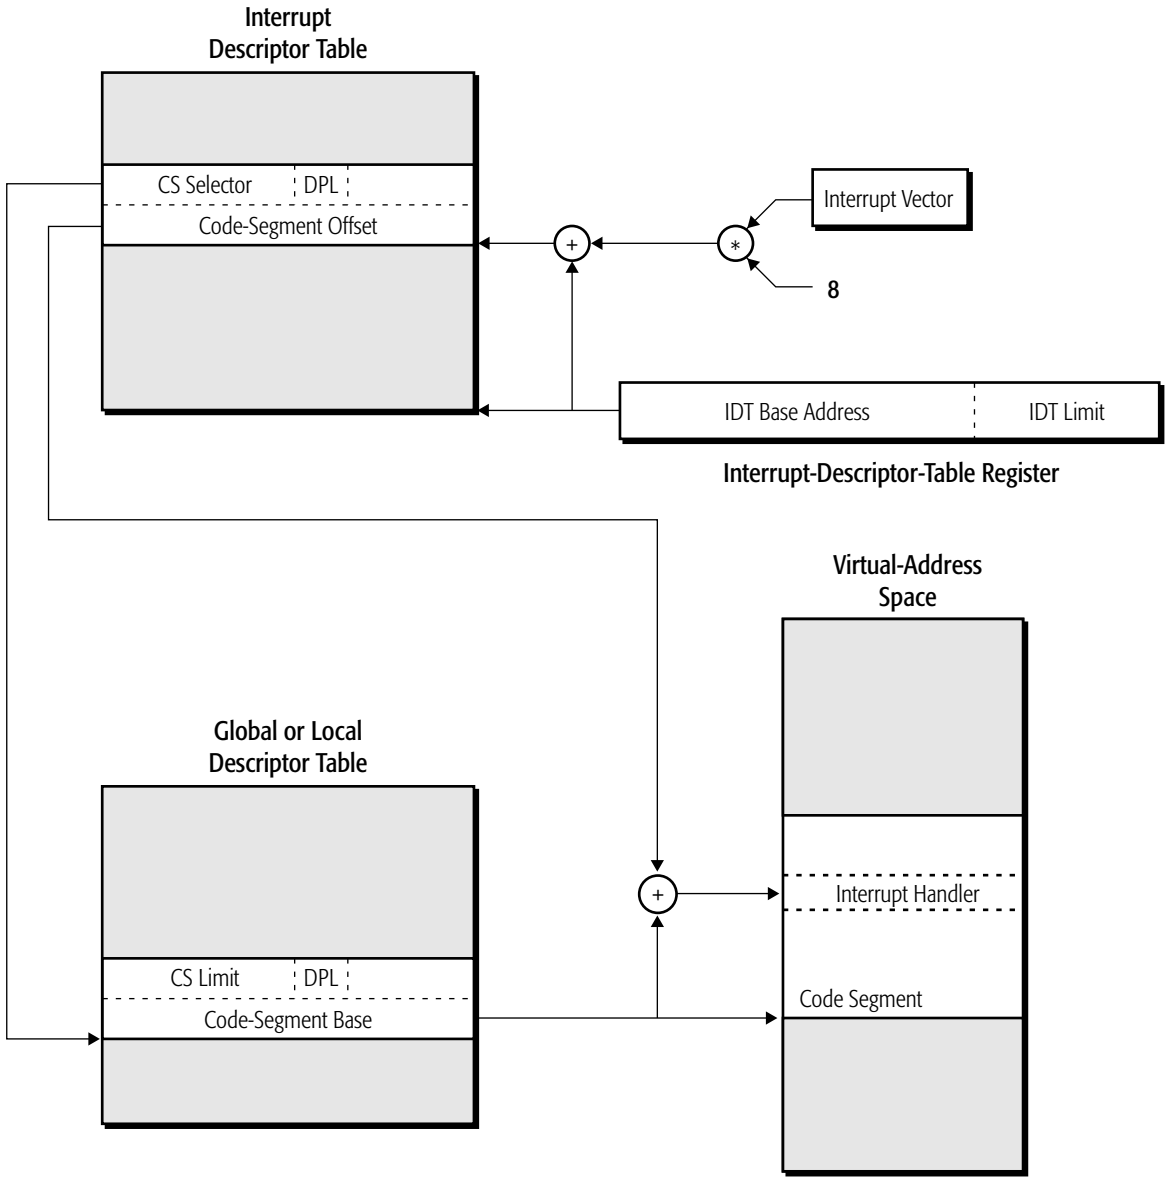

Figure 8-8. Protected-Mode Interrupt Control Transfer

8.7.2 Interrupt To Same Privilege

When a control transfer to an exception or interrupt handler at the same privilege level occurs (through an interrupt gate or a trap gate), the processor performs the following:

1. Pushes the EFLAGS register onto the stack.
2. Clears the TF, NT, RF, and VM bits in EFLAGS to 0.

3. The processor handles EFLAGS.IF based on the gate-descriptor type:
   - If the gate descriptor is an interrupt gate, EFLAGS.IF is cleared to 0.
   - If the gate descriptor is a trap gate, EFLAGS.IF is not modified.
4. Saves the return CS register and EIP register (RIP[31:0]) by pushing them onto the stack. The CS value is padded with two bytes to form a doubleword.
5. If the interrupt has an associated error code, the error code is pushed onto the stack.
6. The CS register is loaded from the segment-selector field in the gate descriptor, and the EIP is loaded from the offset field in the gate descriptor.
7. The interrupt handler begins executing with the instruction referenced by new CS:EIP.

Figure 8-9 shows the stack after control is transferred to the interrupt handler.

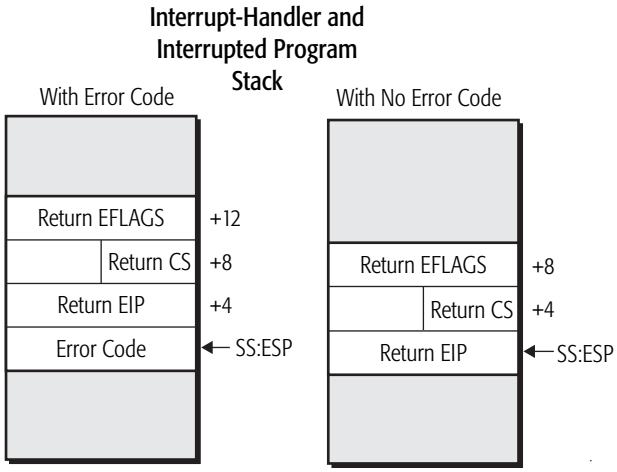

Figure 8-9. Stack After Interrupt to Same Privilege Level

8.7.3 Interrupt To Higher Privilege

When a control transfer to an exception or interrupt handler running at a higher privilege occurs (numerically lower CPL value), the processor performs a stack switch using the following steps:

1. The target CPL is read by the processor from the target code-segment DPL and used as an index into the TSS for selecting the new stack pointer (SS:ESP). For example, if the target CPL is 1, the processor selects the SS:ESP for privilege-level 1 from the TSS.
2. Pushes the return stack pointer (old SS:ESP) onto the new stack. The SS value is padded with two bytes to form a doubleword.
3. Pushes the EFLAGS register onto the new stack.
4. Clears the following EFLAGS bits to 0: TF, NT, RF, and VM.

5. The processor handles the EFLAGS.IF bit based on the gate-descriptor type:
   - If the gate descriptor is an interrupt gate, EFLAGS.IF is cleared to 0.
   - If the gate descriptor is a trap gate, EFLAGS.IF is not modified.
6. Saves the return-address pointer (CS:EIP) by pushing it onto the stack. The CS value is padded with two bytes to form a doubleword.
7. If the interrupt vector number has an error code associated with it, the error code is pushed onto the stack.
8. The CS register is loaded from the segment-selector field in the gate descriptor, and the EIP is loaded from the offset field in the gate descriptor.
9. The interrupt handler begins executing with the instruction referenced by new CS:EIP.

Figure 8-10 shows the new stack after control is transferred to the interrupt handler.

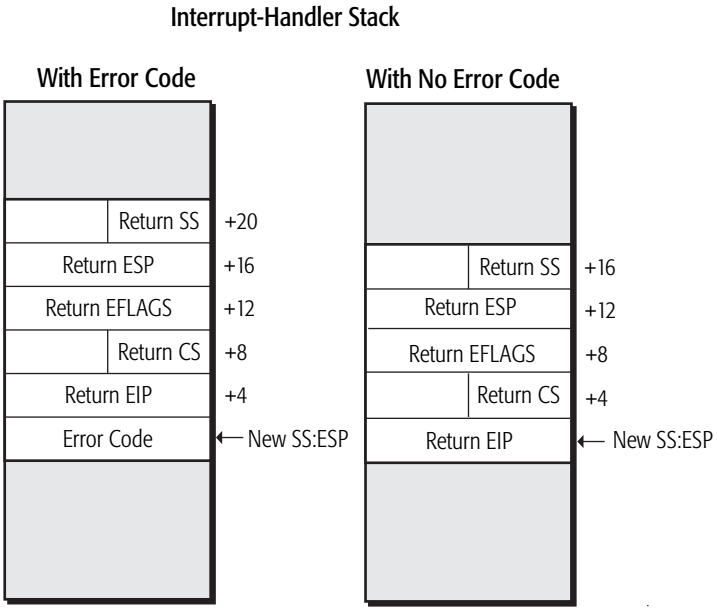

Figure 8-10. Stack After Interrupt to Higher Privilege

8.7.4 Privilege Checks

Before loading the CS register with the interrupt-handler code-segment selector (located in the gate descriptor), the processor performs privilege checks similar to those performed on call gates. The checks are performed when either conforming or nonconforming interrupt handlers are referenced:

1. The processor reads the gate DPL from the interrupt-gate or trap-gate descriptor. The gate DPL is the *minimum privilege-level* (numerically-highest value) needed by a program to access the gate. The processor compares the CPL with the gate DPL. The CPL must be numerically *less-than or equal-to* the gate DPL for this check to pass.

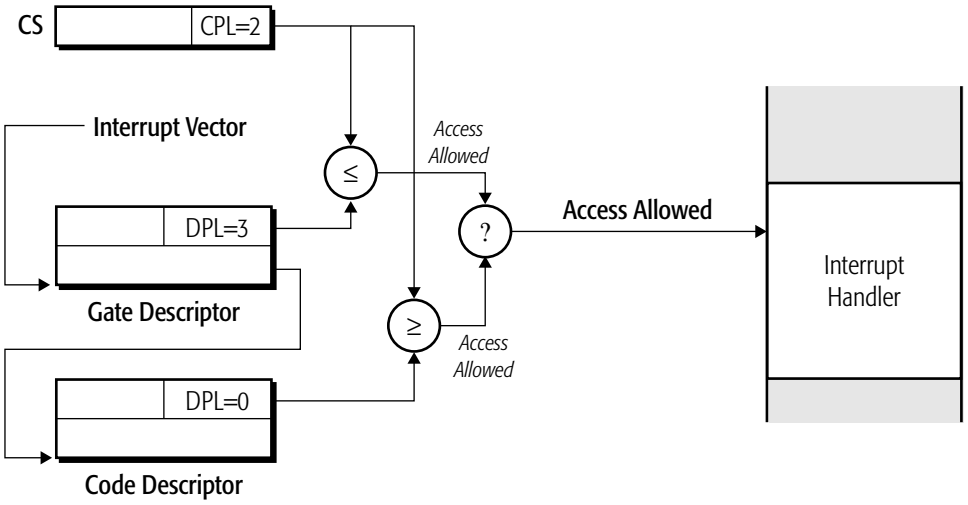
2. The processor compares the CPL with the interrupt-handler code-segment DPL. For this check to pass, the CPL must be numerically *greater-than or equal-to* the code-segment DPL. This check prevents control transfers to less-privileged interrupt handlers.

Unlike call gates, no RPL comparison takes place. This is because the gate descriptor is referenced in the IDT using the interrupt vector number rather than a selector, and no RPL field exists in the interrupt vector number.

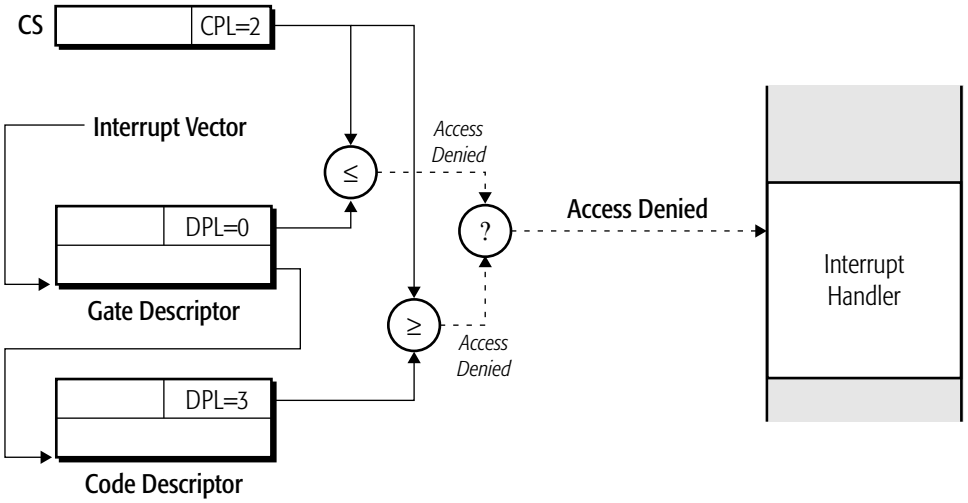
Exception and interrupt handlers should be made reachable from software running at any privilege level that requires them. If the gate DPL value is too low (requiring more privilege), or the interrupt-handler code-segment DPL is too high (runs at lower privilege), the interrupt control transfer can fail the privilege checks. Setting the gate DPL=3 and interrupt-handler code-segment DPL=0 makes the exception handler or interrupt handler reachable from any privilege level.

Figure 8-11 on page 267 shows two examples of interrupt privilege checks. In Example 1, both privilege checks pass:

- The interrupt-gate DPL is at the lowest privilege (3), which means that software running at any privilege level (CPL) can access the interrupt gate.
- The interrupt-handler code segment is at the highest-privilege level, as indicated by DPL=0. This means software running at any privilege can enter the interrupt handler through the interrupt gate.



Example 1: Privilege Check Passes



Example 2: Privilege Check Fails

Figure 8-11. Privilege-Check Examples for Interrupts

In Example 2, both privilege checks fail:

- The interrupt-gate DPL specifies that only software running at privilege-level 0 can access the gate. The current program does not have a high enough privilege level to access the interrupt gate, since its CPL is set at 2.

- The interrupt handler has a lower privilege (DPL=3) than the currently-running software (CPL=2). Transitions from more-privileged software to less-privileged software are not allowed, so this privilege check fails as well.

Although both privilege checks fail, only one such failure is required to deny access to the interrupt handler.

8.7.5 Returning From Interrupt Procedures

A return to an interrupted program should be performed using the IRET instruction. An IRET is a far return to a different code segment, with or without a change in privilege level. The actions of an IRET in both cases are described in the following sections.

IRET, Same Privilege. Before performing the IRET, the stack pointer must point to the return EIP. If there was an error code pushed onto the stack as a result of the exception or interrupt, that error code should have been popped off the stack earlier by the handler. The IRET reverses the actions of the interrupt mechanism:

1. Pops the return pointer off of the stack, loading both the CS register and EIP register (RIP[31:0]) with the saved values. The return code-segment RPL is read by the processor from the CS value stored on the stack to determine that an equal-privilege control transfer is occurring.
2. Pops the saved EFLAGS image off of the stack and into the EFLAGS register.
3. Transfers control to the return program at the target CS:EIP.

IRET, Less Privilege. If an IRET changes privilege levels, the return program must be at a lower privilege than the interrupt handler. The IRET in this case causes a stack switch to occur:

1. The return pointer is popped off of the stack, loading both the CS register and EIP register (RIP[31:0]) with the saved values. The return code-segment RPL is read by the processor from the CS value stored on the stack to determine that a lower-privilege control transfer is occurring.
2. The saved EFLAGS image is popped off of the stack and loaded into the EFLAGS register.
3. The return-program stack pointer is popped off of the stack, loading both the SS register and ESP register (RSP[31:0]) with the saved values.
4. Control is transferred to the return program at the target CS:EIP.

8.7.6 Shadow Stack Support for Interrupts and Exceptions

The operation of the shadow stack for an interrupt control transfer depends whether or not the interrupt handler runs at the same privilege or at a higher privilege level than the CPL when the interrupt or exception occurred.

Interrupt Control Transfer to Same Privilege Level. When a control transfer to a interrupt handler at the same privilege occurs, and the shadow stack feature is enabled for the current CPL, the processor pushes the interrupted procedure's CS and LIP (CS.base + EIP) onto the current shadow stack.

Interrupt Control Transfer to Higher Privilege Level. When a control transfer to a interrupt handler at a higher privilege occurs, the actions taken by the processor depend on the CPL when the interrupt or exception occurred.

- If the CPL = 3:

  - if shadow stacks are enabled in user-mode, the current SSP is saved to MSR PL3_SSP.

  - if shadow stacks are enabled in supervisor mode, a new SSP is loaded from MSR PLn_SSP (where n = the target CPL 0, 1 or 2).

  - the shadow stack token located at the base of the new shadow stack is checked, and if valid, the token's busy bit is set to 1.

  Note: the CS and LIP are not pushed onto the new shadow stack.

- If the CPL =1 or 2, and shadow stacks are enabled in supervisor mode:

  - the new SSP is loaded from MSR PLn_SSP (where n = the target CPL 0 or 1).

  - the shadow stack token located at the base of the new shadow stack is checked, and if valid, the token's busy bit is set to 1.

  - the CS, LIP and old SSP are pushed onto the new shadow stack.

For a detailed description of shadow stack operations, see Section “Shadow Stacks” on page 647.

8.8 Virtual-8086 Mode Interrupt Control Transfers

This section describes interrupt control transfers as they relate to virtual-8086 mode. Virtual-8086 mode is not supported by long mode. Therefore, the control-transfer mechanism described here is not applicable to long mode.

When a software interrupt occurs (not external interrupts, INT1, or INT3) while the processor is running in virtual-8086 mode (EFLAGS.VM=1), the control transfer that occurs depends on three system controls:

- *EFLAGS.IOPL*—This field controls interrupt handling based on the CPL. See Section “I/O Privilege Level Field (IOPL) Field” on page 54 for more information on this field.

  Setting IOPL<3 redirects the interrupt to the general-protection exception (#GP) handler.
- *CR4.VME*—This bit enables virtual-mode extensions. See Section “Virtual-8086 Mode Extensions (VME)” on page 48 for more information on this bit.
- *TSS Interrupt-Redirection Bitmap*—The TSS interrupt-redirection bitmap contains 256 bits, one for each possible INT*n* vector (software interrupt). When CR4.VME=1, the bitmap is used by the processor to direct interrupts to the handler provided by the currently-running 8086 program (bitmap entry is 0), or to the protected-mode operating-system interrupt handler (bitmap entry is 1). See Section “Legacy Task-State Segment” on page 367 for information on the location of this field within the TSS.

If IOPL<3, CR4.VME=1, and the corresponding interrupt redirection bitmap entry is 0, the processor uses the virtual-interrupt mechanism. See Section “Virtual Interrupts” on page 279 for more information on this mechanism.

Table 8-11 summarizes the actions of the above system controls on interrupts taken when the processor is running in virtual-8086 mode.

Table 8-11. Virtual-8086 Mode Interrupt Mechanisms

EFLAGS.IOPL	CR4.VME	TSS Interrupt Redirection Bitmap Entry	Interrupt Mechanism
0, 1, or 2	0	—	General-Protection Exception
	1	1	
	1	0	Virtual Interrupt
3	0	—	Protected-Mode Handler
	1	1	
	1	0	Virtual 8086 Handler

8.8.1 Protected-Mode Handler Control Transfer

Control transfers to protected-mode handlers from virtual-8086 mode differ from standard protected-mode transfers in several ways. The processor follows these steps in making the control transfer:

1. Reads the CPL=0 stack pointer (SS:ESP) from the TSS.
2. Pushes the GS, FS, DS, and ES selector registers onto the stack. Each push is padded with two bytes to form a doubleword.
3. Clears the GS, FS, DS, and ES selector registers to 0. This places a null selector in each of the four registers
4. Pushes the return stack pointer (old SS:ESP) onto the new stack. The SS value is padded with two bytes to form a doubleword.
5. Pushes the EFLAGS register onto the new stack.
6. Clears the following EFLAGS bits to 0: TF, NT, RF, and VM.
7. Handles EFLAGS.IF based on the gate-descriptor type:
   - If the gate descriptor is an interrupt gate, EFLAGS.IF is cleared to 0.
   - If the gate descriptor is a trap gate, EFLAGS.IF is not modified.
8. Pushes the return-address pointer (CS:EIP) onto the stack. The CS value is padded with two bytes to form a doubleword.
9. If the interrupt has an associated error code, pushes the error code onto the stack.
10. Loads the segment-selector field from the gate descriptor into the CS register, and loads the offset field from the gate descriptor into the EIP register.

11. Begins execution of the interrupt handler with the instruction referenced by the new CS:EIP.

Figure 8-12 shows the new stack after control is transferred to the interrupt handler with an error code.

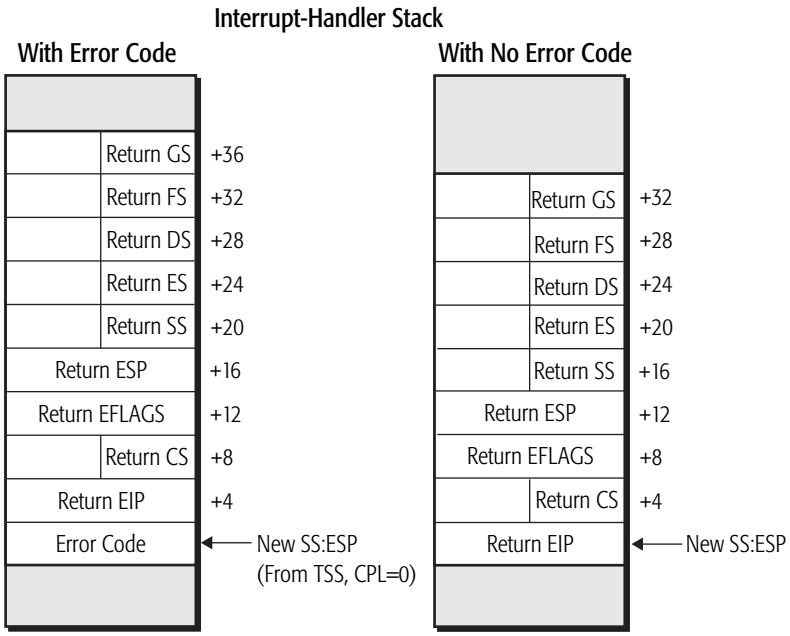


Figure 8-12. Stack After Virtual-8086 Mode Interrupt to Protected Mode

An IRET from privileged protected-mode software (CPL=0) to virtual-8086 mode reverses the stack-build process. After the return pointer, EFLAGS, and return stack-pointer are restored, the processor restores the ES, DS, FS, and GS registers by popping their values off the stack.

8.8.2 Virtual-8086 Handler Control Transfer

When a control transfer to an 8086 handler occurs from virtual-8086 mode, the processor creates an interrupt-handler stack identical to that created when an interrupt occurs in real mode (see Figure 8-7 on page 261). The processor performs the following actions during a control transfer:

1. Pushes the FLAGS register (EFLAGS[15:0]) onto the stack.
2. Clears the EFLAGS.IF and EFLAGS.RF bits to 0.
3. Saves the CS register and IP register (RIP[15:0]) by pushing them onto the stack.
4. Locates the interrupt-handler pointer (CS:IP) in the 8086 IDT by scaling the interrupt vector by four and adding the result to the virtual (linear) address 0. The value in the IDTR is not used.
5. Transfers control to the interrupt handler referenced by the CS:IP in the IDT.

An IRET from the 8086 handler back to virtual-8086 mode reverses the stack-build process.

8.9 Long-Mode Interrupt Control Transfers

The long-mode architecture expands the legacy interrupt-mechanism to support 64-bit operating systems and applications. These changes include:

- All interrupt handlers are 64-bit code and operate in 64-bit mode.
- The size of an interrupt-stack push is fixed at 64 bits (8 bytes).
- The interrupt-stack frame is aligned on a 16-byte boundary.
- The stack pointer, SS:RSP, is pushed unconditionally on interrupts, rather than conditionally based on a change in CPL.
- The SS selector register is loaded with a null selector as a result of an interrupt, if the CPL changes.
- The IRET instruction behavior changes, to unconditionally pop SS:RSP, allowing a null SS to be popped.
- A new interrupt stack-switch mechanism, called the interrupt-stack table or IST, is introduced.
- When shadow stacks are enabled, a new shadow stack-switch mechanism, called the Interrupt SSP Table or ISST, is introduced.

8.9.1 Interrupt Gates and Trap Gates

Only long-mode interrupt and trap gates can be referenced in long mode (64-bit mode and compatibility mode). The legacy 32-bit interrupt-gate and 32-bit trap-gate types (0Eh and 0Fh, as described in Section “System Descriptors” on page 99) are redefined in long mode as 64-bit interrupt-gate and 64-bit trap-gate types. 32-bit and 16-bit interrupt-gate and trap-gate types do not exist in long mode, and software is prohibited from using task gates. If a reference is made to any gate other than a 64-bit interrupt gate or a 64-bit trap gate, a general-protection exception (#GP) occurs.

The long-mode gate types are 16 bytes (128 bits) long. They are an extension of the legacy-mode gate types, allowing a full 64-bit segment offset to be stored in the descriptor. See Section “Legacy Segment Descriptors” on page 88 for a detailed description of the gate-descriptor format and fields.

8.9.2 Locating the Interrupt Handler

When an interrupt occurs in long mode, the processor multiplies the interrupt vector number by 16 and uses the result as an offset into the IDT. The gate descriptor referenced by the IDT offset contains a segment-selector and a 64-bit segment-offset field. The gate-descriptor segment-offset field contains the complete virtual address for the interrupt handler. The gate-descriptor segment-selector field points to the target code-segment descriptor located in either the GDT or LDT. The code-segment descriptor is only used for privilege-checking purposes and for placing the processor in 64-bit mode. The code segment-descriptor base field, limit field, and most attributes are ignored.

Figure 8-13 shows how the long-mode interrupt handler is located by the interrupt mechanism.

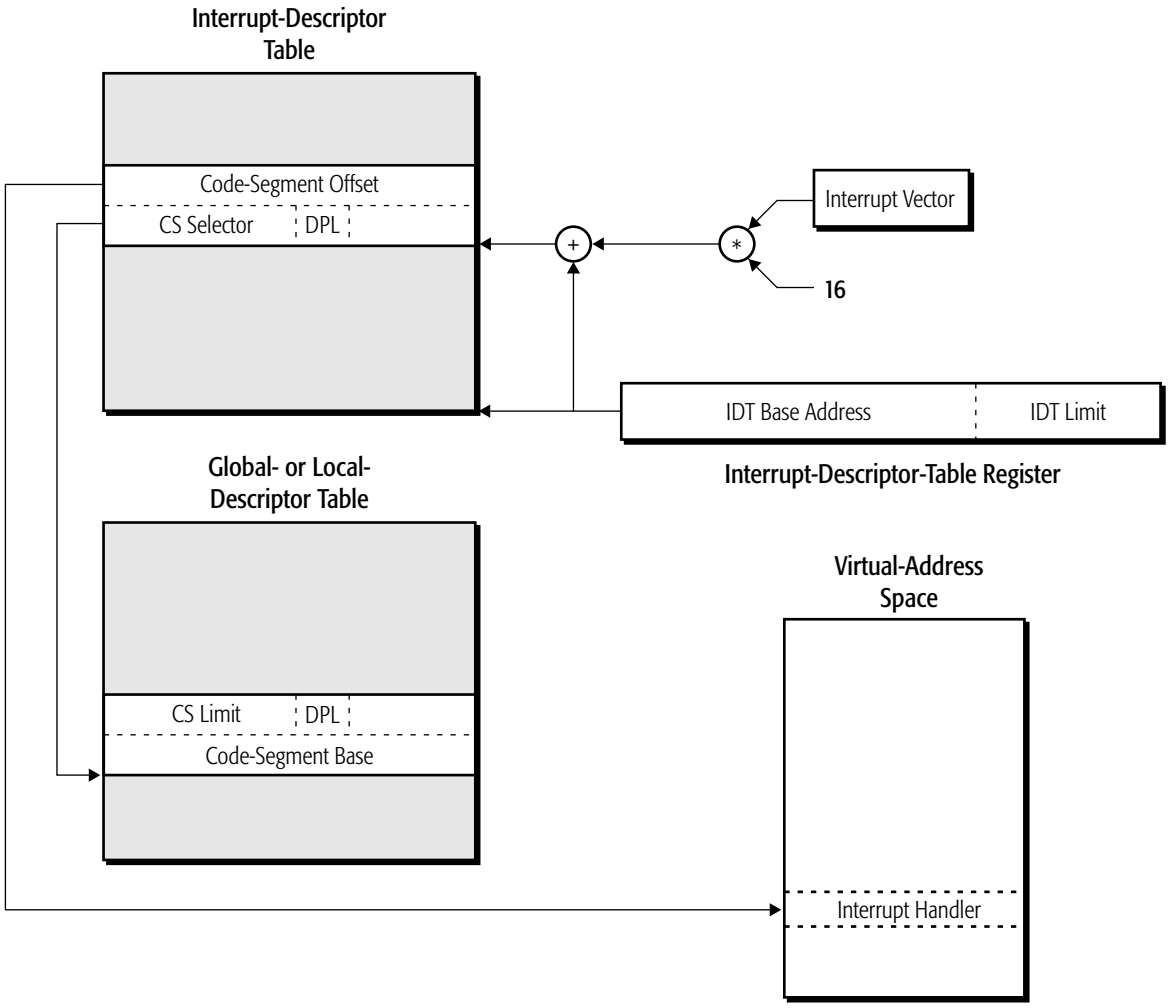

Figure 8-13. Long-Mode Interrupt Control Transfer

8.9.3 Interrupt Stack Frame

In long mode, the return-program stack pointer (SS:RSP) is always pushed onto the interrupt-handler stack, regardless of whether or not a privilege change occurs. Although the SS register is not used in 64-bit mode, SS is pushed to allow returns into compatibility mode. Pushing SS:RSP unconditionally presents operating systems with a consistent interrupt-stack-frame size for all interrupts, except for error codes. Interrupt service-routine entry points that handle interrupts generated by non-error-code interrupts can push an error code on the stack for consistency.

In long mode, when a control transfer to an interrupt handler occurs, the processor performs the following:

1. Aligns the new interrupt-stack frame by masking RSP with FFFF_FFFF_FFFF_FFF0h.
2. If IST field in interrupt gate is not 0, reads IST pointer into RSP.
3. If a privilege change occurs, the target DPL is used as an index into the long-mode TSS to select a new stack pointer (RSP).
4. If a privilege change occurs, SS is cleared to zero indicating a null selector.
5. Pushes the return stack pointer (old SS:RSP) onto the new stack. The SS value is padded with six bytes to form a quadword.
6. Pushes the 64-bit RFLAGS register onto the stack. The upper 32 bits of the RFLAGS image on the stack are written as zeros.
7. Clears the TF, NT, and RF bits in RFLAGS bits to 0.
8. Handles the RFLAGS.IF bit according to the gate-descriptor type:
   - If the gate descriptor is an interrupt gate, RFLAGS.IF is cleared to 0.
   - If the gate descriptor is a trap gate, RFLAGS.IF is not modified.
9. Pushes the return CS register and RIP register onto the stack. The CS value is padded with six bytes to form a quadword.
10. If the interrupt vector number has an error code associated with it, pushes the error code onto the stack. The error code is padded with four bytes to form a quadword.
11. Loads the segment-selector field from the gate descriptor into the CS register. The processor checks that the target code-segment is a 64-bit mode code segment.
12. Loads the offset field from the gate descriptor into the target RIP. The interrupt handler begins execution when control is transferred to the instruction referenced by the new RIP.

Figure 8-14 on page 275 shows the stack after control is transferred to the interrupt handler.

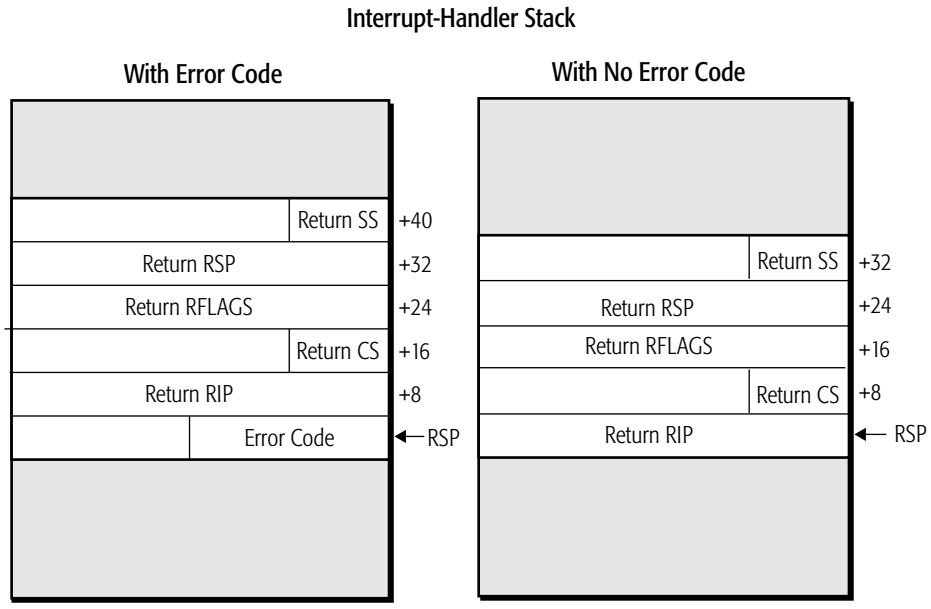

Figure 8-14. Long-Mode Stack After Interrupt—Same Privilege

Interrupt-Stack Alignment. In legacy mode, the interrupt-stack pointer can be aligned at any address boundary. Long mode, however, aligns the stack on a 16-byte boundary. This alignment is performed by the processor in hardware before pushing items onto the stack frame. The previous RSP is saved unconditionally on the new stack by the interrupt mechanism. A subsequent IRET instruction automatically restores the previous RSP.

Aligning the stack on a 16-byte boundary allows optimal performance for saving and restoring the 16-byte XMM registers. The interrupt handler can save and restore the XMM registers using the faster 16-byte aligned loads and stores (MOVAPS), rather than unaligned loads and stores (MOVUPS). Although the RSP alignment is always performed in long mode, it is only of consequence when the interrupted program is already running at CPL=0, and it is generally used only within the operating-system kernel. The operating system should put 16-byte aligned RSP values in the TSS for interrupts that change privilege levels.

Stack Switch. In long mode, the stack-switch mechanism differs slightly from the legacy stack-switch mechanism (see Section “Interrupt To Higher Privilege” on page 264). When stacks are switched during a long-mode privilege-level change resulting from an interrupt, a new SS descriptor is *not* loaded from the TSS. Long mode only loads an inner-level RSP from the TSS. However, the SS selector is loaded with a null selector, allowing nested control transfers, including interrupts, to be handled properly in 64-bit mode. The SS.RPL is set to the new CPL value. See Section “Nested IRETs to 64-Bit Mode Procedures” on page 278 for additional information.

The interrupt-handler stack that results from a privilege change in long mode looks identical to a long-mode stack when no privilege change occurs. Figure 8-15 shows the stack after the switch is performed and control is transferred to the interrupt handler.

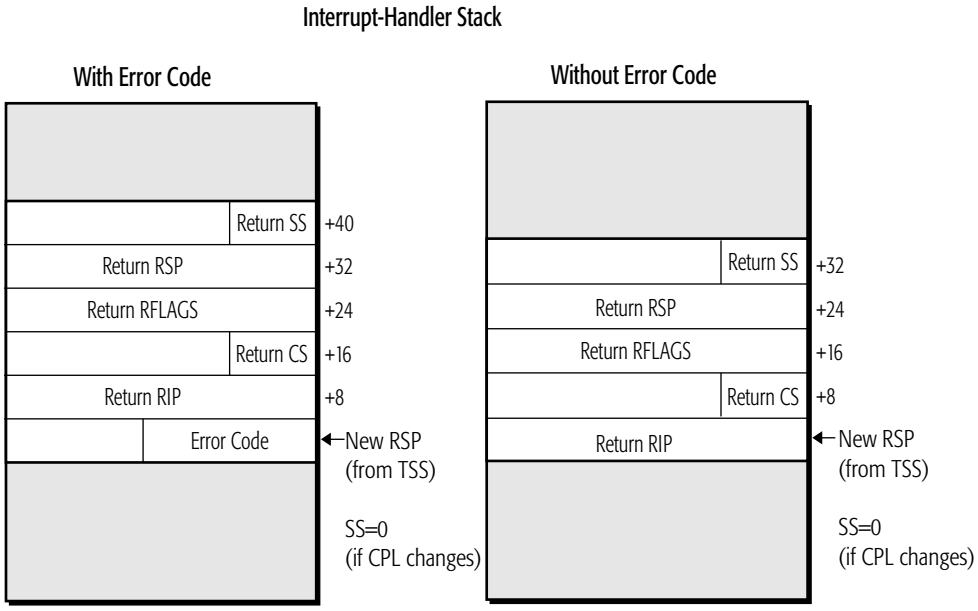

Figure 8-15. Long-Mode Stack After Interrupt—Higher Privilege

8.9.4 Interrupt-Stack Table

In long mode, a new interrupt-stack table (IST) mechanism is introduced as an alternative to the modified legacy stack-switch mechanism described above. The IST mechanism provides a method for specific interrupts, such as NMI, double-fault, and machine-check, to always execute on a known-good stack. In legacy mode, interrupts can use the hardware task-switch mechanism to set up a known-good stack by accessing the interrupt service routine through a task gate located in the IDT. However, the hardware task-switch mechanism is not supported in long mode.

When enabled, the IST mechanism unconditionally switches stacks. It can be enabled on an individual interrupt vector basis using a new field in the IDT gate-descriptor entry. This allows some interrupts to use the modified legacy mechanism, and others to use the IST mechanism. The IST mechanism is only available in long mode.

The IST mechanism uses new fields in the 64-bit TSS format and the long-mode interrupt-gate and trap-gate descriptors:

- Figure 12-8 on page 373 shows the format of the 64-bit TSS and the location of the seven IST pointers. The 64-bit TSS offsets from 24h to 5Bh provide space for seven IST pointers, each of which are 64 bits (8 bytes) long.

- The long-mode interrupt-gate and trap-gate descriptors define a 3-bit IST-index field in bits 2:0 of byte +4. Figure 4-24 on page 102 shows the format of long-mode interrupt-gate and trap-gate descriptors and the location of the IST-index field.

To enable the IST mechanism for a specific interrupt, system software stores a non-zero value in the interrupt gate-descriptor IST-index field. If the IST index is zero, the modified legacy stack-switching mechanism (described in the previous section) is used.

Figure 8-16 shows how the IST mechanism is used to create the interrupt-handler stack. When an interrupt occurs and the IST index is non-zero, the processor uses the index to select the corresponding IST pointer from the TSS. The IST pointer is loaded into the RSP to establish a new stack for the interrupt handler. The SS register is loaded with a null selector if the CPL changes and the SS.RPL is set to the new CPL value. After the stack is loaded, the processor pushes the old stack pointer, RFLAGS, the return pointer, and the error code (if applicable) onto the stack. Control is then transferred to the interrupt handler.

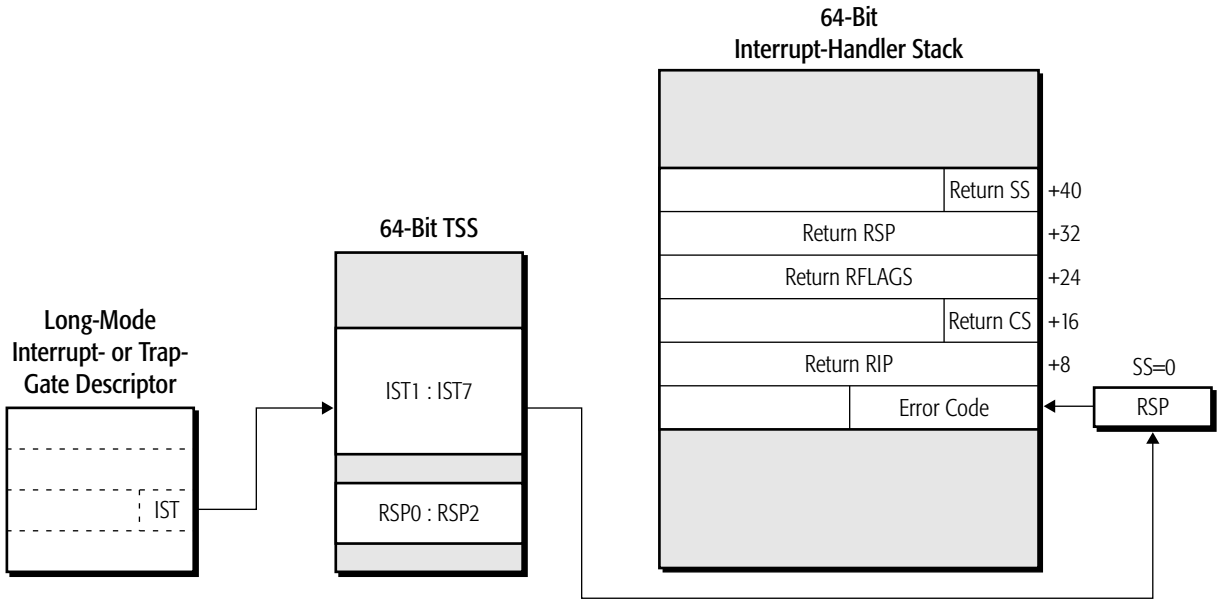

Figure 8-16. Long-Mode IST Mechanism

Software must make sure that an interrupt or exception handler using an IST pointer doesn't take another exception using the same IST pointer, as this will result in the first stack exception frame being overwritten.

8.4.9.1 Interrupt Shadow Stack Table.

When the shadow stack feature is enabled in long mode (EFER.LMA=1), a mechanism similar to the IST is provided to switch shadow stacks. This mechanism, the Interrupt Shadow Stack Table (ISST) is described in Section “Shadow Stacks” on page 647.

8.9.5 Returning From Interrupt Procedures

As with legacy mode, a return to an interrupted program in long mode should be performed using the IRET instruction. However, in long mode, the IRET semantics are different from legacy mode:

- *In 64-bit mode*, IRET pops the return-stack pointer unconditionally off the interrupt-stack frame and into the SS:RSP registers. This reverses the action of the long-mode interrupt mechanism, which saves the stack pointer whether or not a privilege change occurs. IRET also allows a null selector to be popped off the stack and into the SS register. See Section “Nested IRETs to 64-Bit Mode Procedures” on page 278 for additional information.
- *In compatibility mode*, IRET behaves as it does in legacy mode. The SS:ESP is popped off the stack only if a control transfer to less privilege (numerically greater CPL) is performed. Otherwise, it is assumed that a stack pointer is not present on the interrupt-handler stack.

The long-mode interrupt mechanism always uses a 64-bit stack when saving values for the interrupt handler, and the interrupt handler is always entered in 64-bit mode. To work properly, an IRET used to exit the 64-bit mode interrupt-handler requires a series of eight-byte pops off the stack. This is accomplished by using a 64-bit operand-size prefix with the IRET instruction. The default stack size assumed by an IRET in 64-bit mode is 32 bits, so a 64-bit REX prefix is needed by 64-bit mode interrupt handlers.

Nested IRETs to 64-Bit Mode Procedures. In long mode, an interrupt causes a null selector to be loaded into the SS register if the CPL changes (this is the same action taken by a far CALL in long mode). If the interrupt handler performs a far call, or is itself interrupted, the null SS selector is pushed onto the stack frame, and another null selector is loaded into the SS register. Using a null selector in this way allows the processor to properly handle returns nested within 64-bit-mode procedures and interrupt handlers.

The null selector enables the processor to properly handle nested returns to 64-bit mode (which do not use the SS register), and returns to compatibility mode (which do use the SS register). Normally, an IRET that pops a null selector into the SS register causes a general-protection exception (#GP) to occur. However, in long mode, the null selector indicates the existence of nested interrupt handlers and/or privileged software in 64-bit mode. Long mode allows an IRET to pop a null selector into SS from the stack under the following conditions:

- The target mode is 64-bit mode.
- The target CPL<3.

In this case, the processor does not load an SS descriptor, and the null selector is loaded into SS without causing a #GP exception.

8.10 Virtual Interrupts

The term *virtual interrupts* includes two classes of extensions to the interrupt-handling mechanism:

- *Virtual-8086 Mode Extensions (VME)*—These allow virtual interrupts and interrupt redirection in virtual-8086 mode. VME has no effect on protected-mode programs.
- *Protected-Mode Virtual Interrupts (PVI)*—These allow virtual interrupts in protected mode when CPL=3. Interrupt redirection is not available in protected mode. PVI has no effect on virtual-8086-mode programs.

Because virtual-8086 mode is not supported in long mode, VME extensions are not supported in long mode. PVI extensions are, however, supported in long mode.

8.10.1 Virtual-8086 Mode Extensions

The virtual-8086-mode extensions (VME) enable performance enhancements for 8086 programs running as protected tasks in virtual-8086 mode. These extensions are enabled by setting CR4.VME (bit 0) to 1. The extensions enabled by CR4.VME are:

- Virtualizing control and notification of maskable external interrupts with the EFLAGS VIF (bit 19) and VIP (bit 20) bits.
- Selective interception of software interrupts (INT*n* instructions) using the TSS interrupt redirection bitmap (IRB).

Background. Legacy-8086 programs expect to have full access to the EFLAGS interrupt flag (IF) bit, allowing programs to enable and disable maskable external interrupts. When those programs run in virtual-8086 mode under a multitasking protected-mode environment, it can disrupt the operating system if programs enable or disable interrupts for their own purposes. This is particularly true if interrupts associated with one program can occur during execution of another program. For example, a program could request that an area of memory be copied to disk. System software could suspend the program before external hardware uses an interrupt to acknowledge that the block has been copied. System software could subsequently start a second program which enables interrupts. This second program could receive the external interrupt indicating that the memory block of the first program has been copied. If that were to happen, the second program would probably be unprepared to handle the interrupt properly.

Access to the IF bit must be managed by system software on a task-by-task basis to prevent corruption of system resources. In order to completely manage the IF bit, system software must be able to interrupt all instructions that can read or write the bit. These instructions include STI, CLI, PUSHF, POPF, INT*n*, and IRET. These instructions are part of an instruction class that is *IOPL-sensitive*. The processor takes a general-protection exception (#GP) whenever an IOPL-sensitive instruction is executed and the EFLAGS.IOPL field is less than the CPL. Because all virtual-8086 programs run at CPL=3, system software can interrupt all instructions that modify the IF bit by setting IOPL<3.

System software maintains a virtual image of the IF bit for each virtual-8086 program by emulating the actions of IOPL-sensitive instructions that modify the IF bit. When an external maskable-interrupt occurs, system software checks the state of the IF image for the current virtual-8086 program to determine whether the program is masking interrupts. If the program is masking interrupts, system software saves the interrupt information until the virtual-8086 program attempts to re-enable interrupts. When the virtual-8086 program unmasks interrupts with an IOPL-sensitive instruction, system software traps the action with the #GP handler.

The performance of a processor can be significantly degraded by the overhead of trapping and emulating IOPL-sensitive instructions, and the overhead of maintaining images of the IF bit for each virtual-8086 program. This performance loss can be eliminated by running virtual-8086 programs with IOPL set to 3, thus allowing changes to the real IF flag from any privilege level. Unfortunately, this can leave critical system resources unprotected.

In addition to the performance problems caused by virtualizing the IF bit, software interrupts (INT*n* instructions) cannot be masked by the IF bit or virtual copies of the IF bit. The IF bit only affects maskable external interrupts. Software interrupts in virtual-8086 mode are normally directed to the real mode interrupt vector table (IVT), but it can be desirable to redirect certain interrupts to the protected-mode interrupt-descriptor table (IDT).

The virtual-8086-mode extensions are designed to support both external interrupts and software interrupts, with mechanisms that preserve high performance without compromising protection. Virtualization of external interrupts is supported using two bits in the EFLAGS register: the virtual-interrupt flag (VIF) bit and the virtual-interrupt pending (VIP) bit. Redirection of software interrupts is supported using the interrupt-redirection bitmap (IRB) in the TSS. A separate TSS can be created for each virtual-8086 program, allowing system software to control interrupt redirection independently for each virtual-8086 program.

VIF and VIP Extensions for External Interrupts. When VME extensions are enabled, the IF-modifying instructions normally trapped by system software are allowed to execute. However, instead of modifying the IF bit, they modify the EFLAGS VIF bit. This leaves control over maskable interrupts to the system software. It can also be used as an indicator to system software that the virtual-8086 program is able to, or is expecting to, receive external interrupts.

When an unmasked external interrupt occurs, the processor transfers control from the virtual-8086 program to a protected-mode interrupt handler. If the interrupt handler determines that the interrupt is for the virtual-8086 program, it can check the state of the VIF bit in the EFLAGS value pushed on the stack for the virtual-8086 program. If the VIF bit is set (indicating the virtual-8086 program attempted to unmask interrupts), system software can allow the interrupt to be handled by the appropriate virtual-8086 interrupt handler.

If the VIF bit is clear (indicating the virtual-8086 program attempted to mask interrupts) and the interrupt is for the virtual-8086 program, system software can hold the interrupt pending. System software holds an interrupt pending by saving appropriate information about the interrupt, such as the interrupt vector, and setting the virtual-8086 program's VIP bit in the EFLAGS image on the stack. When the virtual-8086 program later attempts to set IF, the previously set VIP bit causes a general-

protection exception (#GP) to occur. System software can then pass the saved interrupt information to the virtual-8086 interrupt handler.

To summarize, when the VME extensions are enabled (CR4.VME=1), the VIF and VIP bits are set and cleared as follows:

- *VIF Bit*—This bit is set and cleared by the processor in virtual-8086 mode in response to an attempt by a virtual-8086 program to set and clear the EFLAGS.IF bit. VIF is used by system software to determine whether a maskable external interrupt should be passed on to the virtual-8086 program, emulated by system software, or held pending. VIF is also cleared during software interrupts through interrupt gates, with the original VIF value preserved in the EFLAGS image on the stack.
- *VIP Bit*—System software sets and clears this bit in the EFLAGS image saved on the stack after an interrupt. It can be set when an interrupt occurs for a virtual-8086 program that has a clear VIF bit. The processor examines the VIP bit when an attempt is made by the virtual-8086 program to set the IF bit. If VIP is set when the program attempts to set IF, a general-protection exception (#GP) occurs *before* execution of the IF-setting instruction. System software must clear VIP to avoid repeated #GP exceptions when returning to the interrupted instruction.

The VIF and VIP bits can be used by system software to minimize the overhead associated with managing maskable external interrupts because virtual copies of the IF flag do not have to be maintained by system software. Instead, VIF and VIP are maintained during context switches along with the remaining EFLAGS bits.

Table 8-12 on page 283 shows how the behavior of instructions that modify the IF bit are affected by the VME extensions.

Interrupt Redirection of Software Interrupts. In virtual-8086 mode, software interrupts (INT*n* instructions) are trapped using a #GP exception handler if the IOPL is less than 3 (the CPL for virtual-8086 mode). This allows system software to interrupt and emulate 8086-interrupt handlers. System software can set the IOPL to 3, in which case the INT*n* instruction is vectored through a gate descriptor in the protected-mode IDT. System software can use the gate to control access to the virtual-8086 mode interrupt vector table (IVT), or to redirect the interrupt to a protected-mode interrupt handler.

When VME extensions are enabled, for INT*n* instructions to execute normally, vectoring directly to a virtual-8086 interrupt handler through the virtual-8086 IVT (located at address 0 in the virtual-address space of the task). For security or performance reasons, however, it can be necessary to intercept INT*n* instructions on a vector-specific basis to allow servicing by protected-mode interrupt handlers. This is performed by using the interrupt-redirection bitmap (IRB), located in the TSS and enabled when CR4.VME=1. The IRB is available only in virtual-8086 mode.

Figure 12-6 on page 368 shows the format of the TSS, with the interrupt redirection bitmap located near the top. The IRB contains 256 bits, one for each possible software-interrupt vector. The most-significant bit of the IRB controls interrupt vector 255, and is located immediately before the IOPB base. The least-significant bit of the IRB controls interrupt vector 0.

The bits in the IRB function as follows:

- When set to 1, the INT*n* instruction behaves as if the VME extensions are not enabled. The interrupt is directed through the IDT to a protected-mode interrupt handler if IOPL=3. If IOPL<3, the INT*n* causes a #GP exception.
- When cleared to 0, the INT*n* instruction is directed through the IVT for the virtual-8086 program to the corresponding virtual-8086 interrupt handler.

Only software interrupts can be redirected using the IRB mechanism. External interrupts are asynchronous events that occur outside the context of a virtual-8086 program. Therefore, external interrupts require system-software intervention to determine the appropriate context for the interrupt. The VME extensions described in Section “VIF and VIP Extensions for External Interrupts” on page 280 are provided to assist system software with external-interrupt intervention.

8.10.2 Protected Mode Virtual Interrupts

The protected-mode virtual-interrupt (PVI) bit in CR4 enables support for interrupt virtualization in protected mode. When enabled, the processor maintains program-specific VIF and VIP bits similar to the manner defined by the virtual-8086 mode extensions (VME). However, unlike VME, only the STI and CLI instructions are affected by the PVI extension. When a program is running at CPL=3, it can use STI and CLI to set and clear its copy of the VIF flag without causing a general-protection exception. The last section of Table 8-12 on page 283 describes the behavior of instructions that modify the IF bit when PVI extensions are enabled.

The interrupt redirection bitmap (IRB) defined by the VME extensions is not supported by the PVI extensions.

8.10.3 Effect of Instructions that Modify EFLAGS.IF

Table 8-12 on page 283 shows how the behavior of instructions that modify the IF bit are affected by the VME and PVI extensions. The table columns specify the following:

- *Operating Mode*—the processor mode in effect when the instruction is executed.
- *Instruction*—the IF-modifying instruction.
- *IOPL*—the value of the EFLAGS.IOPL field.
- *VIP*—the value of the EFLAGS.VIP bit.
- *#GP*—indicates whether the conditions in the first four columns cause a general-protection exception (#GP) to occur.
- *Effect on IF Bit*—indicates the effect the conditions in the first four columns have on the EFLAGS.IF bit and the image of EFLAGS.IF on the stack.
- *Effect on VIF Bit*—indicates the effect the conditions in the first four columns have on the EFLAGS.VIF bit and the image of EFLAGS.VIF on the stack.

Table 8-12. Effect of Instructions that Modify the IF Bit

Operating Mode	Instruction	IOPL	VIP	#GP	Effect on IF Bit	Effect on VIF Bit
Real Mode *CR0.PE=0* *EFLAGS.VM=0* *CR4.VME=0* *CR4.PVI=0*	CLI			no	IF = 0	
	STI				IF = 1	
	PUSHF				EFLAGS.IF Stack Image = IF	
	POPF				IF = EFLAGS.IF stack image	
	INT*n*				EFLAGS.IF Stack Image = IF IF = 0	
	IRET				IF = EFLAGS.IF Stack Image	
Protected Mode *CR0.PE=1* *EFLAGS.VM=0* *CR4.VME=x* *CR4.PVI=0*	CLI	³CPL		no	IF = 0	
		<CPL		yes	—	
	STI	³CPL		no	IF = 1	
		<CPL		yes	—	
	PUSHF	x		no	EFLAGS.IF Stack Image = IF	
	POPF	³CPL			IF = EFLAGS.IF Stack Image	
		<CPL			No Change	
	INT*n* gate	x			EFLAGS.IF Stack Image = IF IF = 0	
	IRET				IF = EFLAGS.IF Stack Image	
	IRETD					

Note:

Gray-shaded boxes indicate the bits are unsupported (ignored) in the specified operating mode.
"x" indicates the value of the bit is a "don't care".
"—" indicates the instruction causes a general-protection exception (#GP).

Note:

1. *If the EFLAGS.IF stack image is 0, no #GP exception occurs and the IRET instruction is executed.*
2. *If the EFLAGS.IF stack image is 1, the IRET is not executed, and a #GP exception occurs.*

Table 8-12. Effect of Instructions that Modify the IF Bit (continued)

Operating Mode	Instruction	IOPL	VIP	#GP	Effect on IF Bit	Effect on VIF Bit
Virtual-8086 Mode *CR0.PE=1* *EFLAGS.VM=1* *CR4.VME=0* *CR4.PVI=x*	CLI	3		no	IF = 0	
		< 3		yes	—	
	STI	3		no	IF = 1	
		< 3		yes	—	
	PUSHF	3		no	EFLAGS.IF Stack Image = IF	
		< 3		yes	—	
	POPF	3		no	IF = EFLAGS.IF Stack Image	
		< 3		yes	—	
	INT*n* gate	3		no	EFLAGS.IF Stack Image = IF IF = 0	
		< 3		yes	—	
	IRET	3		no	IF = EFLAGS.IF Stack Image	
		< 3		yes	—

1. *If the EFLAGS.IF stack image is 0, no #GP exception occurs and the IRET instruction is executed.*
2. *If the EFLAGS.IF stack image is 1, the IRET is not executed, and a #GP exception occurs.*

9 Machine Check Architecture

The AMD64 Machine Check Architecture (MCA) plays a vital role in the reliability, availability, and serviceability (RAS) of AMD processors, as well as the RAS of the computer systems in which they are embedded. MCA defines the facilities by which processor and system hardware errors are logged and reported to system software. This allows system software to serve a strategic role in recovery from and diagnosis of hardware errors.

Error checking hardware is configured and information about detected error conditions is conveyed via an architecturally-defined set of registers. The system programming interface of MCA is described below in Section 9.3 “Machine Check Architecture MSRs” on page 291.

9.1 Introduction

All computer systems are susceptible to errors—results that are contrary to the system design. Errors can be categorized as *soft* or *hard*. Soft errors are caused by transient interference and are not necessarily indicative of any damage to the computer circuitry. These external events include noise from electromagnetic radiation and the incursion of sub-atomic particles that cause bit cell storage capacitors to change state.

Hard errors are repeatable malfunctions that are generally attributable to physical damage to computer circuitry. Damage may be caused by external forces (for example, voltage surges) or wear processes inherent in the circuit technology. Damaged circuit elements can manifest symptoms similar to those that are caused by soft error processes. An increase in the frequency of errors attributable to one circuit element may indicate that the element has sustained damage or is wearing-out and may, in the future, cause a hard error.

9.1.1 Reliability, Availability, and Serviceability

This section describes the concepts of reliability, availability, and serviceability (RAS) and shows how they are interrelated.

The rate at which errors occur in a computer system is a measure of the system’s *reliability*. *Availability* is the percentage of time that the system is available to do useful work. Errors that prevent a computer system from continued operation result in *down-time*, that is, periods of unavailability. Down-time includes the amount of time required to restore the system to operation. This may include the time to diagnose a failure, determine the field replaceable unit (FRU) containing the faulty circuitry, carry out the repair action required to replace the identified FRU, and restart the system. This time directly impacts the system’s availability and is a measure of the system’s *serviceability*.

The availability of a computer system can be increased without decreasing performance or significantly increasing cost through the judicious addition of data and control path redundancy in concert with dedicated error-checking hardware. Together, redundancy and error checking *detect* and

often *correct* hardware errors. When errors are corrected by hardware, system operation continues without any perceptible disruption or loss in performance.

Another important technique that can prevent down-time is *error containment*. Error containment limits the propagation of an erroneous data. This enhances system availability by limiting the effects of errors to a subset of software or hardware resources. System software may either correct the error and resume the interrupted program or, if the error cannot be corrected, terminate software processes that cannot continue due to the error.

Error logging enhances serviceability by providing information that is used to identify the FRU that contains the failed circuitry. The mechanical design of the computer system can enhance serviceability (and thus availability) by making the task of physically replacing a failed FRU quicker and easier.

9.1.2 Error Detection, Logging, and Reporting

Error detection requires specific error-checking hardware that compares the actual result of some data transfer or transformation to the expected result. Any disparity indicates that an error has occurred. Error detection is controlled through implementation-specific means. Disabling detection is normally only appropriate when hardware is being debugged in the laboratory.

When an error is detected, hardware autonomously acts to either correct the error or contain the propagation of the corrupting effects of an uncorrected error. For some error sources, hardware action can be disabled by software through the MCA interface.

As hardware acts to correct or contain a detected error, it gathers information about the error to aid in recovery, diagnosis, and repair. The architecture provides software control of error *logging* and *reporting*. The following describes the characteristics of each:

- Logging

  Logging involves saving information about the error in specific MCA registers. If the error reporting bank associated with the error source is enabled, logging occurs; if disabled, error information is generally discarded (there are implementation-specific exceptions).

- Reporting

  An uncorrected error may be reported to system software via a machine-check exception, if error reporting for the specific error source is enabled.

Reporting is the hardware-initiated action of interrupting the processor using a machine-check exception (#MC). Reporting for each specific error type can be enabled or disabled by system software though the MCA register interface. Even if reporting for an error type is disabled, logging may continue.

Disabling reporting can negatively impact both error containment and error recovery (see the next section) and should be avoided.

Hardware categorizes errors into three classes. These are:

- *corrected*

- *uncorrected*
- *deferred*

The following sections describe the characteristics of each of these error classes:

If an error can be corrected by hardware, no immediate action by software is required. In this case, information is logged, if enabled, to aid in later diagnosis and possible repair.

If correction is not possible, the error is classified as uncorrected. The occurrence of an uncorrected error requires immediate action by system software to either correct the error and resume the interrupted program or, if software-based correction is not possible, to determine the extent of the impact of the uncorrected error to any executing instruction stream or the architectural state of the processor or system and take actions to contain the error condition by terminating corrupted software processes.

For errors that are not corrected, but have no immediate impact on the architectural state of the system, processor core, or any current thread of execution, the error may be classified by hardware as a deferred error. Information about deferred errors is logged, if enabled, but not reported via a machine-check exception. Instead hardware monitors the error and escalates the error classification to uncorrected at the point in time where the error condition is about to impact the execution of an instruction stream or cause the corruption of the processor core or system architectural state.

This escalation results in a #MC exception, assuming that reporting for that error source is enabled. If software can correct the error, it may be possible to resume the affected program. If not, software can terminate the affected program rather than bringing down the entire system. This is referred to as *error localization*.

A common example of deferred error processing and localization is the conversion of globally uncorrected DRAM errors to process-specific consumed memory errors. In this example, uncorrected ECC-protected data that has not yet been consumed by any processor core is tagged as “poison.” Hardware reports the uncorrected data as a localized error via a #MC exception when it is about to be used (“consumed”) by an instruction execution stream.

In contrast, an error that cannot be contained and is of such severity that it has compromised the continued operation of a processor core requires immediate action to terminate system processing and may result in a hardware-enforced *shutdown*. In the shutdown state, the execution of instructions by that processor core is halted. See Section 8.2.9 “#DF—Double-Fault Exception (Vector 8)” on page 242 for a description of the shutdown processor state.

If supported, system software can chose to configure and enable hardware to generate an interrupt when a deferred error is first detected. Corrected errors may be counted as they are logged. If supported and enabled, exceeding a software-configured count threshold may be signalled via an interrupt. These notification mechanisms are independent of machine-check reporting.

Specific details on hardware error detection, logging, and reporting are implementation-dependent and are described in the *BIOS and Kernel Developer’s Guide (BKDG)* or *Processor Programming Reference Manual* applicable to your product.

9.1.3 Error Recovery

When errors cannot be corrected by hardware, *error recovery* comes into play. Error recovery, as defined by MCA, always involves software intervention. Logged information about the uncorrected error condition that caused the exception allows system software to take actions to either correct the error and resume the interrupted execution stream or terminate software processes (or higher-level software constructs) that are known to be affected by the uncorrected error.

From a system perspective, all errors are either recoverable or unrecoverable. The following outlines the characteristics of each:

- *Recoverable*—Hardware has determined that the architectural state of the processor experiencing the uncorrected error has not been compromised. Software execution can continue if system software can determine the extent of the error and take actions to either:
  - *correct* the error and *resume* the interrupted stream of execution or,
  - if this is not possible, *terminate* software processes that have incurred a loss of architectural state and *continue* other software processes that are unaffected by the error.
- *Unrecoverable*—Hardware has determined that the architectural state of the processor experiencing the uncorrected error has been corrupted. Software execution cannot reliably continue.

  Software saves any diagnostic information that it may be able to gather and halts.

The fact that an error is recoverable does not mean that recovery software will be able to resume program execution. If it is unable to determine the extent of the corruption or if it determines that essential state information has been lost, it may only be able to save information about the error and halt processing.

System software has many options to recover from an uncorrected error. The following is a partial list of possible actions that system software might take:

- If it can be determined that the corruption caused by the uncorrected error is contained within a software process, software can kill the process.
- If the uncorrected error has corrupted the architectural state of a virtual machine, the VMM can rebuild the container (using only hardware resources that are known to be good) and reboot the guest operating system.
- If the uncorrected error is a part of a block of data being transferred to or from an I/O device, the data transfer can be flushed and retried or terminated with an error.
- If the uncorrected error is due to a hard link failure, software can reconfigure the network to route information around the failed link.
- If the uncorrected error is in a cache and the cache line containing the uncorrected (known bad) data is in the shared state, software can invalidate the line so that it will be reloaded from memory or another cache that has the line in the owned state.

Many more error scenarios are recoverable depending on the effectiveness of hardware error containment, the logging capabilities of the system, and the sophistication of the recovery software that acts on the information conveyed through the MCA reporting structure.

If recovery software is unable to restore a valid system architectural state at some level of software abstraction (process, guest operating system, virtual machine, or virtual machine monitor), the uncorrected error is considered *system fatal*. In this situation, system software must halt the execution of instructions. A system reset is required to restore the system to a known-good architectural state.

9.2 Determining Machine-Check Architecture Support

Support for the machine-check architecture is implementation-dependent. System software executes the CPUID instruction to determine whether a processor implements the machine-check exception (#MC) and the global MCA MSRs. The CPUID Fn0000_0001_EDX[MCE] feature bit indicates support for the machine-check exception and the CPUID Fn0000_0001_EDX[MCA] feature bit indicates support for the base set of global machine-check MSRs.

Once system software determines that the base set of MCA MSRs is available, it determines the implemented number of machine-check reporting banks by reading the machine-check capabilities register (MCG_CAP), which is the first of the global MCA MSRs.

For a processor implementation to provide an architecturally compliant MCA interface, it must provide support for the machine-check exception, the global machine-check MSRs, the watchdog timer (see “CPU Watchdog Timer Register” on page 295.), and at least one bank of the machine-check reporting registers.

Support for the deferred reporting and software-based containment of uncorrected data errors is indicated by the feature bit CPUID Fn8000_0007_EBX[SUCCOR]. See “Machine-Check Recovery” on page 298.

Support for recoverable MCA overflow conditions is indicated by feature bit CPUID Fn8000_0007_EBX[McaOverflowRecov]. See the discussion of recoverable status overflow in Section 9.3.2.1 “MCA Overflow” on page 297.

Implementation-specific information concerning the machine-check mechanism can be found in the *BIOS and Kernel Developer’s Guide (BKDG)* or *Processor Programming Reference Manual* applicable to your product. For more information on using the CPUID instruction, see Section 3.3, “Processor Feature Identification,” on page 71.

9.3 Machine Check Architecture MSRs

The AMD64 Machine-Check Architecture defines the set of model-specific registers (MCA MSRs) used to log and report hardware errors. These registers are:

- Global status and control registers:
  - Machine-check global-capabilities register (MCG_CAP)

  - Machine-check global-status register (MCG_STATUS)
  - Machine-check global-control register (MCG_CTL)
  - Machine-check exception configuration register (MCA_INTR_CFG)
- One or more error-reporting register banks, each containing:
  - Machine-check control register (MC*i*_CTL)
  - Machine-check status register (MC*i*_STATUS)
  - Machine-check address register (MC*i*_ADDR)
  - At least one machine-check miscellaneous error-information register (MC*i*_MISC0)

  Each error-reporting register bank is associated with a specific processor unit (or group of processor units).
- CPU Watchdog Timer register (CPU_WATCHDOG_TIMER)

The error-reporting registers retain their values through a warm reset. (A warm reset occurs while power to the processor is stable. This in contrast to a cold reset, which occurs during the application of power after a period of power loss.) This preservation of error information allows the platform firmware or other system-boot software to recover and report information associated with the error when the processor is forced into a shutdown state.

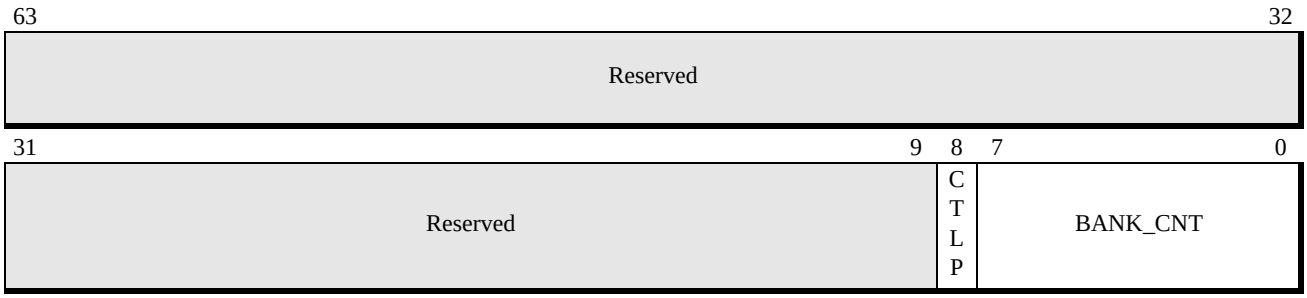
The RDMSR and WRMSR instructions are used to read and write the machine-check MSRs. See “Machine-Check MSRs” on page 671 for a listing of the machine-check MSR numbers and their reset values. The following sections describe each MCA MSR and its function.

9.3.1 Global Status and Control Registers

The global status and control MSRs are the MCG_CAP, MCG_STATUS, MCG_CTL and MCA_INTR_CFG registers.

9.3.1.1 Machine-Check Global-Capabilities Register

Figure 9-1 shows the format of the machine-check global-capabilities register (MCG_CAP). MCG_CAP is a read-only register that specifies the machine-check mechanism capabilities supported by the processor implementation.



Bits	Mnemonic	Description	Access type
63:9	—	Reserved	R
8	CTLP	MCG_CTL register present	R
7:0	BANK_CNT	Number of reporting banks	R

Figure 9-1. MCG_CAP Register

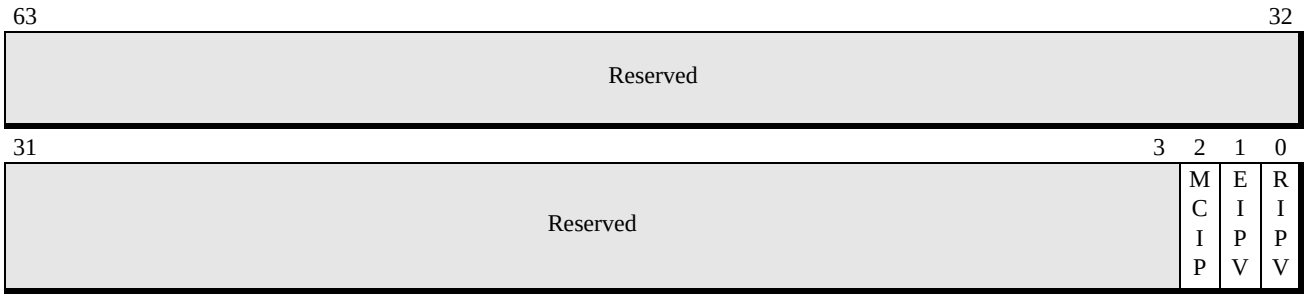
The fields within the MCG_CAP register are:

- *BANK_CNT (MCi Bank Count)*—Bits 7:0. This field specifies how many error-reporting register banks are supported by the processor implementation.
- *CTLP(MCG_CTL Register Present)*—Bit 8. This bit specifies whether or not the Machine-Check Global-Control (MCG_CTL) Register is supported by the processor. When the bit is set to 1, the register is supported. When the bit is cleared to 0, the register is unsupported. The MCG_CTL register is described on page 294.

All remaining bits in the MCG_CAP register are reserved. Writing values to the MCG_CAP register produces undefined results.

9.3.1.2 Machine-Check Global-Status Register

Figure 9-2 shows the format of the machine-check global-status register (MCG_STATUS). MCG_STATUS provides basic information about the processor state after the occurrence of a machine-check error.



Bits	Mnemonic	Description	R/W
63:3	—	Reserved	
2	MCIP	Machine Check In-Progress	R/W
1	EIPV	Error IP Valid Flag	R/W
0	RIPV	Restart IP Valid Flag	R/W

Figure 9-2. MCG_STATUS Register

The fields within the MCG_STATUS register are:

- *Restart-IP Valid (RIPV)*—Bit 0. When this bit is set to 1, the interrupted program can be reliably restarted at the instruction addressed by the instruction pointer pushed onto the stack by the machine-check error mechanism. If this bit is cleared to 0, the interrupted program cannot be reliably restarted.
- *Error-IP Valid (EIPV)*—Bit 1. When this bit is set to 1, the process thread that was interrupted by the #MC is responsible for the machine-check error, which occurred at the privilege level indicated by the CS selector that was pushed on the stack by the exception. If this bit is cleared to 0, it is possible that the interrupted thread is not responsible for the machine-check error.
- *Machine Check In-Progress (MCIP)*—Bit 2. When this bit is set to 1, it indicates that a machine-check error is in progress. If another machine-check error occurs while this bit is set, the processor enters the shutdown state. The processor sets this bit whenever a machine check exception is generated. Software is responsible for clearing it after the machine check exception is handled.

All remaining bits in the MCG_STATUS register are reserved.

9.3.1.3 Machine-Check Global-Control Register

Figure 9-3 shows the format of the machine-check global-control register (MCG_CTL). MCG_CTL is used by software to enable or disable the logging and reporting of machine-check errors from the implemented error-reporting banks. Depending on the implementation, detected errors from some error sources associated with a reporting bank that is disabled are still logged. Setting all bits to 1 in this register enables all implemented error-reporting register banks to log errors.

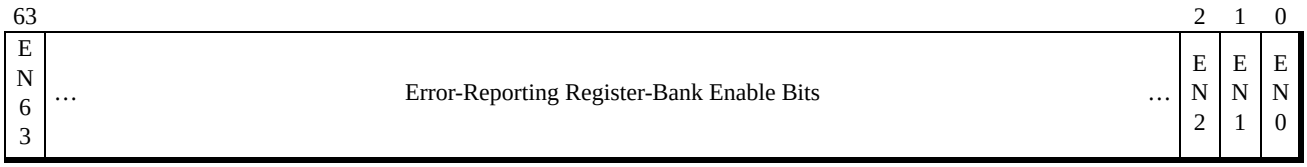


Figure 9-3. MCG_CTL Register

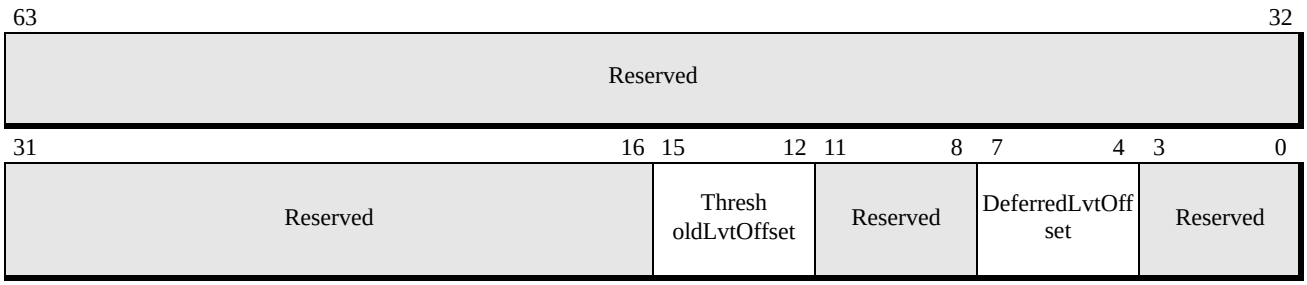
9.3.1.4 Machine-Check Exception Configuration Register

In addition to the standard Machine Check exception (#MC) signaling, certain machine check events can raise an interrupt via the APIC LVT mechanism. Configuration of these interrupts are provided, in part, in register MCA_INTR_CFG located at MSR C000_0410, see Figure 9-4. See Section 16.4 “Local Interrupts” on page 608 for details on configuring LVT entries.



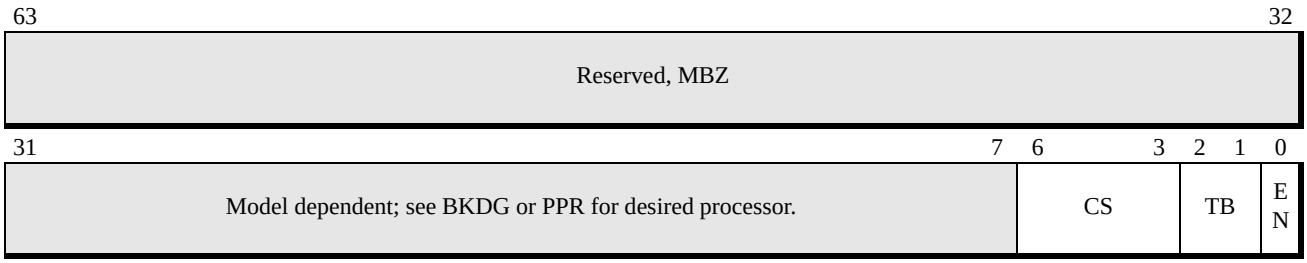
Bits	Mnemonic	Description	R/W
63:16	—	Reserved	R
15:12	ThresholdLvtOffset	For error thresholding interrupts, specifies the address of the LVT entry in the APIC registers as follows: LVT address = (ThresholdLvtOffset < < 4) + 500h (see APIC[530:500]).	R/W
11:8	—	Reserved	R
7:4	DeferredLvtOffset	For deferred error interrupts, specifies the address of the LVT entry in the APIC registers as follows: LVT address = (DeferredLvtOffset < < 4) + 500h (see APIC[530:500]).	R/W
3:0	—	Reserved	R

Figure 9-4. MCA_INTR_CFG Register

9.3.1.5 CPU Watchdog Timer Register

The CPU watchdog timer is used to generate a machine check condition when an instruction does not complete within a time period specified by the CPU Watchdog Timer register. The timer restarts the count each time an instruction completes, when enabled by the *CPU Watchdog Timer Enable* bit. The time period is determined by the *Count Select* and *Time Base* fields. The timer does not count during halt or stop-grant.

The format of the CPU watchdog timer is shown in Figure 9-5.



Bits	Mnemonic	Description	R/W
63:7	Reserved	Reserved, Must be Zero	
6:3	CS	CPU Watchdog Timer Count Select	R/W
2:1	TB	CPU Watchdog Timer Time Base	R/W
0	EN	CPU Watchdog Timer Enable	R/W

Figure 9-5. CPU Watchdog Timer Register Format

CPU Watchdog Timer Enable (EN) - Bit 0. This bit specifies whether the CPU Watchdog Timer is enabled. When the bit is set to 1, the timer increments and generates a machine check when the timer expires. When cleared to 0, the timer does not increment and no machine check is generated.

CPU Watchdog Timer Time Base (TB) - Bits 2:1. Specifies the time base for the time-out period indicated in the *Count Select* field. The allowable time base values are provided in Table 9-1.

Table 9-1. CPU Watchdog Timer Time Base

TB[1:0]	Time Base
00b	1 millisecond
01b	1 microsecond
10b	Reserved
11b	Reserved

CPU Watchdog Timer Count Select (CS) - Bits 6:3. Specifies the time period required for the CPU Watchdog Timer to expire. The time period is this value times the time base specified in the *Time Base* field. The allowable values are shown in Table 9-2.

Table 9-2. CPU Watchdog Timer Count Select

CS[3:0]	Value
0000b	4095
0001b	2047
0010b	1023
0011b	511
0100b	255

Table 9-2. CPU Watchdog Timer Count Select (continued)

0101b	127
0110b	63
0111b	31
1000b	8191
1001b	16383
1010b–1111b	Reserved

9.3.2 Error-Reporting Register Banks

Each error-reporting register bank contains the following registers:

- Machine-check control register (MC*i*_CTL).
- Machine-check status register (MC*i*_STATUS).
- Machine-check address register (MC*i*_ADDR).
- Machine-check miscellaneous error-information register 0 (MC*i*_MISC0).

The *i* in each register name corresponds to the number of a supported register bank. Each error-reporting register bank is normally associated with a specific execution unit. The number of error-reporting register banks is implementation-specific. For more information, see the *BIOS and Kernel Developer's Guide (BKDG)* or *Processor Programming Reference Manual* applicable to your product.

Software reads the MCG_CAP register to determine the number of supported register banks. The first error-reporting register (MC0_CTL) always starts with MSR address 400h, followed by MC0_STATUS (401h), MC0_ADDR (402h), and MC0_MISC0 (403h). The addresses of any additional error-reporting MSRs are assigned sequentially starting at 404h through the remaining supported register banks.

9.3.2.1 MCA Overflow

If an error occurs within an error reporting bank while the status register for that bank contains valid data (MC*i*_STATUS[VAL] = 1), an MCA overflow condition results. In this situation, information about the new error will either be discarded or will replace the information about the prior error.

Hardware sets the MC*i*_STATUS[OVER] bit to indicate this condition has occurred and follows a set of rules to determine whether to overwrite the previously logged error information or discard the new error information. These rules are shown in Table 9-3 below.

Table 9-3. Error Logging Priorities

		Previous Error Type		
		Corrected	Deferred	Uncorrected
Current Error Type	**Corrected**	Discard Current	Discard Current	Discard Current
	Deferred	Overwrite Previous	Discard Current	Discard Current
	Uncorrected	Overwrite Previous	Overwrite Previous	Discard Current

Note(s):

1. *Logging a deferred error has priority over the retention of information concerning a prior corrected error.*
2. *Logging an uncorrected error has priority over the retention of information concerning either a prior deferred or corrected error.*
3. *Valid Information concerning an uncorrected error is not overwritten by any subsequent errors.*

If the VAL bit is not set, hardware writes the appropriate logging registers based on the type of error (writing the MC*i*_STATUS register last) and then sets the VAL bit to indicate to software that the information currently contained in the MC*i*_STATUS register is valid. Software clears the VAL bit after reading the contents of this register (after reading and saving valid information stored in any of the other logging registers) to indicate to hardware that it has saved the information, making the registers available to log the next error.

If survivable MCA overflow is supported by the implementation (as indicated by CPUID Fn8000_0007_EBX[McaOverflowRecov] = 1), the state of the MC*i*_STATUS[PCC] bit indicates whether system execution can continue. If a particular processor does not support survivable MCA overflow and overflow occurs, software must halt instruction execution on that processor core regardless of the state of the PCC bit because critical information may have been lost as a result of the overflow. See the description of the Machine-Check Status registers below for more information on the PCC bit.

9.3.2.2 Machine-Check Recovery

Machine Check Recovery is a feature allowing recovery of the system when the hardware cannot correct an error. Machine Check Recovery is supported when CPUID Fn8000_0007_EBX[SUCCOR]=1.

When Machine Check Recovery is supported and an uncorrected error has been detected that the hardware can contain to the task or process to which the machine check has been delivered, it logs a context-synchronous uncorrectable error (MCi_STATUS[UC]=1, MCi_STATUS[PCC]=0). The rest of the system is unaffected and may continue running if supervisory software can terminate only the affected process context.

9.3.2.3 Machine-Check Control Registers

The machine-check control registers (MC*i*_CTL), as shown in Figure 9-6, contain an enable bit for each error source within an error-reporting register bank. Setting an enable bit to 1 enables error reporting for the specific feature controlled by the bit, and clearing the bit to 0 disables error reporting

for the feature. It is recommended that the value FFFF_FFFF_FFFF_FFFFh be programmed into each MC*i*_CTL register.

Disabling the reporting of errors from error sources that are capable of detecting uncorrected errors can compromise future error recovery and is not recommended. Other implementation-specific values are documented in the product's *BIOS and Kernel Developer's Guide (BKDG)* or *Processor Programming Reference Manual*.

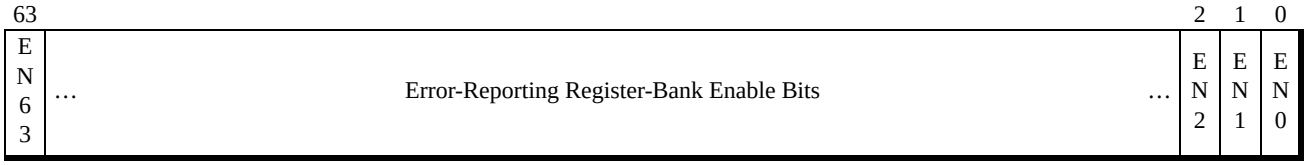


Figure 9-6. MC*i*_CTL Register

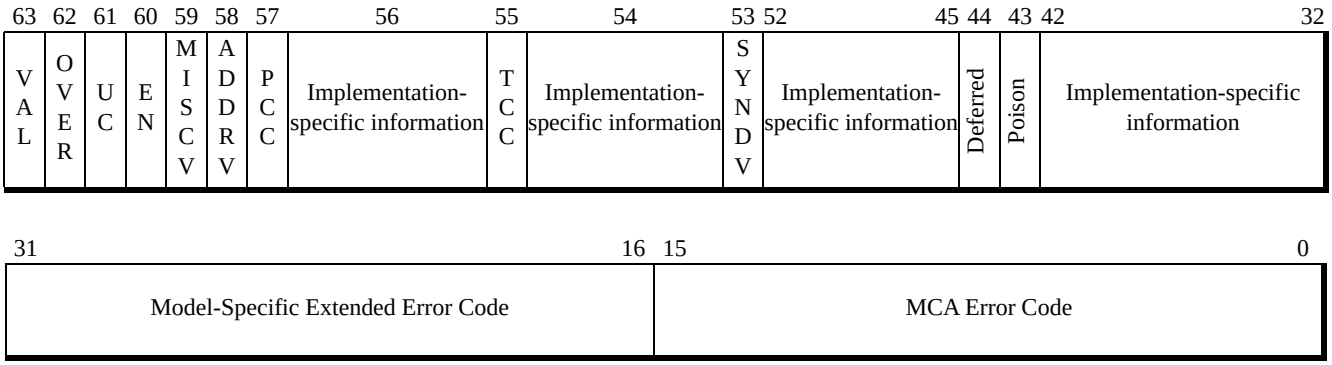
9.3.2.4 Machine-Check Status Registers

Each error-reporting register bank includes a machine-check status register (MC*i*_STATUS) that the processor uses to log error information. Hardware writes the status register bits when an error is detected, and sets the VAL bit of the register to 1, indicating that the status information is valid. Error reporting for the error source associated with the detected error *does not* need to be enabled in the MC*i*_CTL Register for the processor to write the status register. Error reporting must be enabled for the error to be reported via a #MC exception. Software is responsible for clearing the status register after the exception has been handled. Attempting to write a value other than 0 to an MC*i*_STATUS register in an implemented MCA bank may raise a general-protection (#GP) exception.

Figure 9-7 on page 300 shows the format of the MC*i*_STATUS register.



Bits	Mnemonic	Description	R/W
63	VAL	Valid	R/W*
62	OVER	Status Register Overflow	R/W*
61	UC	Uncorrected Error	R/W*
60	EN	Error Condition Enabled	R/W*
59	MISCV	Miscellaneous-Error Register Valid	R/W*
*System software can only clear this bit to 0.			
58	ADDRV	Error-Address Register Valid	R/W*
57	PCC	Processor-Context Corrupt	R/W*
56		Implementation-specific information	R/W*
55	TCC	Task-Context Corrupt	R/W*
54		Implementation-specific information	R/W*
53	SYNDV	Syndrome Register Valid	R/W*
52:45		Implementation-specific information	R/W*
44	Deferred	Deferred error	R/W*
43	Poison	Poisoned data consumed	R/W*
42:32		Implementation-specific information	R/W*
31:16		Model-Specific Extended Error Code	R/W*
15:0		MCA Error Code	R/W*

Figure 9-7. MC*i*_STATUS Register

The fields within the MC*i*_STATUS register are:

- *MCA Error Code*—Bits 15:0. This field encodes information about the error, including:
  - The type of transaction that caused the error.
  - The memory-hierarchy level involved in the error.
  - The type of request that caused the error.
  - Other information concerning the transaction type.

  See the *BIOS and Kernel Developer's Guide (BKDG)* or *Processor Programming Reference Manual* applicable to your product for information on the format and encoding of the MCA error code.

- *Model-Specific Extended Error Code*—Bits 31:16. This field encodes model-specific information about the error. For further information, see the documentation for particular implementations of the architecture.
- *Implementation-specific Information*—Bits 56, 54:45, 42:32. These bit ranges hold model-specific error information. Software should not rely on the field definitions in these ranges being consistent between processor implementations. For details see the BKDG or PPR for desired implementations of the architecture.
- *Poison*—Bit 43. When set to 1, this bit indicates that the uncorrected error condition being reported is due to the attempted use of data that was previous detected as in error (and could not be corrected) and marked as known-bad.
- *Deferred*—Bit 44. When set to 1, this bit indicates that hardware has determined that the error condition being logged has not affected the execution of any instruction stream and that action by system software to prevent or correct an error is not required. No machine-check exception is signalled. Hardware will monitor the error and log an uncorrected error when the execution of any thread of execution is impacted.
- *SYNDV*—Bit 53. When set to 1, this bit indicates that the contents of the corresponding syndrome register (MCA_SYND) are valid. When this bit is cleared, the contents of MCA_SYND are not valid.
- *TCC*—Bit 55. When set to 1, this bit indicates that the hardware context of the process thread to which the error was reported may have been corrupted. Continued operation of the thread may have unpredictable results. When this bit is cleared, the hardware context of the process thread to which the error was reported is not corrupted and recovery of the process thread is possible. This bit is only meaningful when MCA_STATUS[PCC]=0.
- *PCC*—Bit 57. When set to 1, this bit indicates that the processor state is likely to be corrupt due to an uncorrected error. In this case, it is possible that software cannot reliably continue execution. When this bit is cleared, the processor state is not corrupted and recovery is still possible. If the PCC bit is set in any error bank, the processor will clear RIPV and EIPV in the MCG_STATUS register.
- *ADDRV*—Bit 58. When set to 1, this bit indicates that the contents of the corresponding error-reporting address register (MC*i*_ADDR) are valid. When this bit is cleared, the contents of MC*i*_ADDR are not valid.
- *MISCV*—Bit 59. When set to 1, this bit indicates that additional information about the error is saved in the corresponding error-reporting miscellaneous register (MC*i*_MISC0). When cleared, this bit indicates that the contents of the MC*i*_MISC0 register are not valid.
- *EN*—Bit 60. When set to 1, this bit indicates that the error condition is enabled in the corresponding error-reporting control register (MC*i*_CTL). Errors disabled by MC*i*_CTL do not cause a machine-check exception.
- *UC*—Bit 61. When set to 1, this bit indicates that the logged error status is for an uncorrected error. When cleared, the error class is determined by looking at the Deferred bit; the error is a Corrected error if the Deferred bit is clear or a Deferred error if the Deferred bit is set. (See Section 9.1.2, “Error Detection, Logging, and Reporting,” on page 288, for more detail on these error classes.)

- *OVER*—Bit 62. This bit is set to 1 by the processor if the VAL bit is already set to 1 as the processor attempts to write error information into MC*i*_STATUS. In this situation, the machine-check mechanism handles the contents of MC*i*_STATUS as follows:
  - For processor implementations that log errors for disabled reporting banks, status for an enabled error replaces status for a disabled error.
  - Status for a deferred error replaces status for a corrected error.
  - Status for an uncorrected error replaces status for a corrected or deferred error.
  - Status for an enabled uncorrected error is never replaced.

  See Section 9.3.2.1 “MCA Overflow” on page 297 for more information on this field.
- *VAL*—Bit 63. This bit is set to 1 by the processor if the contents of MC*i*_STATUS are valid. Software should clear the VAL bit after reading the MC*i*_STATUS register, otherwise a subsequent machine-check error sets the OVER bit as described above.

When a machine-check error occurs, the processor writes an error code into the appropriate MC*i*_STATUS register MCA error-code field. The MC*i*_STATUS[VAL] bit is set to 1, indicating that the MC*i*_STATUS register contents are valid.

MCA error-codes are used to report errors in the memory hierarchy, the system bus, and the system-interconnection logic. Error-codes are divided into subfields that are used to describe the cause of an error. The information is implementation-specific. For further information, see the *BIOS and Kernel Developer’s Guide (BKDG)* or *Processor Programming Reference Manual* applicable to your product.

9.3.2.5 Machine-Check Address Registers

Each error-reporting register bank includes a machine-check address register (MC*i*_ADDR) that the processor uses to report the address or location associated with the logged error. The address field can hold a virtual (linear) address, a physical address, or a value indicating an internal physical location, depending on the type of error. For further information, see the documentation for particular implementations of the architecture. The contents of this register are valid only if the ADDRV bit in the corresponding MC*i*_STATUS register is set to 1.

9.3.2.6 Machine-Check Miscellaneous-Error Information Register 0 (MC*i*_MISC0)

Each error-reporting register bank includes the Machine-Check Miscellaneous 0 register that the processor uses to report additional error information.

In some implementations, the MC*i*_MISC0 register is used for error thresholding. Thresholding is a mechanism provided by hardware to:

- count detected errors, and
- (optionally) generate an APIC-based interrupt when a programmed number of errors has been counted.

Processor hardware counts detected errors and ensures that multiple error sources do not share the same thresholding register. Software can use corrected error counts to help predict which components might soon fail (begin generating uncorrectable errors) and schedule their replacement.

Threshold counters increment for error sources that are enabled for logging.

9.3.2.7 Additional Machine-Check Miscellaneous-Error Information Registers (MC*i*_MISC*j*)

The MC*i*_MISC0[BLKP] field is used to point to any additional MC*i*_MISC*j* registers, where j > 0. If this field is zero, no additional MC*i*_MISC registers are implemented. If this field is one, and CPUID Fn8000_0007_EBX[ScalableMca]=1, refer to Section 9.3.3, “Machine-Check Architecture Extension Registers,” on page 305 for addresses of additional MC*i*_MISC*j* registers.

If the MC*i*_MISC0[BLKP] field is non-zero and CPUID Fn8000_0007_EBX[ScalableMca]=0, up to 8 additional MC*i*_MISC*j* registers can be implemented for the error-reporting bank *i* (for a total of 9). These registers are allocated in contiguous blocks of 8, with MC*i*_MISC1 addressed by:

MC*i*_MISC1 address = C000_0400h + (MC*i*_MISC0[BLKP] << 3)

This is illustrated in Figure 9-8 below.

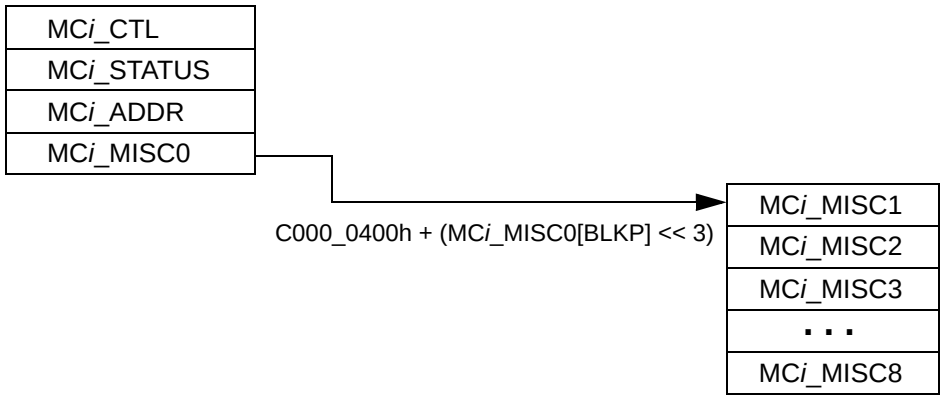


Figure 9-8. MC*i*_MISC1 Addressing

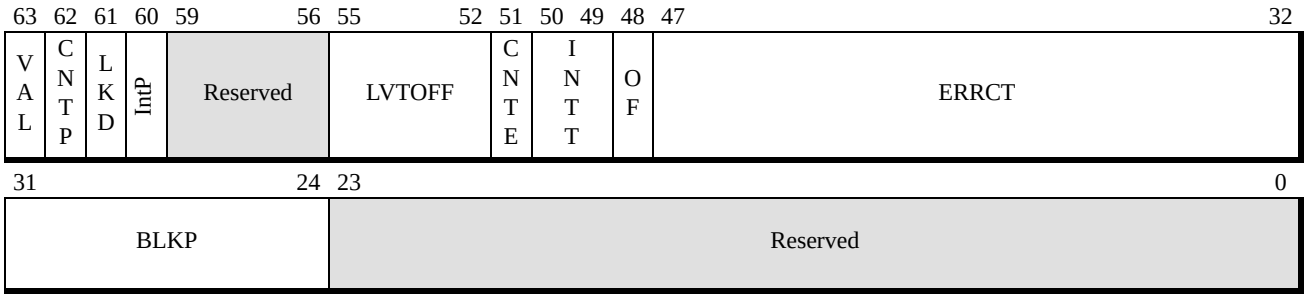
The format of implemented MC*i*_MISC*j* registers depends upon their use and use can vary from one implementation to another. Figure 9-9 below illustrates the format of a miscellaneous error information register when used as an error thresholding register.

All miscellaneous error information registers will contain the VAL field in bit position 63. MC*i*_MISC0 must contain the BLKP field in bits 31:24.



Bits	Mnemonic	Description	R/W	Reset
63	VAL	Valid	R	1b
62	CNTP	Counter Present	R	1b
61	LKD	Locked	R/W	0b
60	IntP	Thresholding Interrupt Supported	R	Implementation Dependent
59:56	Reserved			
55:52	LVTOFF	LVT Offset	R/W	0000b
51	CNTE	Counter Enable	R/W	0b
50:49	INTT	Interrupt Type	R/W	00b
48	OF	Overflow	R/W	Undefined
47:32	ERRCT	Error Counter	R/W	Undefined
31:24	BLKP	Block pointer for additional MISC registers	R	Undefined
23:0	Reserved			

Figure 9-9. Miscellaneous Information Register (Thresholding Register Format)

The fields within the MC*i*_MISC*j* register are:

- *Valid (VAL)*—Bit 63. When set to 1, indicates that the counter present (CNTP) and block pointer (BLKP) fields in this register are valid.
- *Counter Present (CNTP)*—Bit 62. When set to 1, indicates the presence of a threshold counter.
- *Locked (LKD)*—Bit 61. When set to 1, indicates that the threshold counter is not available for OS use. If this is the case, writes to bits 60:0 of this register are ignored and do not generate a fault. Software must check the Locked bit before writing into the thresholding register.

  This field is write-enabled by MSR C001_0015h Hardware Configuration Register [MCSTATUSWrEn].
- *IntP (Thresholding Interrupt Supported)*—Bit 60. When set, this bit indicates that the reporting of threshold overflow via interrupt is supported. Interrupt type is determined by the setting of the INTT field.
- *LVT Offset (LVTOFF)*—Bits 55:52. This field specifies the address of the APIC LVT entry to deliver the threshold counter interrupt. Software must initialize the APIC LVT entry before enabling the threshold counter to generate the APIC interrupt; otherwise, undefined behavior may result. This field is aliased to MCA_INTR_CFG[ThresholdLvtOffest].

- *Counter Enable (CNTE)*—Bit 51. When set to 1, counting of implementation-dependent errors is enabled; otherwise, counting is disabled.
- *Interrupt Type (INTT)*—Bits 50:49. The value of this field specifies the type of interrupt signaled when the value of the overflow bit changes from 0 to 1.
  - 00b = No interrupt
  - 01b = APIC-based interrupt
  - 10b = Reserved
  - 11b = Reserved
- *Overflow (OF)*—Bit 48. The value of this field is maintained through a warm reset. This bit is set by hardware when the error counter increments to its maximum implementation-supported value (from FFFEh to FFFFh for the maximum implementation-supported value). This is defined as the threshold level. When the overflow bit is set, the interrupt selected by the interrupt type field is generated. Software must reset this bit to zero in the interrupt handler routine when they update the error counter.
- *Error Counter (ERRCT)*—Bits 47:32. This field is maintained through a warm reset. The size of the threshold counter is implementation-dependent. Implementations with less than 16 bits fill the most significant unimplemented bits with zeros.

  Software enumerates the counter bits to discover the size of the counter and the threshold level (when counter increments to the maximum count implemented). Software sets the starting error count as follows:

  Starting error count = threshold level – desired software error count to cause overflow

  The error counter is incremented by hardware when errors for the associated error counter are logged. When this counter overflows, it stays at the maximum error count (with no rollover).
- *Block pointer for additional MISC registers (BLKP)*—Bits 31:24. This field is only valid when valid (VAL) bit is set. When non-zero, this field is used to indicate the presence of additional MCi_MISC registers.

Other formats for miscellaneous information registers are implementation-dependent, see the *BIOS and Kernel Developer's Guide (BKDG)* or *Processor Programming Reference Manual* applicable to your product for more details.

9.3.3 Machine-Check Architecture Extension Registers

This section describes the Machine Check Architecture Extension (MCAX). MCAX is available on a processor when CPUID Fn8000_0007_EBX[ScalableMca] returns 1.

A processor that supports MCAX supports up to 64 MCA banks per thread, with 16 MCAX registers per bank, at MSRs C000_2[3FF:000]. MSRs C000_2[FFF:400] are reserved for future use.

Software can identify an MCA bank as MCAX-capable by checking for MCA_CONFIG[Mcax]=1. An MCAX bank contains the following MCAX registers: MCA_CTL, MCA_STATUS, MCA_ADDR, MCA_MISC0, MCA_CONFIG, MCA_IPID, MCA_SYND, MCA_DESTAT,

MCA_MISC[4:1], and MCA_SYND[2:1]. See Figure 9-10 for address mapping of registers in a MCAX bank.

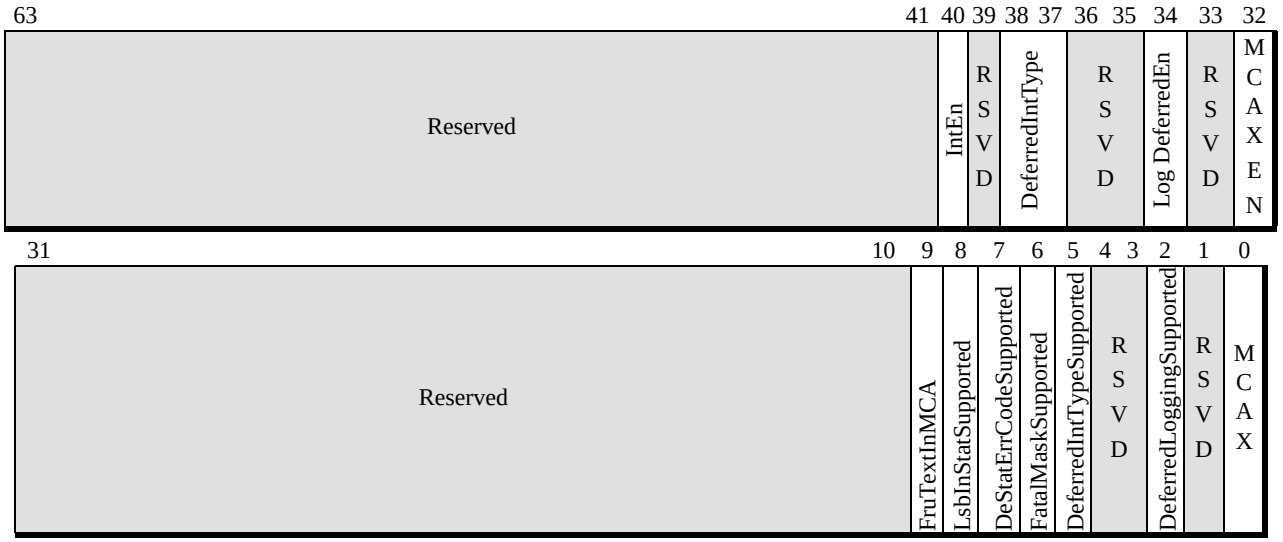
MCAX bank registers MCA_CTL, MCA_STATUS, MCA_ADDR, and MCA_MISC0 are aliased to MCA bank registers MCi_CTL, MCi_STATUS, MCi_ADDR, and MCi_MISC0 in MCA banks 0 to 31. The format of MCA_CTL, MCA_STATUS, MCA_ADDR, and MCA_MISC0 is the same as the format of the corresponding MCA bank register.

MCA bank number (decimal)	MCAX Bank registers (MSR C000_2xxx)				MCAX Bank registers (MSR C000_2xxx)							
	MCA_CTL	MCA_STATUS	MCA_ADDR	MCA_MISC0	MCA_CONFIG	MCA_IPID	MCA_SYND	Reserved	MCA_DESTAT	MCA_DEADDR	MCA_MISC [1:4]	MCA_SYND [1:2]
0	000h	001h	002h	003h	004h	005h	006h	007h	008h	009h	00Ah:00Dh	00Eh:00Fh
n	000h + n*10h	001h + n*10h	002h + n*10h	003h + n*10h	004h + n*10h	005h + n*10h	006h + n*10h	007h + n*10h	008h + n*10h	009h + n*10h	(00Ah:00Dh) + n*10h	(00Eh:00Fh) + n*10h

Figure 9-10. Address Mapping of Registers in MCAX Bank

9.3.3.1 MCA Configuration Register

The MCA_CONFIG register holds configuration information for the MCA bank.



Bits	Mnemonic	Description	R/W
63:41	Reserved		
40	IntEn	Interrupt Enable	RW
39	Reserved		
38:37	DeferredIntType	Deferred Error Interrupt Type	RW
36:35	Reserved		
34	LogDeferredEn	Deferred Error Logging Enable	RW
33	Reserved		
32	McaxEn	MCAX Enable	RW
31:10	Reserved		
9	FruTextInMCA	MCA FruText Supported	RW
8	LsbInStatSupported	Address LSB in MCA_STATUS Supported	R
7	DeStatErrCodeSupported	Deferred Error Status Error Code Supported	R
6	FatalMaskSupported	System fatal error event supported.	R
5	DeferredIntTypeSupported	Deferred Interrupt Type Supported	R
4:3	Reserved		
2	DeferredLoggingSupported	Deferred Error Logging Supported	R
1	Reserved		
0	MCAX	MCAX Capable	R

Figure 9-11. MCA_CONFIG Register

IntEn—Bits 40. When this bit is set to 0, an interrupt will not occur for corrected errors. When this bit is set to 1 and IntPresent=1, this bank will generate an interrupt on a corrected error to the interrupt vector configured in MCA_INTR_CFG[ThresholdLvtOffset].

DeferredIntType—Bits 38:37. When MCA_CONFIG[McaxEn]=1, specifies the type of interrupt to generate on a deferred error.

00b	No interrupt
01b	APIC based interrupt
10b	SMI
11b	Reserved

LogDeferredEn—Bit 34. Enable logging of deferred errors in MCA_STATUS. 0=Log deferred errors only in MCA_DESTAT and MCA_DEADDR. 1=Log deferred errors in MCA_STATUS and MCA_ADDR in addition to MCA_DESTAT and MCA_DEADDR. This bit does not affect logging of deferred errors in MCA_SYND or MCA_MISCx.

McaxEn—Bit 32. Enable MCAX feature set. 1=System software acknowledges support for the MCAX feature set. 0=System software has not acknowledged support for the MCAX feature set; all uncorrected errors and fatal errors cause a system fatal event.

FruTextInMca—Bit 9. 1=MCA_SYND1 and MCA_SYND2 contain an ASCII-formatted Field Replaceable Unit (FRU) identifier for the error logged in MCA_STATUS or MCA_DESTAT. 0=MCA_SYND1 and MCA_SYND2 contain implementation-specific information.

LsbInStatSupported—Bit 8. 1=MCA_STATUS[29:24] and MCA_DESTAT[29:24] contain the least significant valid bit of the address logged in MCA_ADDR and MCA_DEADDR.

DeStatErrCodeSupported—Bit 7. 1=MCA_DESTAT contains an MCA Error Code and a Model-specific Extended Error Code for the error logged in MCA_DESTAT.

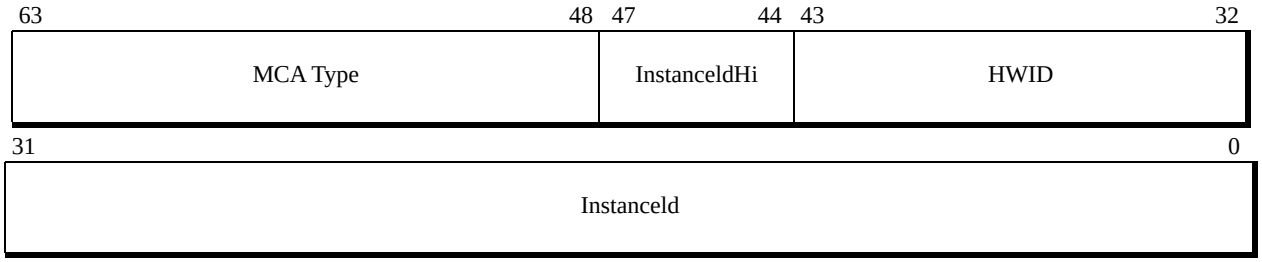
DeferredIntTypeSupported—Bit 5. 1=MCA_CONFIG[DeferredIntType] controls the type of interrupt generated on a deferred error. Deferred errors are supported in this bank only if MCA_CONFIG[DeferredLoggingSupported]=1.

DeferredLoggingSupported—Bit 2. 1= MCA_CONFIG[LogDeferredEn] in this bank controls the logging behavior for deferred errors. 0= MCA_CONFIG[LogDeferredEn] is not supported.

MCAX—Bit 0. MCAX: Set by hardware. This MCA bank provides Machine Check Architecture Extensions.

9.3.3.2 MCA IP Identification

This register holds information which identifies the specific bank type: the McaType value, HWID, and the InstanceID. By providing those values as part of the MCA, the bank type information is available to the machine check handler for parsing and for diagnosis.



Bits	Mnemonic	Description	R/W
63:48	McaType	MCA bank type.	RW
47:44	InstanceIdHi	The high bits of the Instance ID.	RW
43:32	Hwid	Hardware ID value.	RW
31:0	InstanceID	The low bits of the Instance ID.	RW

Figure 9-12. MCA_IPID Register

McaType—Bits 63:48. MCA bank type. This field is used to identify the MCA bank type in conjunction with MCA_IPID[Hwid]. For more information, see the Processor Programming Reference Manual applicable to your product.

InstanceIdHi—Bits 47:44. The high bits of the Instance identification for the MCA bank. This field is used to identify the MCA bank instance in conjunction with MCA_IPID[InstanceId]. For more information, see the Processor Programming Reference Manual applicable to your product.

Hwid—Bits 43:32. MCA bank hardware identification. For more information, see the Processor Programming Reference Manual applicable to your product.

InstanceId—Bits 31:0. The Instance identification for the MCA bank. This field is used to identify the MCA bank instance.

9.3.3.3 MCA Syndrome Register

The MCA_SYND register stores a syndrome associated with the error logged in MCA_STATUS or MCA_DESTAT. The “syndrome” may include syndrome values associated with an error correcting code or other information about the error. The contents of this register are valid if MCA_STATUS[SYNDV] bit is set to 1 or MCA_DESTAT[SYNDV] bit is set to 1.

The format and contents of this register are implementation dependent. For more information, see the Processor Programming Reference Manual applicable to your product.

9.3.3.4 MCA Deferred Error Status Register

This register holds status information for deferred errors. This register ensures that software will see a deferred error, even when a later error of higher severity occurs.

If the error being logged is a deferred error, then the error will be logged to MCA_DESTAT. See Section 9.3.2.4, “Machine-Check Status Registers,” on page 299 for more detailed descriptions of the register fields.

When the deferred error has been processed by the deferred error handler, MCA_DESTAT should be cleared. If MCA_STATUS also contains a deferred error, MCA_STATUS should be cleared.

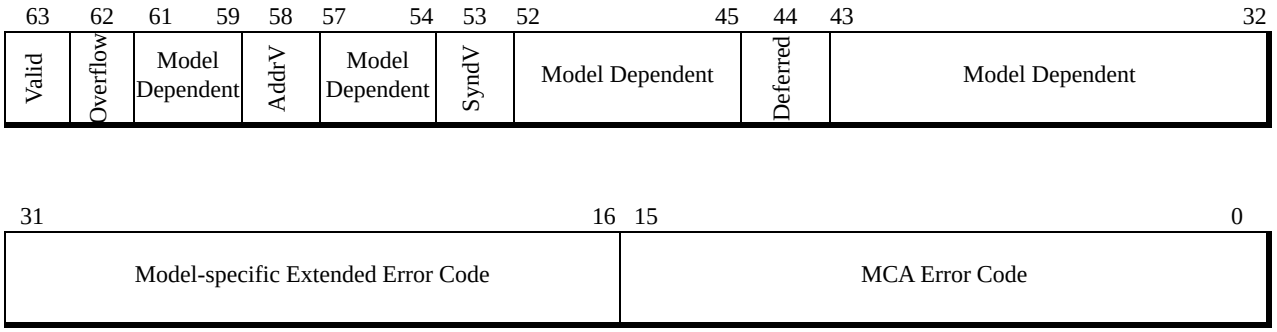


Figure 9-13. MCA_DESTAT Register

Bits	Mnemonic	Description	R/W
63	Valid	A valid error is contained in this register.	R/W
62	Overflow	One or more deferred errors was not logged.	R/W
61:59		Model Dependent.	
58	AddrV	An address is contained in MCA_DEADDR.	R/W
57:54		Model Dependent.	
53	SyndV	Syndrome valid. MCA_SYND contains error syndrome information associated with this deferred error.	R/W
52:45		Model Dependent.	
44	Deferred	Error is a deferred error.	R/W
43:32		Model Dependent.	
31:16	Model-Specific Extended Error Code	This field encodes model-specific information about the error. Valid if MCA_CONFIG[DeStatErrCodeSupported]=1, else Reserved.	R/W
15:0	MCA Error Code	This field encodes information about the error logged in MCA_DESTAT. Valid if MCA_CONFIG[DeStatErrCodeSupported]=1, else Reserved.	R/W

9.3.3.5 MCA Deferred Error Address Register

The MCA_DEADDR register provides the address associated with an error logged in MCA_DESTAT.

The format of this register is the same as MCA_ADDR.

The register is only meaningful if MCA_DESTAT[Valid]=1 and MCA_DESTAT[ADDRV]=1.

9.3.3.6 MCA Miscellaneous Registers 1 - 4

Set by hardware.

The format of MCA_MISC[4-1] is the same as the format of MCA_MISC0.

9.3.3.7 MCA Syndrome Registers 1 - 2

The MCA_SYND[2-1] registers store information associated with the error in MCA_STATUS or MCA_DESTAT. The contents of these registers are valid if MCA_STATUS[SYNDV] is set or MCA_DESTAT[SYNDV] is set.

The format and contents of this register is implementation dependent. For more information, see the Processor Programming Reference Manual applicable to your product.

9.4 Initializing the Machine-Check Mechanism

Following a processor reset, all machine-check error-reporting enable bits are disabled. System software must enable these bits before machine-check errors can be reported. Generally, system software should initialize the machine-check mechanism using the following process:

- Execute the CPUID instruction and verify that the processor supports the machine-check exception (MCE) and machine-check registers (MCA). Software should not proceed with initializing the machine-check mechanism if the machine-check registers are not supported.
- If the machine-check registers are supported, system software should take the following steps:
  - Check to see if the CTLP bit in the MCG_CAP register is set to 1. If it is, then the MCG_CTL register is supported by the processor. If the MCG_CTL register is supported, software should set its enable bits to 1 for the machine-check features it uses. Software can load MCG_CTL with all 1s to enable all available machine-check reporting banks.
  - Read the COUNT field from the MCG_CAP register to determine the number of error-reporting register banks supported by the processor. For each error-reporting register bank, software should set the enable bits to 1 in the MC*i*_CTL register for the error types it wants the processor to report. Software can write each MC*i*_CTL with all 1s to enable all error-reporting mechanisms.

    Not enabling reporting banks that may be involved in the reporting of uncorrected errors can lead to the loss of system reliability and error recoverability.
  - Check the VAL bit on each implemented MC*i*_STATUS register. It is possible that valid error-status information has already been logged in the MC*i*_STATUS registers at the time software is attempting to initialize them. The status can reflect errors logged prior to a warm reset or errors recorded during the system power-up and boot process. Before clearing the MC*i*_STATUS registers, software should examine their contents and log any errors found.
  - After saving any valid error information contained in the MC*i*_STATUS, MC*i*_ADDR, and any implemented miscellaneous error information registers for each implemented reporting bank, software should clear all status fields in the MC*i*_STATUS register for each bank by writing all 0s to the register.
- As a final step in the initialization process, system software should enable the machine-check exception by setting CR4[MCE] to 1.

A machine-check condition that occurs while CR4[MCE] is cleared will result in the processor core entering the shutdown state.

9.5 Using MCA Features

System software can detect and handle logged errors using three methods:

1. Polling

   Software can periodically examine the machine-check status registers for errors, and save any error information found. Uncorrected errors found during polling will require some type of immediate response to initiate recovery or shutdown.

2. Enabling machine-check reporting

   When reporting is enabled, any uncorrected error that occurs causes control to be transferred to the machine-check exception handler. The exception handler can be designed for a specific processor implementation or can be generalized to work on multiple implementations.

3. Setting up and enabling interrupts for deferred and corrected errors

   In many implementations, MCA hardware can be configured to generate an interrupt hardware on the detection of a deferred error or when a programmed corrected error threshold is reached.

These methods are not mutually exclusive.

9.5.1 Determining the Scope of Detected Errors

Table 9-4 details the actions that recovery software should take and the level of recovery possible based on status information returned in the MCi_STATUS and MCG_STATUS registers.

Table 9-4. Error Scope

MC*i*_STATUS				Error Scope
PCC	TCC	UC	Deferred	
1	—	1	—	System fatal error. Error has corrupted the processor core architectural state. System processing must be terminated.
0	0	1	—	Recoverable error. If software can correct the error, the interrupted program can be resumed.
0	1	1	—	Containable error. The interrupted instruction stream cannot be resumed. System-level recovery may be possible if software can localize the error and terminate any affected software processes.
0	0	0	1	Deferred error. Immediate software action is not required. A latent error has been discovered, but not yet consumed. Error handling software may attempt to correct this data error, or prevent access by processes which map the data, or make the physical resource containing the data inaccessible.
0	0	0	0	Hardware corrected error. No software action is required. Error information should be saved for analysis.

9.5.2 Handling Machine Check Exceptions

The processor uses the interrupt control-transfer mechanism to invoke an exception handler after a machine-check exception occurs. This requires system software to initialize the interrupt-descriptor table (IDT) with either an interrupt gate or a trap gate that references the interrupt handler. See “Legacy Protected-Mode Interrupt Control Transfers” on page 261 and “Long-Mode Interrupt Control Transfers” on page 272 for more information on interrupt control transfers.

At a minimum, the machine-check exception handler must be capable of logging errors for later examination. This can be a sufficient implementation for some handlers. More thorough exception-handler implementations can analyze the error to determine if it is unrecoverable, and whether it can be recovered in software.

Machine-check exception handlers that attempt recovery must be thorough in their analysis and their corrective actions. The following guidelines should be used when writing such a handler:

- The status registers in all the enabled error-reporting register banks must be examined to identify the cause of the machine-check exception. Read the COUNT field from MCG_CAP to determine the number of status registers supported by the processor.
- Check the valid bit in each status register (MC*i*_STATUS[VAL]). The MC*i*_STATUS register does not need to be examined when its valid bit is clear.
- Check the valid MC*i*_STATUS registers to see if error recovery is possible. Error recovery is not possible when:
  - The processor-context corrupt bit (MC*i*_STATUS[PCC]) is set to 1.
  - The error-overflow status bit (MC*i*_STATUS[OVER]) is set and the processor does not support recoverable MC*i*_STATUS overflow (as indicated by feature bit CPUID Fn8000_0007_EBX[McaOverflowRecov] = 0).
  - The processor does not support Machine Check Recovery as indicated by feature bit CPUID Fn8000_0007_EBX[SUCCOR].

  If error recovery is not possible, the handler should log the error information and return to the system software responsible for shutting down the processor core.
- Check the MC*i*_STATUS[UC] bit to see if the processor corrected the error. If UC is set, the processor did not correct the error and the exception handler must correct the error before restarting the interrupted program.
  - If MCA Recovery is supported:
    - Check MCA_STATUS[TCC].
    - If TCC is set, the context of the process executing on the interrupted thread may be corrupt and the thread cannot be recovered. The rest of the system is unaffected; it is possible to terminate only the affected process thread.
    - If TCC is clear, the context of the process thread executing on the interrupted logical core is not corrupt. Recovery of the process thread may be possible, but only if the uncorrected error condition is first corrected by software; otherwise, the interrupted process thread must be terminated.

If the handler cannot correct the error or the MCG_STATUS[RIPV] bit is cleared, it should not return control to the interrupted program, but should log the error information and terminate the software process that was about to consume the uncorrected data. If the error has compromised the state of a guest operating system, the guest should be restarted. If the state of the virtual machine has been corrupted, the virtual machine must be reinitialized.

- When identifying the error condition, portable exception handlers should examine only the architecturally defined fields of the MC*i*_STATUS register.
- If the MCG_STATUS[RIPV] bit is set, the interrupted program can be restarted reliably at the instruction pointer address pushed onto the exception handler stack. If RIPV = 0, the interrupted program cannot be restarted reliably at that location, although it can be restarted at that location for debugging purposes.
- When logging errors, particularly those that are not recoverable, check the MCG_STATUS[EIPV] bit to see if the instruction-pointer address pushed onto the exception handler stack is related to the process thread interrupted by the machine-check exception. If EIPV = 0, the address is not guaranteed to be related to the interrupted process thread.
- Before exiting the machine-check handler, clear the MCG_STATUS[MCIP] bit. MCIP indicates a machine-check exception occurred. If this bit is set when another machine-check exception occurs, the processor enters the shutdown state.
- When an exception handler is able to, at a minimum, successfully log an error condition, the MC*i*_STATUS registers should be cleared before exiting the machine-check handler. Software is responsible for clearing at least the MC*i*_STATUS[VAL] bits.
- Additional machine-check exception-handler portability can be added by having the handler use the CPUID instruction to identify the processor and its capabilities. Implementation-specific software can be added to the machine-check exception handler based on the processor information reported by CPUID.

9.5.3 Reporting Corrected Errors

Machine-check exceptions do not occur if the error is corrected by the processor. If system software wishes to detect and save information concerning corrected machine-check errors, a system-service routine must be provided to check the contents of the machine-check status registers for corrected errors. The service routine can be invoked by system software on a periodic basis, or by an error-thresholding interrupt.

A service routine that gathers error information for corrected errors should perform the following:

- Examine the status register (MC*i*_STATUS) in each of the enabled error-reporting register banks. For each MC*i*_STATUS register with a set valid bit (VAL=1), the service routine should:
  - Save the contents of the MC*i*_STATUS register.
  - Save the contents of the corresponding MC*i*_ADDR register if MC*i*_STATUS[ADDRV] = 1.
  - Save the contents of the corresponding MC*i*_MISC register if MC*i*_STATUS[MISCV] = 1.

- Once the information found in the error-reporting register banks is saved, the MC*i*_STATUS register should be cleared. This allows the processor to properly report any subsequent errors in the MC*i*_STATUS registers.
- The service routine can save the time-stamp counter with each error logged. This can help in determining how frequently errors occur. For further information, see “Time-Stamp Counter” on page 407.
- In multiprocessor configurations, the service routine can save the processor-node identifier. This can help locate a failing multiprocessor-system component, which can then be isolated from the rest of the system. For further information, see the documentation for particular implementations of the architecture.

10 System-Management Mode

System-management mode (SMM) is an operating mode designed for system-control activities like power management. Normally, these activities are transparent to conventional operating systems and applications. SMM is used by platform firmware and specialized low-level device drivers, rather than the operating system.

The SMM interrupt-handling mechanism differs substantially from the standard interrupt-handling mechanism described in Chapter 8, “Exceptions and Interrupts.” SMM is entered using a special external interrupt called the *system-management interrupt* (SMI). After an SMI is received by the processor, the processor saves the processor state in a separate address space, called *SMRAM*. The SMM-handler software and data structures are also located in the SMRAM space. Interrupts and exceptions that ordinarily cause control transfers to the operating system are disabled when SMM is entered. The processor exits SMM, restores the saved processor state, and resumes normal execution by using a special instruction, *RSM*.

In SMM, address translation is disabled and addressing is similar to real mode. SMM programs can address up to 4 Gbytes of physical memory. See “SMM Operating-Environment” on page 327 for additional information on memory addressing in SMM.

The following sections describe the components of the SMM mechanism:

- *“SMM Resources” on page 318*—this section describes SMRAM, the SMRAM save-state area used to hold the processor state, and special SMRAM save-state entries used in support of SMM.
- *“Using SMM” on page 327*—this section describes the mechanism of entering and exiting SMM. It also describes SMM memory allocation, addressing, and interrupts and exceptions.

Of these mechanisms, only the format of the SMRAM save-state area differs between the AMD64 architecture and the legacy architecture.

Note: *Model-independent aspects of SMM operation are described here; see the BIOS and Kernel Developer’s Guide (BKDG) or Processor Programming Reference Manual of a given processor family for possible model-specific details.*

10.1 SMM Differences

There are functional differences between the SMM support in the AMD64 architecture and the SMM support found in previous architectures. These are:

- The SMRAM state-save area layout is changed to hold the 64-bit processor state.
- The initial processor state upon entering SMM is expanded to reflect the 64-bit nature of the processor.
- New conditions exist that can cause a processor shutdown while in SMM.

- The auto-halt restart and I/O-instruction restart entries in the SMRAM state-save area are one byte each instead of two bytes each.
- SMRAM caching considerations are modified because the legacy FLUSH# external signal (writeback, if modified, and invalidate) is not supported on implementations of the AMD64 architecture.
- Some previous AMD x86 processors saved and restored the CR2 register in the SMRAM state-save area. This register is not saved by the SMM implementation in the AMD64 architecture. SMM handlers that save and restore CR2 must perform the operation in software.

10.2 SMM Resources

The SMM resources supported by the processor consist of SMRAM, the SMRAM state-save area, and special entries within the SMRAM state-save area. In addition to the save-state area, SMRAM includes space for the SMM handler.

10.2.1 SMRAM

SMRAM is the memory-address space accessed by the processor when in SMM. The default size of SMRAM is 64 Kbytes and can range in size between 32 Kbytes and 4 Gbytes. System logic can use physically separate SMRAM and main memory, directing memory transactions to SMRAM after recognizing SMM is entered, and redirecting memory transactions back to system memory after recognizing SMM is exited. When separate SMRAM and main memory are used, the system designer needs to provide a method of mapping SMRAM into main memory so that the SMI handler and data structures can be loaded.

Figure 10-1 on page 319 shows the default SMRAM memory map. The default SMRAM code-segment (CS) has a base address of 0003_0000h (the base address is automatically scaled by the processor using the CS-selector register, which is set to the value 3000h). This default SMRAM-base address is known as *SMBASE*. A 64-Kbyte memory region, addressed from 0003_0000h to 0003_FFFFh, makes up the default SMRAM memory space. The top 32 Kbytes (0003_8000h to 0003_FFFFh) must be supported by system logic, with physical memory covering that entire address range. The top 512 bytes (0003_FE00h to 0003_FFFFh) of this address range are the default *SMM state-save area*. The default entry point for the SMM interrupt handler is located at 0003_8000h.

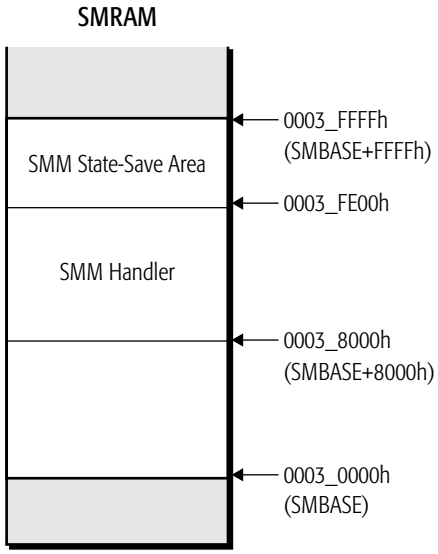

Figure 10-1. Default SMRAM Memory Map

10.2.2 SMBASE Register

The format of the SMBASE register is shown in Figure 10-2. SMBASE is an internal processor register that holds the value of the SMRAM-base address. SMBASE is set to 30000h after a processor reset.

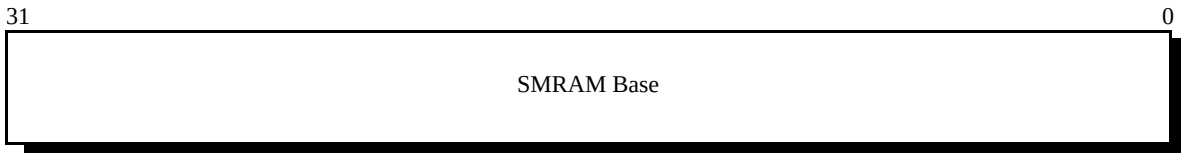

Figure 10-2. SMBASE Register

In some operating environments, relocation of SMRAM to a higher memory area can provide more low memory for legacy software. SMBASE relocation is supported when the SMM-base relocation bit in the SMM-revision identifier (bit 17) is set to 1. In processors implementing the AMD64 architecture, SMBASE relocation is always supported.

Software can only modify SMBASE (relocate the SMRAM-base address) by entering SMM, modifying the SMBASE image stored in the SMRAM state-save area, and exiting SMM. The SMM-

handler entry point must be loaded at the new memory location specified by SMBASE+8000h. The next time SMM is entered, the processor saves its state in the new state-save area at SMBASE+0FE00h, and begins executing the SMM handler at SMBASE+8000h. The new SMBASE address is used for every SMM until it is changed, or a hardware reset occurs.

When SMBASE is used to relocate SMRAM to an address above 1 Mbyte, 32-bit address-size-override prefixes must be used to access this memory. This is because addressing in SMM behaves as it does in real mode, with a 16-bit default operand size and address size. The values in the 16-bit segment-selector registers are left-shifted four bits to form a 20-bit segment-base address. Without using address-size overrides, the maximum computable address is 10FFEFh.

Because SMM memory-addressing is similar to real-mode addressing, the SMBASE address must be less than 4 Gbytes.

10.2.3 SMRAM State-Save Area

When an SMI occurs, the processor saves its state in the 512-byte SMRAM state-save area during the control transfer into SMM. The format of the state-save area defined by the AMD64 architecture is shown in Table 10-1. This table shows the offsets in the SMRAM state-save area relative to the SMRAM-base address. The state-save area is located between offset 0_FE00h (SMBASE+0_FE00h) and offset 0_FFFFh (SMBASE+0_FFFFh). Software should not modify offsets specified as read-only or reserved, otherwise unpredictable results can occur.

Table 10-1. AMD64 Architecture SMM State-Save Area

Offset (Hex) from SMBASE	Contents		Size	Allowable Access
FE00h	ES	Selector	Word	Read-Only
FE02h		Attributes	Word	
FE04h		Limit	Doubleword

Note:
1. *The offset for the SMM-revision identifier is compatible with previous implementations.*

10.2.4 SMM-Revision Identifier

The SMM-revision identifier specifies the SMM version and the available SMM extensions implemented by the processor. Software reads the SMM-revision identifier from offset FEFCh in the SMM state-save area of SMRAM. This offset location is compatible with earlier versions of SMM. Software must not write to this location. Doing so can produce undefined results. Figure 10-3 on page 325 shows the format of the SMM-revision identifier.

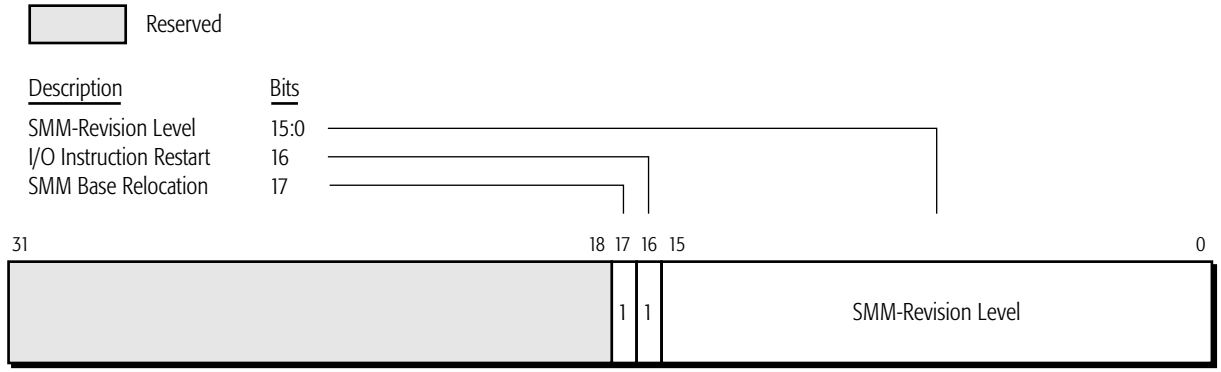

Figure 10-3. SMM-Revision Identifier

The fields within the SMM-revision identifier are:

- *SMM-revision Level*—Bits 15:0. Specifies the version of SMM supported by the processor. The SMM-revision level is of the form 0_xx64h, where *xx* starts with 00 and is incremented for later revisions to the SMM mechanism.
- *I/O Instruction Restart*—Bit 16. When set to 1, the processor supports restarting I/O instructions that are interrupted by an SMI. This bit is always set to 1 by implementations of the AMD64 architecture. See "I/O Instruction Restart" on page 331 for information on using this feature.
- *SMM Base Relocation*—Bit 17. When set to 1, the processor supports relocation of SMRAM. This bit is always set to 1 by implementations of the AMD64 architecture. See "SMBASE Register" on page 319 for information on using this feature.

All remaining bits in the SMM-revision identifier are reserved.

10.2.5 SMRAM Protected Areas

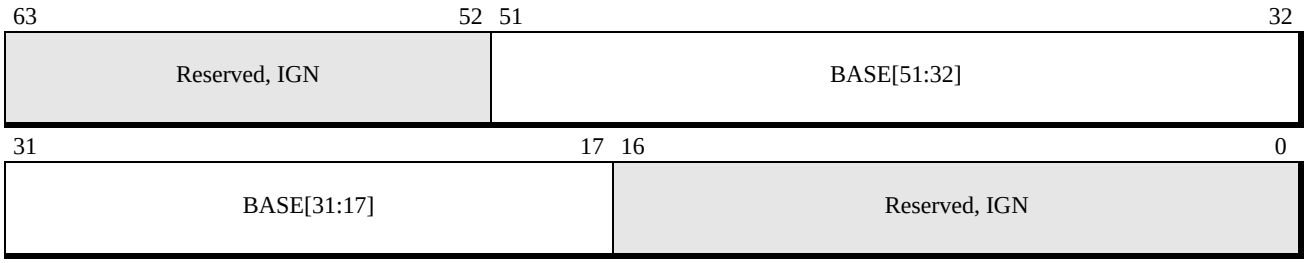
Two areas are provided as safe areas for SMM code and data that are not readily accessible by non-SMM applications. The SMI handler can be located in one of these two ranges, or it can be located outside of these ranges. The handler is placed in the desired range by setting SMBASE accordingly.

The ASeg range is located at a fixed address from A_0000h to B_FFFFh. The TSeg range is located at a variable base specified by the SMM_ADDR MSR with a variable size specified by the SMM_MASK MSR. These ranges must never overlap.

Each CPU memory access is in the TSeg range if the following is true:

Phys Addr[51:17] & SMM_MASK[51:17] = SMM_ADDR[51:17] & SMM_MASK[51:17].

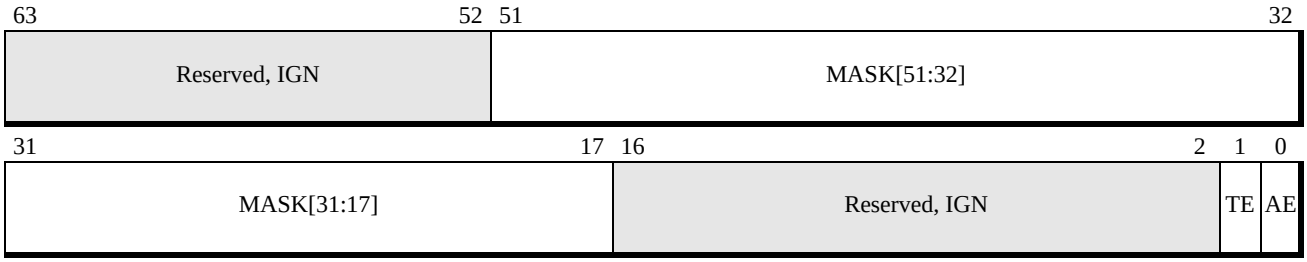
For example, if the TSeg range spans 256 Kbytes starting at address 10_0000h, then SMM_ADDR =0010_0000h and SMM_MASK=FFFC_0000h. This results in a TSeg address range from 0010_0000 to 0013_FFFFh. The TSeg range must be aligned to a 128 Kbyte boundary and the minimum TSeg size is 128 Kbytes.



Bits	Mnemonic	Description	R/W
63:52	Reserved	Reserved, Ignore	
51:17	BASE	SMM TSeg Base Address	R/W
16:0	Reserved	Reserved, Ignore	

Figure 10-4. SMM_ADDR Register Format

- *SMM TSeg Base Address (BASE)*—Bits 51:17. Specifies the base address of the TSeg range of protected addresses.



Bits	Mnemonic	Description	R/W
63:52	Reserved	Reserved, Ignore	
51:17	MASK	TSeg Mask	R/W
16:2	Reserved	Reserved, Ignore	
1	TE	Tseg Address Range Enable	R/W
0	AE	Aseg Address Range Enable	R/W

Figure 10-5. SMM_MASK Register Format

- *ASeg Address Range Enable (AE)*—Bit 0. Specifies whether the ASeg address range is enabled for protection. When the bit is set to 1, the ASeg address range is enabled for protection. When cleared to 0, the ASeg address range is disabled for protection.

- *TSeg Address Range Enable (TE)*—Bit 1. Specifies whether the TSeg address range is enabled for protection. When the bit is set to 1, the TSeg address range is enabled for protection. When cleared to 0, the TSeg address range is disabled for protection.
- *TSeg Mask (MASK)*—Bits 51:17. Specifies the mask used to determine the TSeg range of protected addresses. The physical address is in the TSeg range if the following is true:

  Phys Addr[51:17] & SMM_MASK[51:17] = SMM_ADDR[51:17] & SMM_MASK[51:17].

Note that a processor is not required to implement all 52 bits of the physical address.

10.3 Using SMM

10.3.1 System-Management Interrupt (SMI)

SMM is entered using the system-management interrupt (SMI). SMI is an external non-maskable interrupt that operates differently from and independently of other interrupts. SMI has priority over all other external interrupts, including NMI (see “Priorities” on page 255 for a list of the interrupt priorities). SMIs are disabled when in SMM, which prevents reentrant calls to the SMM handler.

When an SMI is received by the processor, the processor stops fetching instructions and waits for currently-executing instructions to complete and write their results. The SMI also waits for all buffered memory writes to update the caches or system memory. When these activities are complete, the processor uses implementation-dependent external signaling to acknowledge back to the system that it has received the SMI.

10.3.2 SMM Operating-Environment

The SMM operating-environment is similar to real mode, except that the segment limits in SMM are 4 Gbytes rather than 64 Kbytes. This allows an SMM handler to address memory in the range from 0h to 0FFFF_FFFFh. As with real mode, segment-base addresses are restricted to 20 bits in SMM, and the default operand-size and address-size is 16 bits. To address memory locations above 1 Mbyte, the SMM handler must use the 32-bit operand-size-override and address-size-override prefixes.

After saving the processor state in the SMRAM state-save area, a processor running in SMM sets the segment-selector registers and control registers into a state consistent with real mode. Other registers are also initialized upon entering SMM, as shown in Table 10-3.

Table 10-3. SMM Register Initialization

Register		Initial SMM Contents
CS	Selector	SMBASE right-shifted 4 bits
	Base	SMBASE
	Limit	FFFF_FFFFh
	Attr	Read-Write-Execute

Table 10-3. SMM Register Initialization (continued)

Register		Initial SMM Contents
DS, ES, FS, GS, SS	Selector	0000h
	Base	0000_0000_0000_0000h
	Limit	FFFF_FFFFh
	Attr	Read-Write
RIP		0000_0000_0000_8000h
RFLAGS		0000_0000_0000_0002h
CR0		PE, EM, TS, PG bits cleared to 0. All other bits are unmodified.
CR4		0000_0000_0000_0000h
DR7		0000_0000_0000_0400h
EFER		0000_0000_0000_0000h

10.3.3 Exceptions and Interrupts

All hardware interrupts are disabled upon entering SMM, but exceptions and software interrupts are not disabled. If necessary, the SMM handler can re-enable hardware interrupts. Software that handles interrupts in SMM should consider the following:

- *SMI*—If an SMI occurs while the processor is in SMM, it is latched by the processor. The latched SMI occurs when the processor leaves SMM.
- *NMI*—If an NMI occurs while the processor is in SMM, it is latched by the processor, but the NMI handler is not invoked until the processor leaves SMM with the execution of an RSM instruction. A pending NMI causes the handler to be invoked immediately after the RSM completes and before the first instruction in the interrupted program is executed.

  An SMM handler can unmask NMI interrupts by simply executing an IRET. Upon completion of the IRET instruction, the processor recognizes the pending NMI, and transfers control to the NMI handler. Once an NMI is recognized within SMM using this technique, subsequent NMIs are recognized until SMM is exited. Later SMIs cause NMIs to be masked, until the SMM handler unmasks them.
- *Exceptions*—Exceptions (internal processor interrupts) are not disabled and can occur while in SMM. Therefore, the SMM-handler software should be written to avoid generating exceptions.
- *Software Interrupts*—The software-interrupt instructions (BOUND, INT*n*, INT3, and INTO) can be executed while in SMM. However, it is not recommended that the SMM handler use these instructions.
- *Maskable Interrupts*—RFLAGS.IF is cleared to 0 by the processor when SMM is entered. Software can re-enable maskable interrupts while in SMM, but it must follow the guidelines listed below for handling interrupts.
- *Debug Interrupts*—The processor disables the debug interrupts when SMM is entered by clearing DR7 to 0 and clearing RFLAGS.TF to 0. The SMM handler can re-enable the debug facilities while in SMM, but it must follow the guidelines listed below for handling interrupts.

- *INIT*—The processor does not recognize INIT while in SMM.

Because the RFLAGS.IF bit is cleared when entering SMM, the HLT instruction should not be executed in SMM without first setting the RFLAGS.IF bit to 1. Setting this bit to 1 allows the processor to exit the halt state by using an external maskable interrupt.

In the cases where an SMM handler must accept and handle interrupts and exceptions, several guidelines must be followed:

- Interrupt handlers must be loaded and accessible before enabling interrupts.
- A real-mode interrupt vector table located at virtual (linear) address 0 is required.
- Segments accessed by the interrupt handler cannot have a base address greater than 20 bits because of the real-mode addressing used in SMM. In SMM, the 16-bit value stored in the segment-selector register is left-shifted four bits to form the 20-bit segment-base address, like real mode.
- Only the IP (rIP[15:0]) is pushed onto the stack as a result of an interrupt in SMM, because of the real-mode addressing used in SMM. If the SMM handler is interrupted at a code-segment offset above 64 Kbytes, then the return address on the stack must be adjusted by the interrupt-handler, and a RET instruction with a 32-bit operand-size override must be used to return to the SMM handler.
- If the interrupt-handler is located below 1 Mbyte, and the SMM handler is located above 1 Mbyte, a RET instruction cannot be used to return to the SMM handler. In this case, the interrupt handler can adjust the return pointer on the stack, and use a far CALL to transfer control back to the SMM handler.

10.3.4 Invalidating the Caches

The processor can cache SMRAM-memory locations. If the system implements physically separate SMRAM and system memory, it is possible for SMRAM and system memory locations to alias into identical cache locations. In some processor implementations, the cache contents must be written to memory and invalidated when SMM is entered *and* exited. This prevents the processor from using previously-cached main-memory locations as aliases for SMRAM-memory locations when SMM is entered, and vice-versa when SMM is exited.

Implementations of the AMD64 architecture *do not require cache invalidation* when entering and exiting SMM. Internally, the processor keeps track of SMRAM and system-memory accesses separately and properly handles situations where aliasing occurs. Cached system memory and SMRAM locations can persist across SMM mode changes. Removal of the requirement to writeback and invalidate the cache simplifies SMM entry and exit and allows SMM code to execute more rapidly.

10.3.5 Saving Additional Processor State

Several registers are not saved or restored automatically by the SMM mechanism. These are:

- The 128-bit media instruction registers.
- The 64-bit media instruction registers.

- The x87 floating-point registers.
- The page-fault linear-address register (CR2).
- The task-priority register (CR8).
- The debug registers, DR0, DR1, DR2, and DR3.
- The memory-type range registers (MTRRs).
- Model-specific registers (MSRs).

These registers are not saved because SMM handlers do not normally use or modify them. If an SMI results in a processor reset (due to powering down the processor, for example) or the SMM handler modifies the contents of the unsaved registers, the SMM handler should save and restore the original contents of those registers. The unsaved registers, along with those stored in the SMRAM state-save area, need to be saved in a non-volatile storage location if a processor reset occurs. The SMM handler should execute the CPUID instruction to determine the feature set available in the processor, and be able to save and restore the registers required by those features. For more information on using the CPUID instruction, see Section 3.3, “Processor Feature Identification,” on page 71.

The SMM handler can execute any of the 128-bit media, 64-bit media, or x87 instructions. A simple method for saving and restoring those registers is to use the FXSAVE and FXRSTOR instructions, respectively, if it is supported by the processor. See “Saving Media and x87 Execution Unit State” on page 342 for information on saving and restoring those registers.

Floating-point exceptions can occur when the SMM handler uses media or x87 floating-point instructions. If the SMM handler uses floating-point exception handlers, they must follow the usage guidelines established in “Exceptions and Interrupts” on page 328. A simple method for dealing with floating-point exceptions while in SMM is to simply mask all exception conditions using the appropriate floating-point control register. When the exceptions are masked, the processor handles floating-point exceptions internally in a default manner, and allows execution to continue uninterrupted.

10.3.6 Operating in Protected Mode and Long Mode

Software can enable protected mode from SMM and it can also enable and activate long mode. An SMM handler can use this capability to enter 64-bit mode and save additional processor state that cannot be accessed from outside 64-bit mode (for example, the most-significant 32 bits of CR2).

10.3.7 Auto-Halt Restart

The auto-halt restart entry is located at offset FEC9h in the SMM state-save area. The size of this field is one byte, as compared with two bytes in previous versions of SMM.

When entering SMM, the processor loads the auto-halt restart entry to indicate whether SMM was entered from the halt state, as follows:

- Bit 0 indicates the processor state upon entering SMM:
  - When set to 1, the processor entered SMM from the halt state.

- When cleared to 0, the processor did not enter SMM from the halt state.

- Bits 7:1 are cleared to 0.

The SMM handler can write the auto-halt restart entry to specify whether the return from SMM should take the processor back to the halt state or to the instruction-execution state specified by the SMM state-save area. The values written are:

- *Clear to 00h*—The processor returns to the state specified by the SMM state-save area.
- *Set to any non-zero value*—The processor returns to the halt state.

If the return from SMM takes the processor back to the halt state, the HLT instruction is not re-executed. However, the halt special bus-cycle is driven on the processor bus after the RSM instruction executes.

The result of entering SMM from a non-halt state and returning to a halt state is not predictable.

10.3.8 I/O Instruction Restart

The I/O-instruction restart entry is located at offset FEC8h in the SMM state-save area. The size of this field is one byte, as compared with two bytes in previous versions of SMM. The I/O-instruction restart mechanism is supported when the I/O-instruction restart bit (bit 16) in the SMM-revision identifier is set to 1. This bit is always set to 1 in the AMD64 architecture.

When an I/O instruction is interrupted by an SMI, the I/O-instruction restart entry specifies whether the interrupted I/O instruction should be re-executed following an RSM that returns from SMM. Re-executing a trapped I/O instruction is useful, for example, when an I/O write is performed to a powered-down disk drive. When this occurs, the system logic monitoring the access can issue an SMI to have the SMM handler power-up the disk drive and retry the I/O write. The SMM handler does this by querying system logic and detecting the failed I/O write, asking system logic to initiate the disk-drive power-up sequence, enabling the I/O instruction restart mechanism, and returning from SMM. Upon returning from SMM, the I/O write to the disk drive is restarted.

When an SMI occurs, the processor always clears the I/O-instruction restart entry to 0. If the SMI interrupted an I/O instruction, then the SMM handler can modify the I/O-instruction restart entry as follows:

- *Clear to 00h (default value)*—The I/O instruction is not restarted, and the instruction following the interrupted I/O-instruction is executed. When a REP (repeat) prefix is used with an I/O instruction, it is possible that the next instruction to be executed is the next I/O instruction in the repeat loop.
- *Set to any non-zero value*—The I/O instruction is restarted.

While in SMM, the handler must determine the cause of the SMI and examine the processor state at the time the SMI occurred to determine whether or not an I/O instruction was interrupted. Implementations provide state information in the SMM save-state area to assist in this determination:

- I/O Instruction Restart DWORD—indicates whether the SMI interrupted an I/O instruction, and saves extra information describing the I/O instruction.

- I/O Instruction Restart RIP—the RIP of the interrupted I/O instruction.
- I/O Instruction Restart RCX—the RCX of the interrupted I/O instruction.
- I/O Instruction Restart RSI—the RSI of the interrupted I/O instruction.
- I/O Instruction Restart RDI—the RDI of the interrupted I/O instruction.

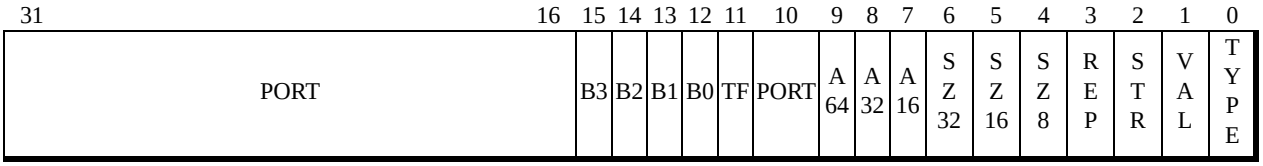


Figure 10-6. I/O Instruction Restart Dword

The fields in the I/O Instruction Restart DWORD are as follows:

- B3—DR6.B3 status
- B2—DR6.B2 status
- B1—DR6.B1 status
- B0 —DR6.B0 status
- TF—The I/O instruction was interrupted with Single Stepping (EFLAGS.TF = 1)
- PORT—Intercepted I/O port
- A64—64-bit address
- A32—32-bit address
- A16—16-bit address
- SZ32—32-bit I/O port size
- SZ16—16-bit I/O port size
- SZ8—8-bit I/O port size
- REP—Repeated port access
- STR—String based port access (INS, OUTS)
- VAL—Valid (SMI was detected during an I/O instruction.)
- TYPE—Access type (0 = OUT instruction, 1 = IN instruction).

10.3.9 SMM Page Configuration Lock

The SMM Page Configuration Lock feature allows the SMM handler to lock the paging configuration. The feature is enabled by setting HWCR.SMM_PGCFG_LOCK=1 (bit 33). Once locked, the paging configuration cannot be modified until SMM is exited using the RSM instruction. The processor clears HWCR.SMM_PGCFG_LOCK when completing the RSM instruction. If page configuration locking is needed when the processor enters SMM again in the future, HWCR.SMM_PGCFG_LOCK must be set again by the SMM handler.

When SMM Page Configuration Lock is enabled, the following will result in a #GP exception:

- Writing Extended Feature Register (EFER) using the WRMSR instruction.
- Writing CR0, CR3, or CR4 using the MOV CRn instruction.

Attempting to set HWCR.SMM_PGCFG_LOCK when not in SMM results in a #GP exception. Before setting HWCR.SMM_PGCFG_LOCK, system software must verify the processor supports the SMM Page Configuration Lock feature by checking that CPUID Fn8000_0021_EAX[SmmPgCfgLock] (bit 3) = 1. For more information on using the CPUID instruction see Section 3.3, “Processor Feature Identification,” on page 71.

10.4 Leaving SMM

Software leaves SMM and returns to the interrupted program by executing the RSM instruction. RSM causes the processor to load the interrupted state from the SMRAM state-save area and then transfer control back to the interrupted program. RSM cannot be executed in any mode other than SMM, otherwise an invalid-opcode exception (#UD) occurs.

An RSM causes a processor shutdown if an invalid-state condition is found in the SMRAM state-save area. Only an external reset, external processor-initialization, or non-maskable external interrupt (NMI) can cause the processor to leave the shutdown state. The invalid SMRAM state-save-area conditions that can cause a processor shutdown during an RSM are:

- CR0.PE=0 and CR0.PG=1.
- CR0.CD=0 and CR0.NW=1.
- Certain reserved bits are set to 1, including:
  - Any CR0 bit in the range 63:32 is set to 1.
  - Any unsupported bit in CR3 is set to 1.
  - Any unsupported bit in CR4 is set to 1.
  - Any DR6 bit or DR7 bit in the range 63:32 is set to 1.
  - Any unsupported bit in EFER is set to 1.
- Invalid returns to long mode, including:
  - EFER.LME=1, CR0.PG=1, and CR4.PAE=0.
  - EFER.LME=1, CR0.PG=1, CR4.PAE=1, CS.L=1, and CS.D=1.
- The SSM revision identifier is modified.

Some SMRAM state-save-area conditions are ignored, and the registers, or bits within the registers, are restored in a default manner by the processor. This avoids a processor shutdown when an invalid condition is stored in SMRAM. The default conditions restored by the processor are:

- The EFER.LMA register bit is set to the value obtained by logically ANDing the SMRAM values of EFER.LME, CR0.PG, and CR4.PAE.

- The RFLAGS.VM register bit is set to the value obtained by logically ANDing the SMRAM values of RFLAGS.VM, CR0.PE, and the inverse of EFER.LMA.
- The base values of FS, GS, GDTR, IDTR, LDTR, and TR are restored in canonical form. Those values are sign-extended to bit 63 using the most-significant implemented bit.
- Unimplemented segment-base bits in the CS, DS, ES, and SS registers are cleared to 0.
- SSP is canonicalized (i.e., sign-extended to bit 63).

10.5 Multiprocessor Considerations

For multiprocessor operation, each logical processor must be given a separate SMBASE value so that the save-state areas do not overlap. For systems with fewer than 64 logical processors it is sufficient to stagger the SMBASE values by 512 bytes. Note that this also offsets theSMI entry point by the same amount for each processor. With 64 or more logical processors, the entry points will start to collide with the save-state areas. Staggering the SMBASE values by 1024 bytes results in 512-byte entry point areas interleaved with the 512-byte state-save areas, and so provides scaling beyond 63 logical processors.

Further details on multiprocessor aspects of SMM may be found in the *BIOS and Kernel Developer's Guide (BKDG)* or *Processor Programming Reference Manual* for a given processor family.

11 SSE, MMX, and x87 Programming

This chapter describes the system-software implications of supporting applications that use the Streaming SIMD Extensions (SSE), MMX™, and x87 instructions. Throughout this chapter, these instructions are collectively referred to as *media and x87* (media/x87) instructions. A complete listing of the instructions that fall in this category—and the detailed operation of each instruction—can be found in volumes 4 and 5. Refer to Volume 1 for information on using these instructions in application software.

The SSE instruction set is comprised of the *legacy SSE* instruction set which includes the SSE1, SSE2, SSE3, SSSE3, SSE4A, SSE4.1, and SSE4.2 subsets and the *extended SSE* instruction set which includes the AVX, FMA4, and XOP subsets. Many of the extended SSE instructions support both 128-bit and 256-bit data types.

11.1 Overview of System-Software Considerations

Processor implementations can support different combinations of the SSE, MMX, and x87 instruction sets. Two sets of registers—independent of the general-purpose registers—support these instructions. The SSE instructions operate on the YMM/XMM registers, and the 64-bit media and x87-instructions operate on the aliased MMX/x87 registers. The SSE and x87 floating-point instruction sets have distinct status registers, control registers, exception vectors, and system-software control bits for managing the operating environment. System software that supports use of these instructions must be able to manage these resources properly including:

- Detecting support for the instruction set, and enabling any optional features, as necessary.
- Saving and restoring the processor media or x87 state.
- Execution of floating-point instructions (media or x87) can produce exceptions. System software must supply exception handlers for all unmasked floating-point exceptions.

11.2 Determining Media and x87 Feature Support

Support for the architecturally defined subsets within the media and x87 instructions is implementation dependent. System software executes the CPUID instruction to determine whether a processor implements any of these features (see Section 3.3, “Processor Feature Identification,” on page 71 for more information on using the CPUID instruction). After CPUID is executed feature support can be determined by examining specific bit fields returned in the EAX, ECX, and EDX registers.

The following table summarizes the architecturally defined SSE subsets and state management instructions and gives the feature bits returned by the CPUID function. If the indicated bit is set, the feature is supported by the processor.

Table 11-1. SSE Subsets – CPUID Feature Identifiers

CPUID Fn	Field Name	Field Bit	Instruction Subset
Legacy SSE			
0000_0001h	EDX[SSE]	EDX[25]	Original Streaming SIMD Extensions (SSE1)
0000_0001h	EDX[SSE2]	EDX[26]	SSE2
0000_0001h	ECX[SSE3]	ECX[0]	SSE3
0000_0001h	ECX[SSSE3]	ECX[9]	SSSE3
0000_0001h	ECX[SSE41]	ECX[19]	SSE4.1
0000_0001h	ECX[SSE42]	ECX[20]	SSE4.2
8000_0001h	ECX[SSE4A]	ECX[6]	SSE4A: EXTRQ, INSERTQ, MOVNTSS, and MOVNTSD instructions
Extended SSE			
0000_0001h	ECX[AVX]	ECX[28]	AVX
8000_0001h	ECX[XOP]	ECX[11]	AMD XOP
0000_0001h	ECX[FMA]	ECX[12]	FMA
8000_0001h	ECX[FMA4]	ECX[16]	AMD FMA4
MMX			
0000_0001h or 8000_0001h	EDX[MMX]	EDX[23]	Original MMX™ Instructions
8000_0001h	EDX[MmxExt]	EDX[22]	AMD Extensions to MMX
8000_0001h	EDX[3DNow]	EDX[31]	AMD 3DNow!™
8000_0001h	EDX[3DNowExt]	EDX[30]	AMD Extensions to 3DNow!
x87			
0000_0001h or 8000_0001h	EDX[FPU]	EDX[0]	x87 instruction set and facilities
Context Management Instructions			
0000_0001h or 8000_0001h	EDX[FXSR]	EDX[24]	FXSAVE / FXRSTOR instructions
8000_0001h	EDX[FFXSR]	EDX[25]	Hardware optimizations for FXSAVE / FXRSTOR
0000_0001h	ECX[XSAVE]	ECX[26]	XSAVE / XRSTOR instructions
0000_000Dh ECX=01h	EAX[XSAVEOPT]	EAX[0]	XSAVEOPT

Some instructions may be listed in more than one subset. If software attempts to execute an instruction belonging to an unsupported instruction subset, an invalid-opcode exception (#UD) occurs. Refer to Appendix D, “Instruction Subsets and CPUID Feature Flags” in Volume 3 for specific information.

11.3 Enabling SSE Instructions

Use of the 256-bit and 128-bit media instructions by application software requires system software support. System software must determine which SSE subsets are supported, enable those that are to be used, and supply code to handle the various exceptions that may occur during the execution of these instructions. The legacy SSE instructions and the extended SSE instructions often require unique exception handling.

11.3.1 Enabling Legacy SSE Instruction Execution

When legacy SSE instructions are supported, system software must set CR4.OSFXSR to let the processor know that the software supports the FXSAVE/FXRSTOR instructions. When the processor detects CR4.OSFXSR = 1, it allows execution of the legacy SSE instructions. If system software does not set CR4.OSFXSR, any attempt to execute these instructions causes an invalid-opcode exception (#UD). System software must also *clear* the CR0.EM (emulate coprocessor) bit to 0, otherwise an attempt to execute a legacy SSE instruction causes a #UD exception. An attempt to execute either FXSAVE or FXRSTOR when CR0.EM is set results in a #NM exception.

System software should also *set* the CR0.MP (monitor coprocessor) bit to 1. When CR0.EM=0 and CR0.MP=1, all media instructions, x87 instructions, and the FWAIT/WAIT instructions cause a device-not-available exception (#NM) when the CR0.TS bit is set. System software can use the #NM exception to perform lazy context switching, saving and restoring media and x87 state only when necessary after a task switch. See “CR0 Register” on page 42 for more information.

11.3.2 Enabling Extended SSE Instruction Execution

After the steps specified above are completed to enable legacy SSE instruction execution, additional steps are required to enable the extended SSE instructions and state management. System software must carry out the following process:

- Confirm that the hardware supports the XSAVE, XRSTOR, XSETBV, and XGETBV instructions and the XCR0 register (XFEATURE_ENABLED_MASK) by executing the CPUID instruction function 0000_0001h. If CPUID Fn0000_0001_ECX[XSAVE] is set, hardware support is verified.
- Optionally confirm hardware support of the XSAVEOPT instruction by executing CPUID function 0000_000Dh, sub-function 1 (ECX = 1). If CPUID Fn0000_000D_EAX_x1[XSAVEOPT] is set, the processor supports the XSAVEOPT instruction. XSAVEOPT is a performance optimized version of XSAVE.
- Confirm that hardware supports the extended SSE instructions by verifying XFeatureSupportedMask[2:0] = 111b. XFeatureSupportedMask is accessed via the CPUID instruction function 0000_000Dh, sub-function 0 (ECX = 0). XFeatureSupportedMask[31:0] is returned in the EAX register.

  If CPUID Fn0000_000D_EAX_x0[2:0] = 111b, hardware supports x87, legacy SSE, and extended SSE instructions. Bit 0 of EAX signifies x87 floating-point and MMX support, bit 1 signifies legacy SSE support, and bit 2 signifies extended SSE support. Support for both x87 and legacy SSE instructions are required for processors that support the extended SSE instructions.

- Set CR4[OSXSAVE] (bit 18) to enable the use of the XSETBV and XGETBV instructions. XSETBV is a privileged instruction that writes the XCRn registers. XCR0 is the XFEATURE_ENABLED_MASK used to manage media and x87 processor state using the XSAVE, XSAVEOPT, and XRSTOR instructions.
- Enable the x87/MMX, legacy SSE, and extended SSE instructions and processor state management by setting the x87, SSE, and YMM bits of XCR0 (XFEATURE_ENABLED_MASK). This is done via the privileged instruction XSETBV. Enabling extended SSE capabilities without enabling legacy SSE capabilities is not allowed. The x87 flag (bit 0) of the XFEATURE_ENABLED_MASK must be set when writing XCR0.
- Determine the XSAVE/XRSTOR memory save area size requirement. The field XFeatureEnabledSizeMax specifies the size requirement in bytes based on the currently enabled extended features and is returned in the EBX register after execution of CPUID Function 0000_000Dh, sub-function 0 (ECX = 0).
- Allocate the save/restore area based on the information obtained in the previous step.

For a detailed description of the XSETBV and XGETBV instructions, see individual instruction reference pages in Volume 4. See the section entitled “XFEATURE_ENABLED_MASK” in Volume 4 for details on the field definitions for XFEATURE_ENABLED_MASK.

For more information on using the CPUID instruction to obtain processor feature information, see Section 3.3, “Processor Feature Identification,” on page 71.

11.3.3 SIMD Floating-Point Exception Handling

System software must supply an exception handler if unmasked SSE floating-point exceptions are allowed to occur. When an unmasked exception is detected, the processor transfers control to the SIMD floating-point exception (#XF) handler provided by the operating system. System software must let the processor know that the #XF handler is available by setting CR4.OSXMMEXCPT to 1. If this bit is set to 1, the processor transfers control to the #XF handler when it detects an unmasked exception, otherwise a #UD exception occurs. When the processor detects a masked exception, it handles it in a default manner regardless of the CR4.OSXMMEXCPT value.

11.4 Media and x87 Processor State

The media and x87 processor state includes the contents of the registers used by SSE, MMX, and x87 instructions. System software that supports such applications must be capable of saving and restoring these registers.

11.4.1 SSE Execution Unit State

Figure 11-1 shows the registers whose contents are affected by execution of SSE instructions. These include:

- YMM/XMM0–15—Sixteen 256-bit/128-bit SSE registers. In legacy and compatibility modes, software access is limited to the first eight registers.

- MXCSR—The 32-bit Media eXtensions Control and Status Register.

All of these registers are visible to application software. Refer to “Streaming SIMD Extensions Media and Scientific Programming” in Volume 1 for more information on these registers.

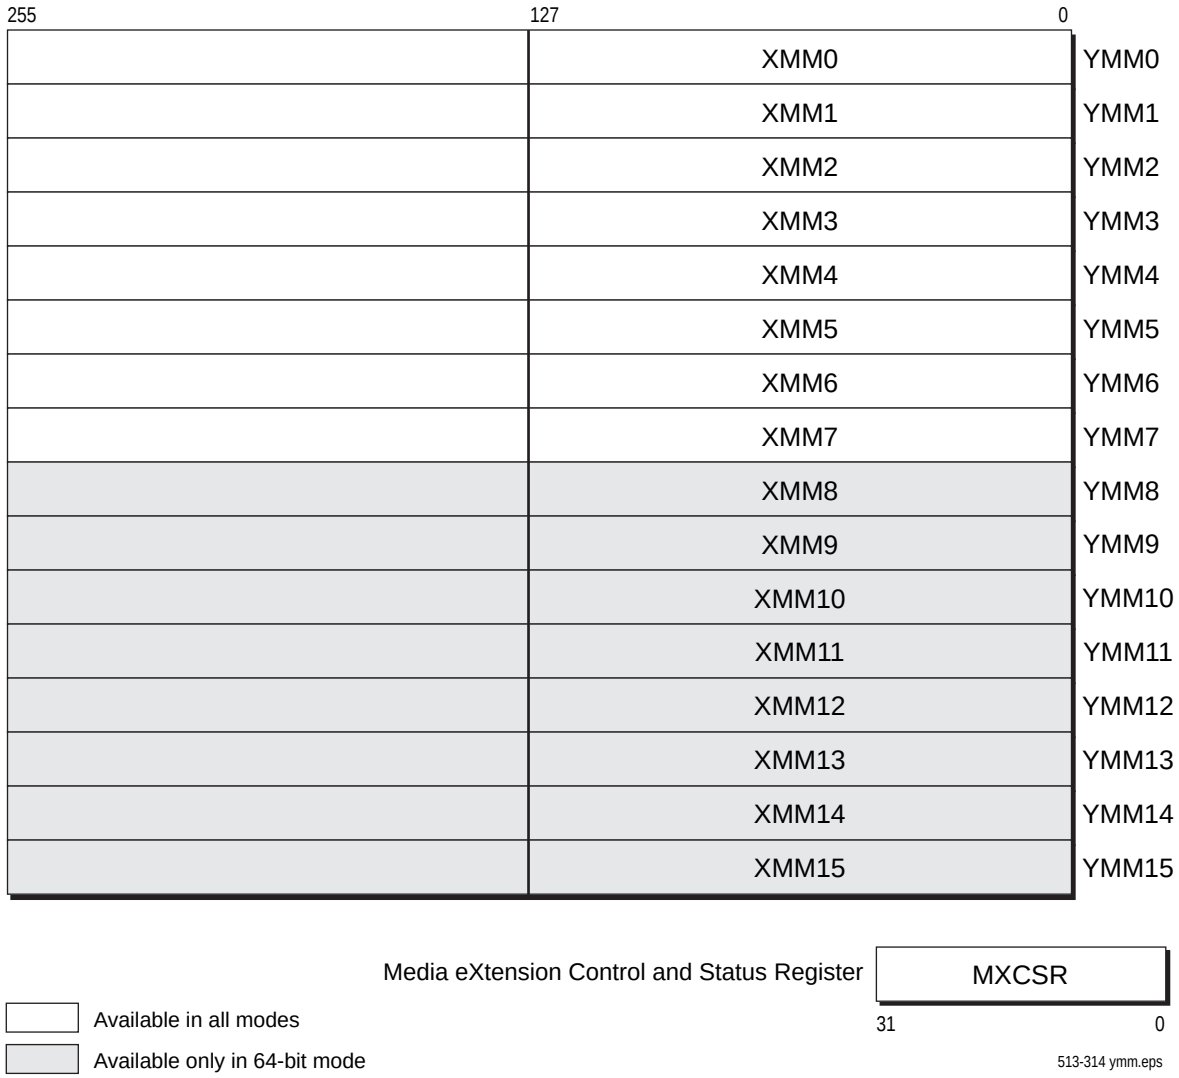

Figure 11-1. SSE Execution Unit State

11.4.2 MMX Execution Unit State

Figure 11-2 on page 340 shows the register contents that are affected by execution of 64-bit media instructions. These registers include:

- *mmx0–mmx7*—Eight 64-bit media registers.
- *FSW*—Two fields (TOP and ES) in the 16-bit x87 status word register.

- *FTW*—The 16-bit x87 tag word.

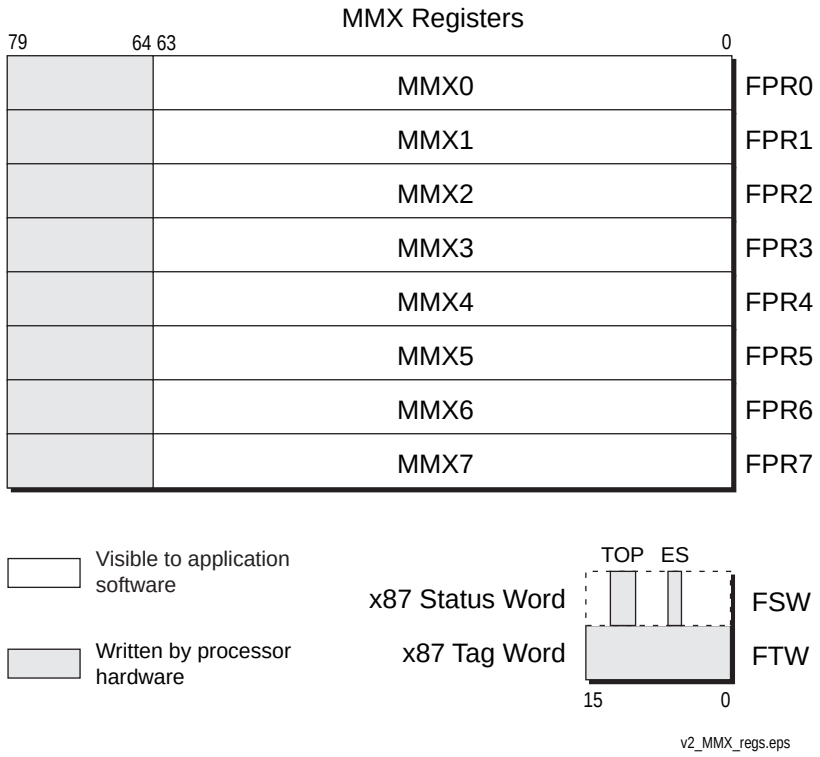

Figure 11-2. MMX Execution Unit State

The 64-bit media instructions and x87 floating-point instructions share the same physical data registers. Figure 11-2 shows how the 64-bit registers (MMX0–MMX7) are aliased onto the low 64 bits of the 80-bit x87 floating-point physical data registers (FPR0–FPR7). Refer to “64-Bit Media Programming” in Volume 1 for more information on these registers.

Of the registers shown in Figure 11-2, only the eight 64-bit MMX registers are visible to 64-bit media application software. The processor maintains the contents of the two fields of the x87 status word—top-of-stack-pointer (TOP) and exception summary (ES)—and the 16-bit x87 tag word during execution of 64-bit media instructions, as described in “Actions Taken on Executing 64-Bit Media Instructions” in Volume 1.

64-bit media instructions do not generate x87 floating-point exceptions, nor do they set any status flags. However, 64-bit media instructions can trigger an unmasked floating-point exception caused by a previously executed x87 instruction. 64-bit media instructions do this by reading the x87 FSW.ES bit to determine whether such an exception is pending.

11.4.3 x87 Execution Unit State

Figure 11-3 on page 342 shows the registers whose contents are affected by execution of x87 floating-point instructions. These registers include:

- *fpr0–fpr7*—Eight 80-bit floating-point physical registers.
- *FCW*—The 16-bit x87 control word register.
- *FSW*—The 16-bit x87 status word register.
- *FTW*—The 16-bit x87 tag word.
- *Last x87 Instruction Pointer*—This value is a pointer (32-bit, 48-bit, or 64-bit, depending on effective operand size and mode) to the last non-control x87 floating-point instruction executed.
- *Last x87 Data Pointer*—The pointer (32-bit, 48-bit, or 64-bit, depending on effective operand size and mode) to the data operand referenced by the last non-control x87 floating-point instruction executed, if that instruction referenced memory; if it did not, then this value is implementation dependent.
- *Last x87 Opcode*—An 11-bit permutation of the instruction opcode from the last non-control x87 floating-point instruction executed.

Of the registers shown in Figure 11-3 on page 342, only FPR0–FPR7, FCW, and FSW are directly updated by x87 application software. The processor maintains the contents of the FTW, instruction and data pointers, and opcode registers during execution of x87 instructions. Refer to “Registers” in Volume 1 for more information on these registers.

The 11-bit instruction opcode register holds a permutation of the two-byte instruction opcode from the last non-control x87 instruction executed by the processor. (For a definition of *non-control x87 instruction*, see “Control” in Chapter 6 of Volume 1.) The opcode field is formed as follows:

- Opcode Register Field[10:8] = First x87 opcode byte[2:0].
- Opcode Register Field[7:0] = Second x87 opcode byte[7:0].

For example, the x87 opcode D9 F8h is stored in the opcode register as 001_1111_1000b. The low-order three bits of the first opcode byte, D9h (1101_1001b), are stored in opcode-register bits 10:8. The second opcode byte, F8h (1111_1000b), is stored in bits 7:0 of the opcode register. The high-order five bits of the first opcode byte (1101_1b) are not needed because they are identical for all x87 instructions.

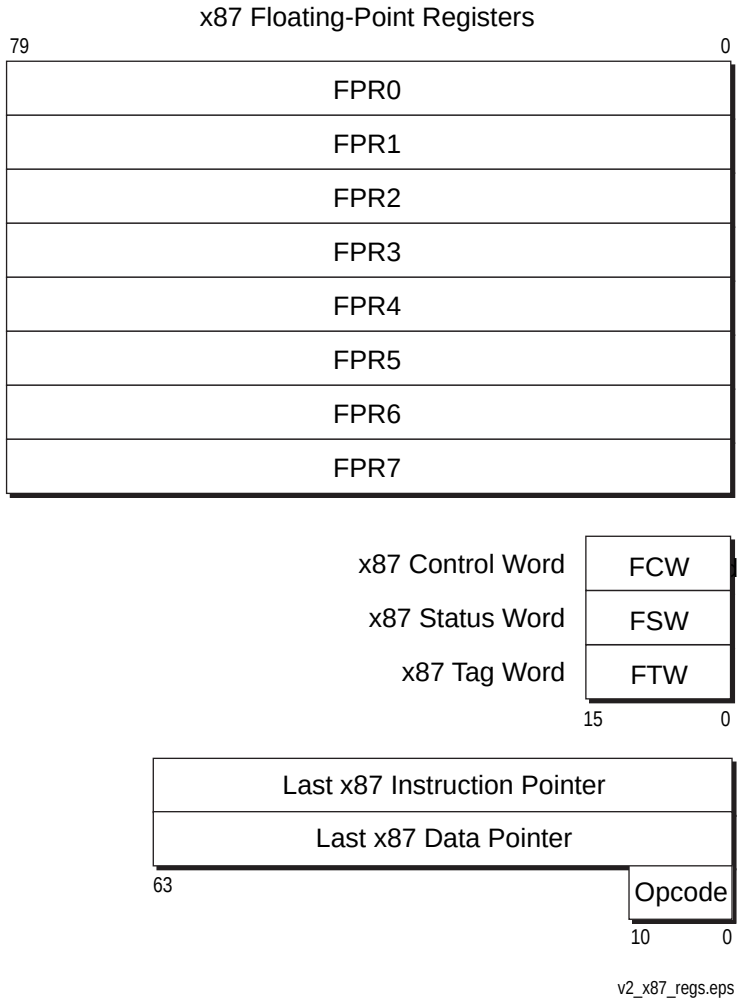

Figure 11-3. x87 Execution Unit State

11.4.4 Saving Media and x87 Execution Unit State

In most cases, operating systems, exception handlers, and device drivers should save and restore the media and/or x87 processor state between task switches or other interventions in the execution of 128-bit, 64-bit, or x87 procedures. Application programs are also free to save and restore state at any time.

In general, system software should use the FXSAVE and FXRSTOR instructions to save and restore the entire media and x87 processor state. The FSAVE/FNSAVE and FRSTOR instructions can be used for saving and restoring the x87 state. Because the 64-bit media registers are physically aliased onto the x87 registers, the FSAVE/FNSAVE and FRSTOR instructions can also be used to save and restore the 64-bit media state. However, FSAVE/FNSAVE and FRSTOR do not save or restore the 128-bit media state.

FSAVE/FNSAVE and FRSTOR Instructions. The FSAVE/FNSAVE and FRSTOR instructions save and restore the entire register state for 64-bit media instructions and x87 floating-point instructions. The FSAVE instruction stores the register state, but only after handling any pending unmasked-x87 floating-point exceptions. The FNSAVE instruction stores the register state but skips the reporting and handling of these exceptions. The state of all MMX/FPR registers is saved, as well as all other x87 state (the control word register, status word register, tag word, instruction pointer, data pointer, and last opcode). After saving this state, the tag state for all MMX/FPR registers is changed to *empty* and is thus available for a new procedure.

Starting on page 344, Figure 11-4 through Figure 11-7 show the memory formats used by the FSAVE/FNSAVE and FRSTOR instructions when storing the x87 state in various processor modes and using various effective-operand sizes. This state includes:

- *x87 Data Registers*
  - FPR0–FPR7 80-bit physical data registers.
- *x87 Environment*
  - FCW: x87 control word register
  - FSW: x87 status word register
  - FTW: x87 tag word
  - Last x87 instruction pointer
  - Last x87 data pointer
  - Last x87 opcode

The eight data registers are stored in the 80 bytes following the environment information. Instead of storing these registers in their physical order (FPR0–FPR7), the processor stores the registers in the their stack order, ST(0)–ST(7), beginning with the top-of-stack, ST(0).

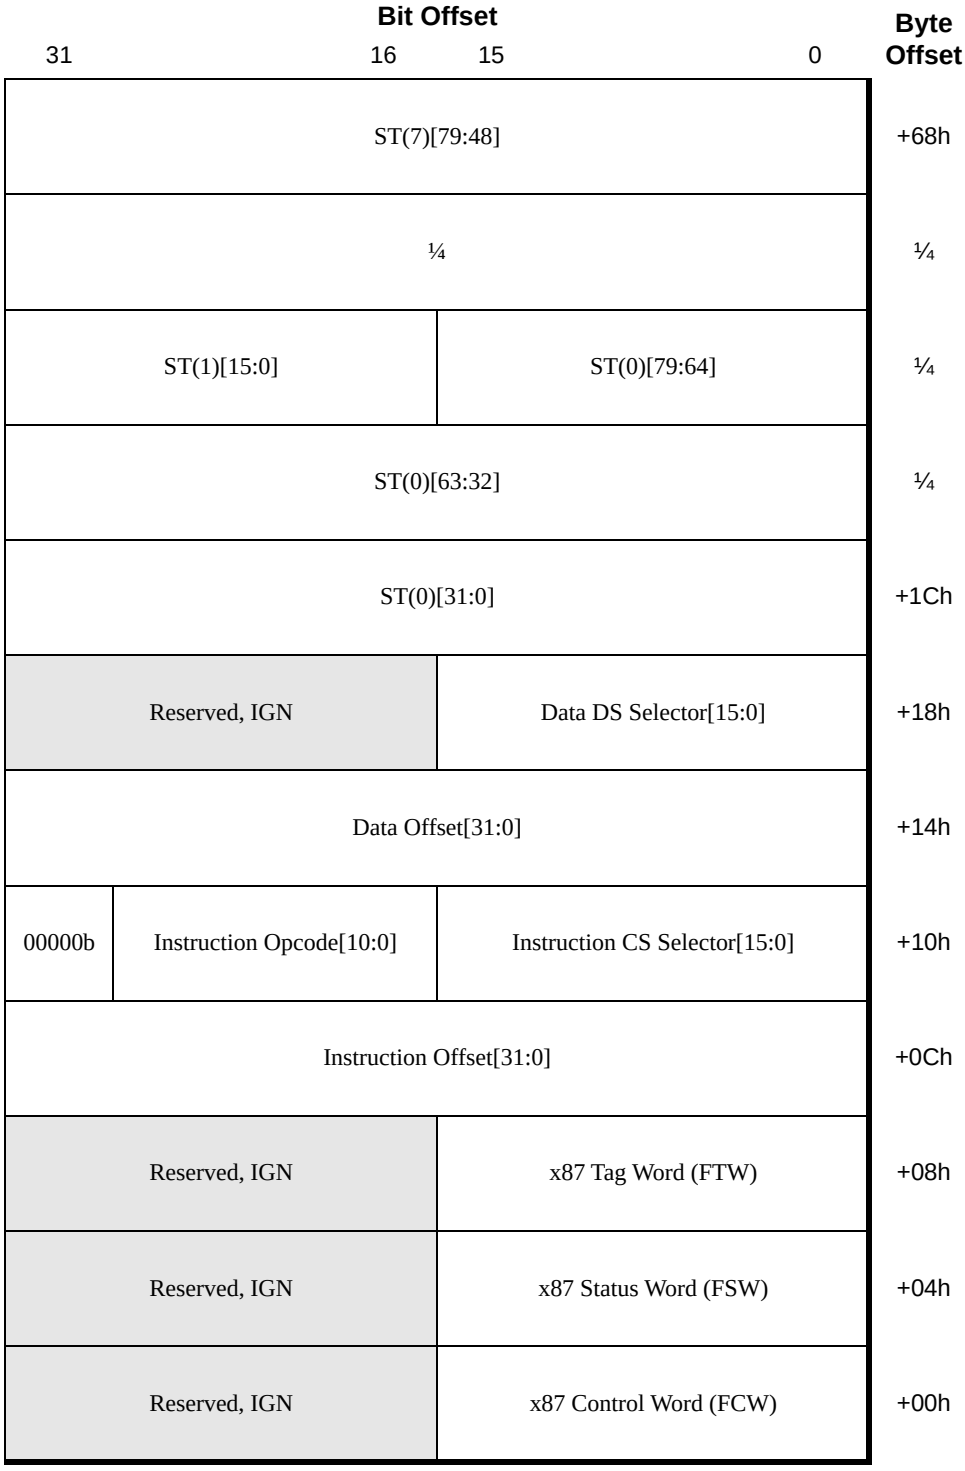

Figure 11-4. FSAVE/FNSAVE Image (32-Bit, Protected Mode)

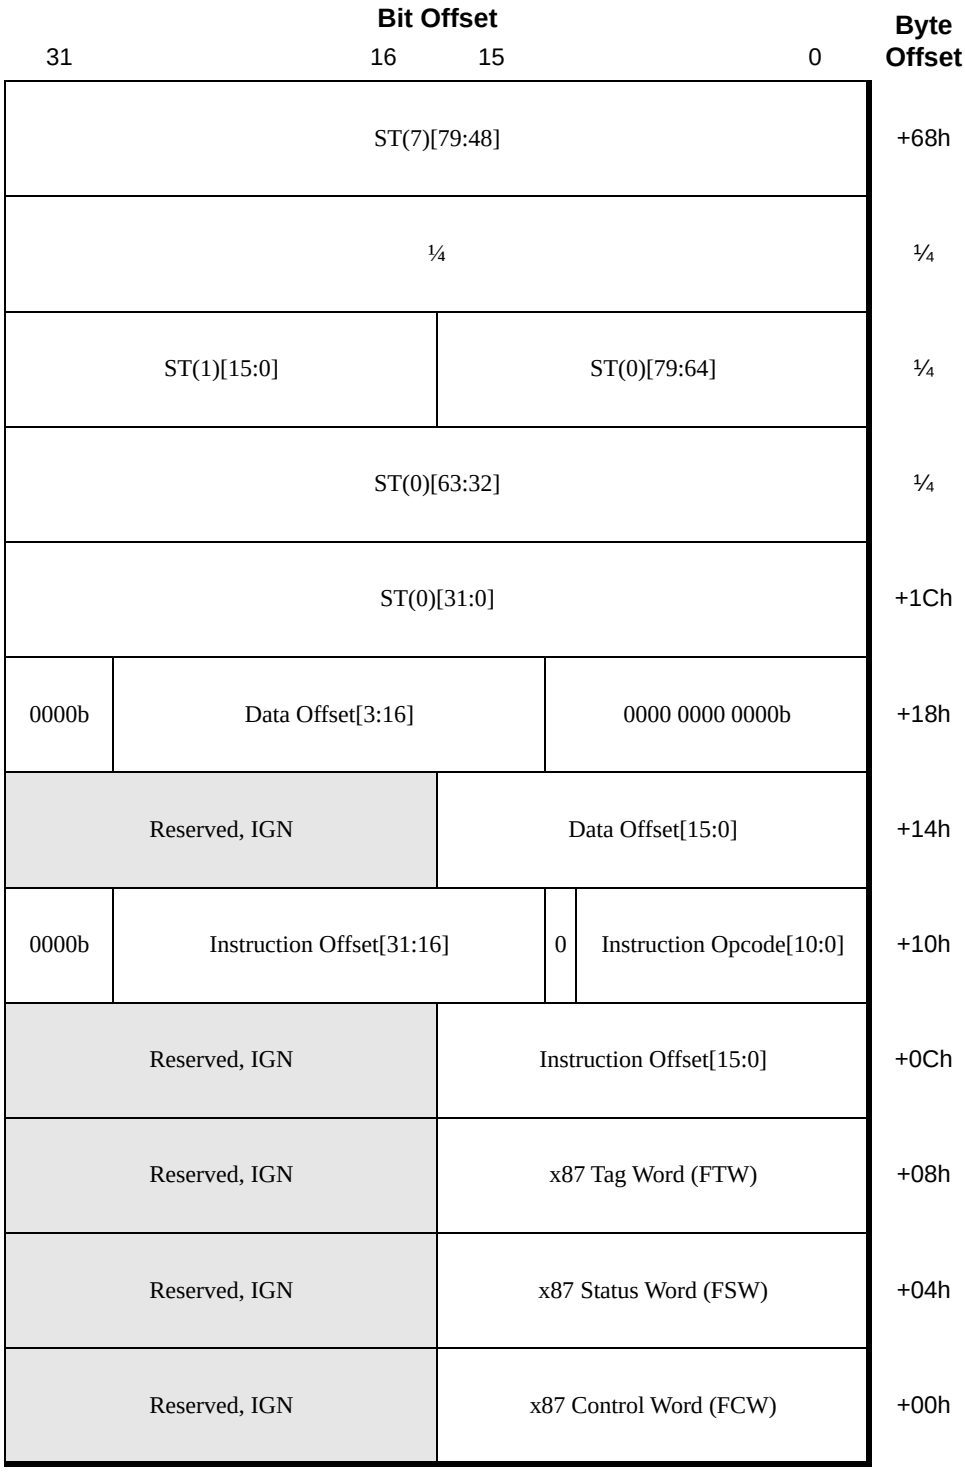

Figure 11-5. FSAVE/FNSAVE Image (32-Bit, Real/Virtual-8086 Modes)

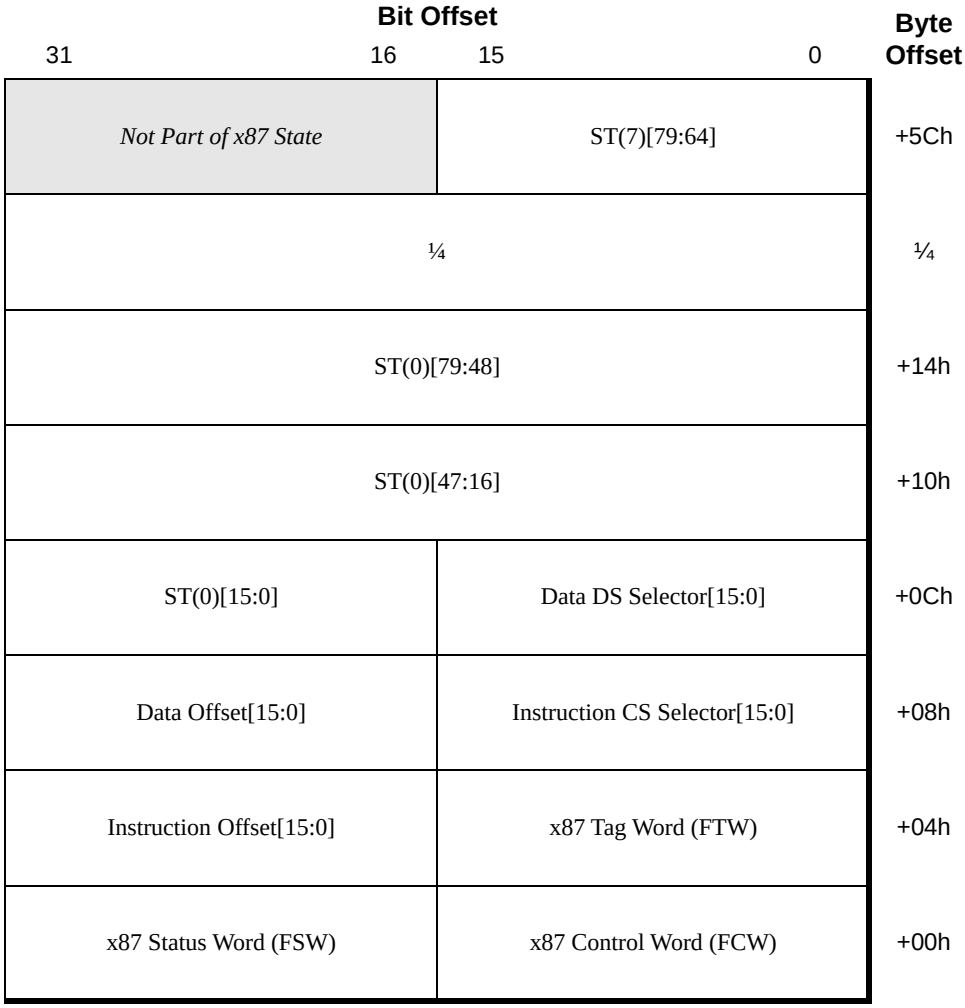

Figure 11-6. FSAVE/FNSAVE Image (16-Bit, Protected Mode)

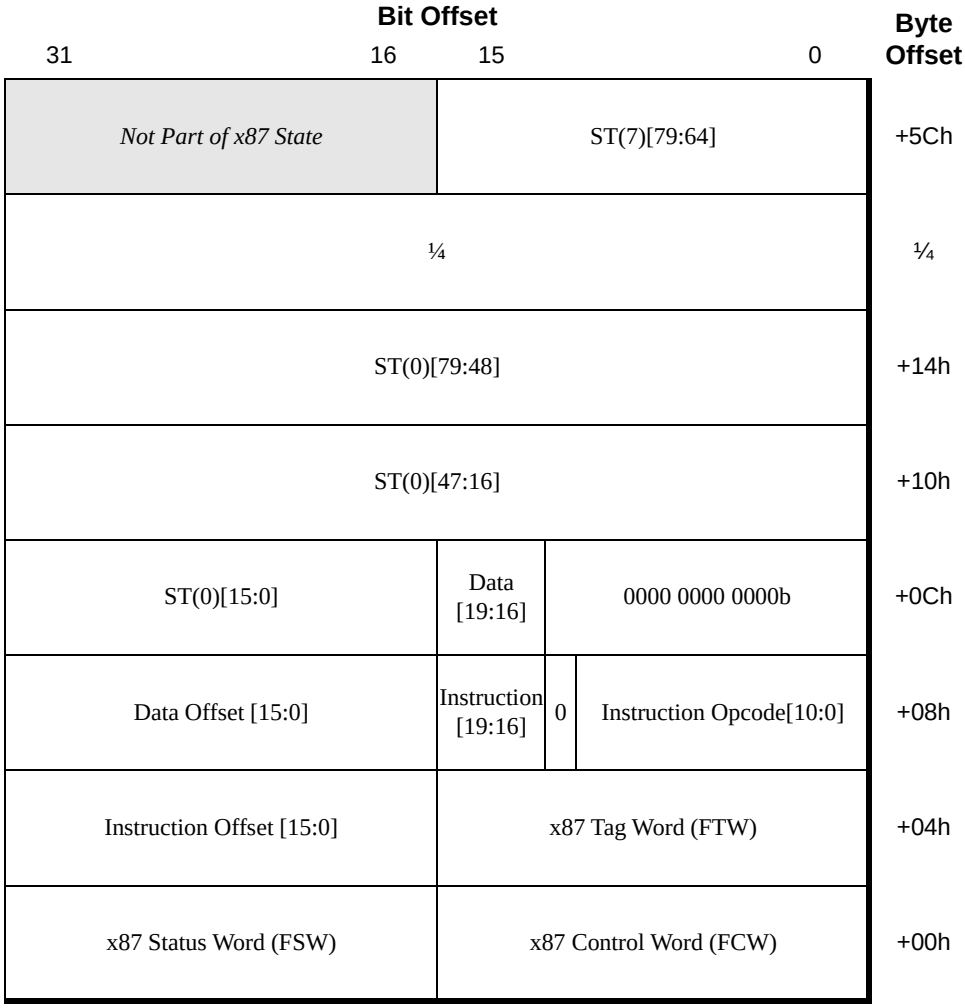

Figure 11-7. FSAVE/FNSAVE Image (16-Bit, Real/Virtual-8086 Modes)

FLDENV/FNLDENV and FSTENV Instructions. The FLDENV/FNLDENV and FSTENV instructions load and store only the x87 floating-point environment. These instructions, unlike the FSAVE/FNSAVE and FRSTOR instructions, do not save or restore the x87 data registers. The FLDENV/FSTENV instructions do not save the full 64-bit data and instruction pointers. 64-bit applications should use FXSAVE/FXRSTOR, rather than FLDENV/FSTENV. The format of the saved x87 environment images for protected mode and real/virtual mode are the same as those of the first 14-bytes of the FSAVE/FNSAVE images for 16-bit operands or 32/64-bit operands, respectively. See Figure 11-4 on page 344, Figure 11-5 on page 345, Figure 11-6 on page 346, and Figure 11-7.

FXSAVE and FXRSTOR Instructions. The FXSAVE and FXRSTOR instructions save and restore the entire 128-bit media, 64-bit media, and x87 state. These instructions usually execute faster than FSAVE/FNSAVE and FRSTOR because they do not normally save and restore the x87 exception pointers (last-instruction pointer, last data-operand pointer, and last opcode). The only case in which they do save the exception pointers is the relatively rare case in which the exception-summary bit in

the x87 status word (FSW.ES) is set to 1, indicating that an unmasked exception has occurred. The FXSAVE and FXRSTOR memory format contains fields for storing these values.

Unlike FSAVE and FNSAVE, the FXSAVE instruction does not alter the x87 tag word. Therefore, the contents of the shared 64-bit MMX and 80-bit FPR registers can remain valid after an FXSAVE instruction (or any other value the tag bits indicated before the save). Also, FXSAVE (like FNSAVE) does not check for pending unmasked-x87 floating-point exceptions.

Figure 11-8 on page 356 shows the memory format of the media x87 state in long mode. If a 32-bit operand size is used in 64-bit mode, the memory format is the same, except that RIP and RDS are stored as *sel:offset* pointers, as shown in Figure 11-9 on page 356.

For more information on the FXSAVE and FXRSTOR instructions, see individual instruction listings in "64-Bit Media Instruction Reference" of Volume 5.

11.5 XSAVE/XRSTOR Instructions

The XSAVE, XSAVEOPT, XRSTOR, XGETBV, and XSETBV instructions and associated data structures extend the FXSAVE/FXRSTOR memory image used to manage processor states and provide additional functionality. These instructions do not obviate the FXSAVE/FXRSTOR instructions. For more information about FXSAVE/FXRSTOR, see *"FXSAVE and FXRSTOR Instructions" in Volume 2*. For detailed descriptions of FXSAVE and FXRSTOR, see individual instruction listings in AMD64 Architecture Programmer's Manual *"Volume 5: 64-Bit Media and x87 Floating-Point Instructions."*

The CPUID instruction is used to identify features supported in processor hardware. Extended control registers are used to enable and disable the handling of processor states associated with supported hardware features and to communicate to an application whether an operating system supports a particular feature that has a processor state specific to it.

11.5.1 CPUID Enhancements

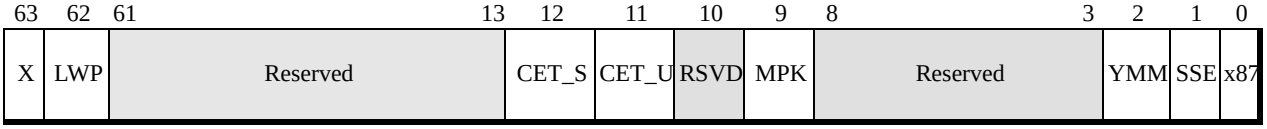
- CPUID Fn0000_00001_ECX[XSAVE] indicates that the processor supports XSAVE/XRSTOR instructions and at least one XCR.
- CPUID Fn0000_00001_ECX[OSXSAVE] indicates whether the operating system has enabled extensible state management and supports processor extended state management.
- CPUID Fn0000_0000D enumerates processor states (including legacy x87 FPU states, SSE states, and processor extended states), the offset, and the size of the save area for each processor extended state. Sub-functions (ECX > 0) provide details concerning features and support of processor states enumerated in the root function.

11.5.2 XFEATURE_ENABLED_MASK

XFEATURE_ENABLED_MASK is set up by privileged software to enable the saving and restoring of extended processor architectural state information supported by a specific processor. Clearing defined bit fields in this mask inhibits the XSAVE instruction from saving (and XRSTOR from restoring) this state information.

XFEATURE_ENABLED_MASK is addressed as XCR0 in the extended control register space and is accessed via the XSETBV and XGETBV instructions.

XFEATURE_ENABLED_MASK is defined as follows:



Bits	Mnemonic	Description
63	X	Reserved specifically for XCR0 bit vector expansion. Reserved, MBZ.
62	LWP	When set, Lightweight Profiling (LWP) extensions are enabled and XSAVE/XRSTOR supports LWP state management.
61:13	—	Reserved, MBZ
12	CET_S	When set, CET supervisor state is supported by XSAVE/XRSTOR
11	CET_U	When set, CET user state is supported by XSAVE/XRSTOR
10	—	Reserved, MBZ
9	MPK	When set, PKRU state management is supported by XSAVE/XRSTOR.
8:3	—	Reserved, MBZ
2	YMM	When set, 256-bit SSE state management is supported by XSAVE/XRSTOR. Must be set to enable AVX extensions.
1	SSE	When set, 128-bit SSE state management is supported by XSAVE/XRSTOR. This bit must be set if YMM is set. Must be set to enable AVX extensions.
0	x87	x87 FPU state management is supported by XSAVE/XRSTOR. Must be set to 1.

Hardware initializes XCR0 to 0000_0000_0000_0001h. On writing this register, software must insure that XCR0[63:3] is clear, XCR0[0] is set, and that XCR0[2:1] is not equal to 10b. An attempt to write data that violates these rules results in a #GP.

11.5.3 Extended Save Area

The XSAVE/XRSTOR save area extends the legacy 512-byte FXSAVE/FXRSTOR memory image to provide a compatible register state management environment as well as an upward migration path. The save area is architecturally defined to be extendable and enumerated by the sub-functions of CPUID Fn 0000_000Dh. Figure 11-2 shows the format of the XSAVE/XRSTOR area.

Table 11-2. Extended Save Area Format

Save Area	Offset (Byte)	Size (Bytes)
FPU/SSE Save Area	0	512
Header	512	64
Reserved, (Ext_Save_Area_2)	CPUID Fn 0000_000D_EBX_x02	CPUID Fn 0000_000D_EAX_x02
Reserved, (Ext_Save_Area_3)	CPUID Fn 0000_000D_EBX_x03	CPUID Fn 0000_000D_EAX_x03
Reserved, (Ext_Save_Area_4)	CPUID Fn 0000_000D_EBX_x04	CPUID Fn 0000_000D_EAX_x04
Reserved, (…)	…	…
Note: *Bytes 464–511 are available for software use. XRSTOR ignores bytes 464–511 of an XSAVE image.*		

The register fields of the first 512 bytes of the XSAVE/XRSTOR area are the same as those of the FXSAVE/FXRSTOR area, but the 512-byte area is organized as x87 FPU states, MXCSR (including MXCSR_MASK), and XMM registers. The layout of the save area is fixed and may contain non-contiguous individual save areas because a processor does not support certain extended states or

because system software does not support certain processor extended states. The save area is not compacted when features are not saved or are not supported by the processor or by system software.

For more information on using the CPUID instruction to obtain processor implementation information, see Section 3.3, “Processor Feature Identification,” on page 71.

11.5.4 Instruction Functions

CR4.OSXSAVE and XCR0 can be read at all privilege levels but written only at ring 0.

- XGETBV reads XCR0.
- XSETBV writes XCR0, ring 0 only.
- XRSTOR restores states specified by bitwise AND of a mask operand in EDX:EAX with XCR0.
- XSAVE (and XSAVEOPT) saves states specified by bitwise AND of a mask operand in EDX:EAX with XCR0.

11.5.5 YMM States and Supported Operating Modes

Extended instructions operate on YMM states by means of extended (XOP/VEX) prefix encoding. When a processor supports YMM states, the states exist in all operating modes, but interfaces to access the YMM states may vary by mode. Processor support for extended prefix encoding is independent of processor support of YMM states.

Instructions that use extended prefix encoding are generally supported in long and protected modes, but are not supported in real or virtual 8086 modes, or when entering SMM mode. Bits 255:128 of the YMM register state are maintained across transitions into and out of these modes. The XSAVE/XRSTOR instructions function in all operating modes; XRSTOR can modify YMM register state in any operating mode, using state information from the XSAVE/XRSTOR area.

11.5.6 Extended SSE Execution State Management

Operating system software must use the XSAVE/XRSTOR instructions for extended SSE execution state management. XSAVEOPT, a performance optimized version of XSAVE, may be used instead of XSAVE once the XSAVE/XRSTOR save area is initialized. In the following discussion XSAVEOPT may be substituted for the instruction XSAVE. The instructions also provide an interface to manage XMM/MXCSR states and x87 FPU states in conjunction with processor extended states. An operating system must enable extended SSE execution state management prior to the execution of extended SSE instructions. Attempting to execute an extended SSE instruction without enabling execution state management causes a #UD exception.

11.5.6.1 Enabling Extended SSE Instruction Execution

To enable extended SSE instruction execution and state management, system software must carry out the following process:

- Confirm that the hardware supports the XSAVE, XRSTOR, XSETBV, and XGETBV instructions and the XCR0 register (XFEATURE_ENABLED_MASK) by executing the CPUID instruction function 0000_0001h. If CPUID Fn0000_0001_ECX[XSAVE] is set, hardware support is verified.
- Optionally confirm hardware support of the XSAVEOPT instruction by executing CPUID function 0000_000Dh, sub-function 1 (ECX = 1). If CPUID Fn0000_000D_EAX_x1[XSAVEOPT] is set, the processor supports the XSAVEOPT instruction. XSAVEOPT is a performance optimized version of XSAVE. (SDCR-3580)
- Confirm that hardware supports the extended SSE instructions by verifying XFeatureSupportedMask[2:0] = 111b. XFeatureSupportedMask is accessed via the CPUID instruction function 0000_000Dh, sub-function 0 (ECX = 0).

  If CPUID Fn0000_000D_EAX_x0[2:0] = 111b, hardware supports x87, legacy SSE, and extended SSE instructions. Bit 0 of EAX signifies x87 floating-point and MMX support, bit 1 signifies legacy SSE support, and bit 2 signifies extended SSE support. Support for both x87 and legacy SSE instructions are required for processors that support the extended SSE instructions.
- Set CR4[OSXSAVE] (bit 18) to enable the use of the XSETBV and XGETBV instructions. XSETBV is a privileged instruction that writes the XCRn registers. XCR0 is the XFEATURE_ENABLED_MASK used to manage media and x87 processor state using the XSAVE, XSAVEOPT, and XRSTOR instructions.
- Enable the x87/MMX, legacy SSE, and extended SSE instructions and processor state management by setting the x87, SSE, and YMM bits of XCR0 (XFEATURE_ENABLED_MASK). Enabling extended SSE capabilities without enabling legacy SSE capabilities is not allowed. The x87 flag (bit 0) of the XFEATURE_ENABLED_MASK must be set when writing XCR0.
- Determine the XSAVE/XRSTOR memory save area size requirement. The field XFeatureEnabledSizeMax specifies the size requirement in bytes based on the currently enabled extended features and is returned in the EAX register after execution of CPUID Function 0000_000Dh, sub-function 0 (ECX = 0).
- Allocate the save/restore area based on the information obtained in the previous step.

For more information on the XSETBV and XGETBV instructions, see individual instruction descriptions in Volume 4. XFEATURE_ENABLED_MASK fields are defined in Section 11.5.2 above.

For more information on using the CPUID instruction to obtain processor implementation information, see Section 3.3, “Processor Feature Identification,” on page 71.

11.5.7 Saving Processor State

The XSTATE header starts at byte offset 512 in the save area. XSTATE_BV is the first 64-bit field in the header. The order of bit vectors in XSTATE_BV matches the order of bit vectors in XCR0. The XSAVE instruction sets bits in the XSTATE_BV vector field when it writes the corresponding processor extended state to a save area in memory. XSAVE modifies only bits for processor states specified by bitwise AND of the XSAVE bit mask operand in EDX:EAX with XCR0. If software modifies the save area image of a particular processor state component directly, it must also set the corresponding bit of XSTATE_BV. If the bit is not set, directly modified state information in a save area image may be ignored by XRSTOR.

XSAVEOPT, a performance optimized version of the XSAVE instruction, may be used (if supported) in lieu of the XSAVE instruction once the XSAVE/XRSTOR save area has been initialized via the execution of the XSAVE instruction.

11.5.8 Restoring Processor State

When XRSTOR is executed, processor state components are updated only if the corresponding bits in the mask operand (EDX:EAX) and XCR0 are both set. For each updated component, when the corresponding bit in the XSTATE_BV field in the save area header is set, the component is loaded from the save area in memory. When the XSTATE_BV bit is cleared, the state is set to the hardware-specified initial values shown in Table 11-3.

Table 11-3. XRSTOR Hardware-Specified Initial Values

Component	Initial Value
x87	FCW = 037Fh FSW = 0000h Empty/Full = 00h (FTW = FFFFh) x87 Error Pointers = 0 ST0 - ST7 = 0
XMM	XMM0 - XMM15 = 0, if 64-bit mode XMM0 - XMM7 = 0, if !64-bit mode
YMM_HI	YMM_HI0 -Y MM_HI15 = 0, if 64-bit mode YMM_HI0-YMM_HI7 = 0, if !64-bit mode
LWP	LWP disabled
MPK	PKRU = 0
CET_S	PL0_SSP = PL1_SSP = PL2_SSP = 0
CET_U	U_CET = 0, PL3_SSP = 0

11.5.9 MXCSR State Management

The MXCSR has no hardware-specified initial state; it is read from the save area in memory whenever either XMM or YMM_HI are updated.

11.5.10 Mode-Specific XSAVE/XRSTOR State Management

Some state is conditionally saved or updated, depending on processor state:

- On processors where CPUID Fn8000_0008_EBX[2] is 0, the x87 error pointers are not saved or restored if the state saved or loaded from memory doesn't have a pending #MF. On processors where CPUID Fn8000_0008_EBX[2] is 1, the error pointers are always restored from the save area (and if in 64-bit mode the CS and DS portions of the error pointer registers are zeroed), and the error pointer fields in the save area are zeroed if there is no pending #MF, else the error pointer offset registers are written to the save area.
- XMM8–XMM15 are not saved or restored in non 64-bit mode.
- YMM_HI8–YMM_HI15 are not saved or restored in non 64-bit mode.

Figure 11-8. FXSAVE and FXRSTOR Image (64-bit Mode)

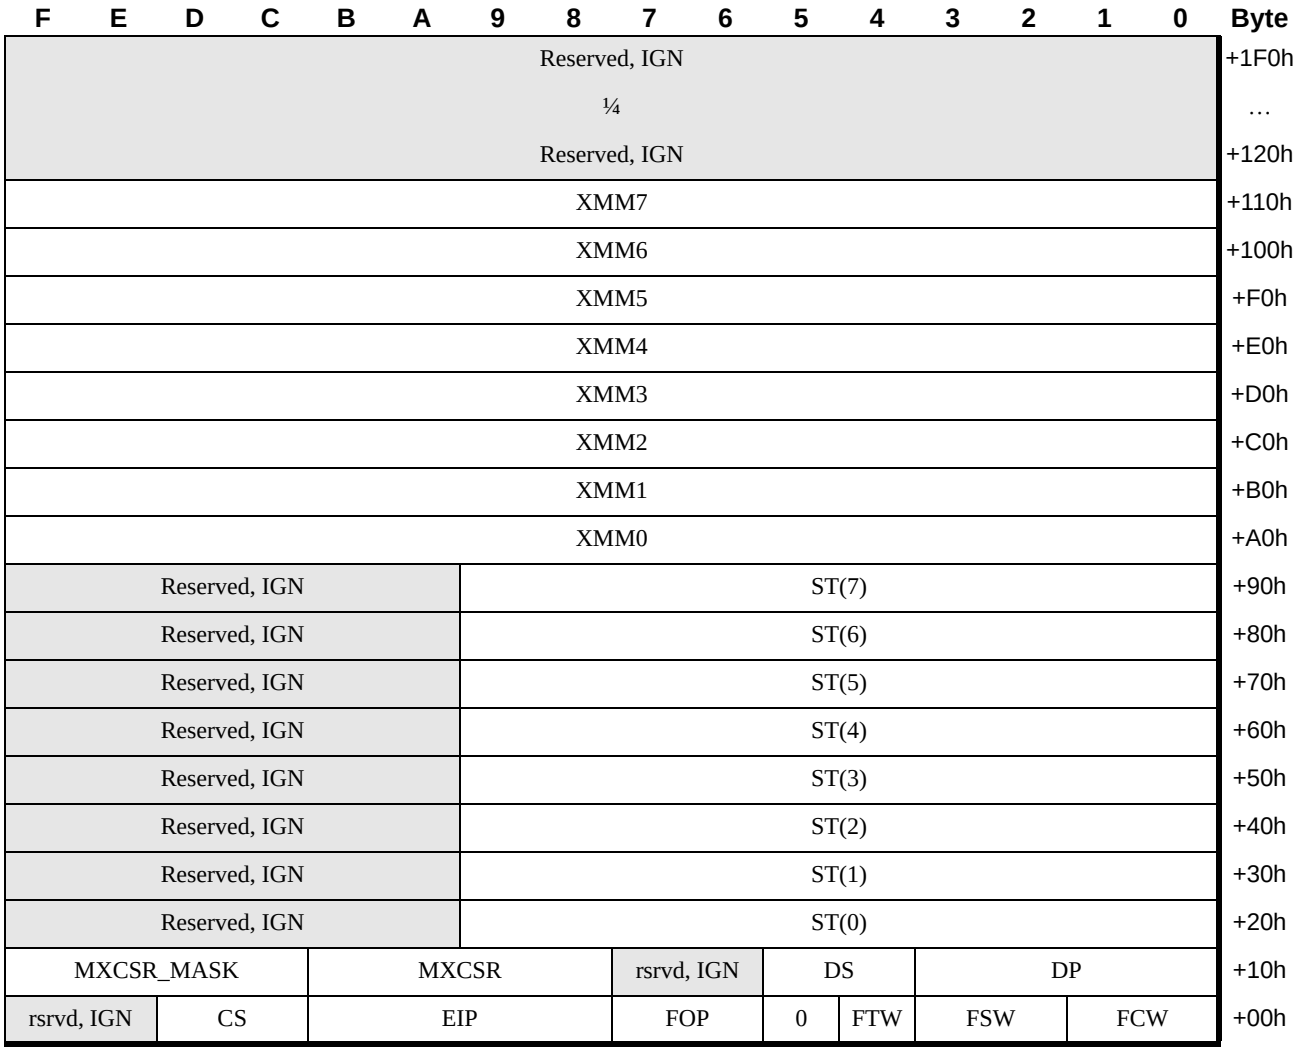

Figure 11-9. FXSAVE and FXRSTOR Image (Non-64-bit Mode)

Software can read and write all fields within the FXSAVE and FXRSTOR memory image. These fields include:

- *FCW*—Bytes 01h–00h. x87 control word.
- *FSW*—Bytes 03h–02h. x87 status word.
- *FTW*—Byte 04h. x87 tag word. See “FXSAVE Format for x87 Tag Word” on page 357 for additional information on the FTW format saved by the FXSAVE instruction.
- (Byte 05h contains the value 00h.)
- *FOP*—Bytes 07h–06h. last x87 opcode.

- *Last x87 Instruction Pointer*—A pointer to the last non-control x87 floating-point instruction executed by the processor:
  - *RIP (64-bit format)*—Bytes 0Fh–08h. 64-bit offset into the code segment (used without a CS selector).
  - *EIP (32-bit format)*—Bytes 0Bh–08h. 32-bit offset into the code segment.
  - *CS (32-bit format)*—Bytes 0Dh–0Ch. Segment selector portion of the pointer.
- *Last x87 Data Pointer*—If the last non-control x87 floating point instruction referenced memory, this value is a pointer to the data operand referenced by the last non-control x87 floating-point instruction executed by the processor:
  - *RDP (64-bit format)*—Bytes 17h–10h. 64-bit offset into the data segment (used without a DS selector).
  - *DP (32-bit format)*—Bytes 13h–10h. 32-bit offset into the data segment.
  - *DS (32-bit format)*—Bytes 15h–14h. Segment selector portion of the pointer.

  If the last non-control x87 instruction did not reference memory, then the value in the pointer is implementation dependent.
- *MXCSR*—Bytes 1Bh–18h. 128-bit media-instruction control and status register. This register is saved only if CR4.OSFXSR is set to 1.
- *MXCSR_MASK*—Bytes 1Fh–1Ch. Set bits in MXCSR_MASK indicate supported feature bits in MXCSR. For example, if bit 6 (the DAZ bit) in the returned MXCSR_MASK field is set to 1, the DAZ mode and the DAZ flag in MXCSR *are* supported. Cleared bits in MXCSR_MASK indicate reserved bits in MXCSR. If software attempts to set a reserved bit in the MXCSR register, a #GP exception will occur. To avoid this exception, after software clears the FXSAVE memory image and executes the FXSAVE instruction, software should use the value returned by the processor in the MXCSR_MASK field when writing a value to the MXCSR register, as follows:
  - *MXCSR_MASK = 0:* If the processor writes a zero value into the MXCSR_MASK field, the denormals-are-zeros (DAZ) mode and the DAZ flag in MXCSR are *not* supported. Software should use the default mask value, 0000_FFBFh (bit 6, the DAZ bit, and bits 31:16 cleared to 0), to mask any value it writes to the MXCSR register to ensure that all reserved bits in MXCSR are written with 0, thus avoiding a #GP exception.
  - *MXCSR_MASK … 0:* If the processor writes a non-zero value into the MXCSR_MASK field, software should AND this value with any value it writes to the MXCSR register.
- *MMXn/FPRn*—Bytes 9Fh–20h. Shared 64-bit media and x87 floating-point registers. As in the case of the x87 FSAVE instruction, these registers are stored in stack order ST(0)–ST(7). The upper six bytes in the memory image for each register are reserved.
- *XMMn*—Bytes 11Fh–A0h. 128-bit media registers. These registers are saved only if CR4.OSFXSR is set to 1.

FXSAVE Format for x87 Tag Word. Rather than saving the entire x87 tag word, FXSAVE saves a single-byte encoded version. FXSAVE encodes each of the eight two-bit fields in the x87 tag word as follows:

- Two-bit values of 00, 01, and 10 are encoded as a 1, indicating the corresponding x87 FPR*n* register holds a value.
- A two-bit value of 11 is encoded as a 0, indicating the corresponding x87 FPR*n* is empty.

For example, assume an FSAVE instruction saves an x87 tag word with the value 83F1h. This tag-word value describes the x87 FPRn contents as follows:

x87 Register	FPR7	FPR6	FPR5	FPR4	FPR3	FPR2	FPR1	FPR0
Tag Word Value (hex)	8		3		F		1	
Tag Value (binary)	10	00	00	11	11	11	00	01
Meaning	Special	Valid	Valid	Empty	Empty	Empty	Valid	Zero

When an FXSAVE is used to write the x87 tag word to memory, it encodes the value as E3h. This encoded version describes the x87 FPRn contents as follows:

x87 Register	FPR7	FPR6	FPR5	FPR4	FPR3	FPR2	FPR1	FPR0
Encoded Tag Byte (hex)	E				3			
Tag Value (binary)	1	1	1	0	0	0	1	1
Meaning	Valid	Valid	Valid	Empty	Empty	Empty	Valid	Valid

If necessary, software can decode the single-bit FXSAVE tag-word fields into the two-bit field FSAVE uses by examining the contents of the corresponding FPR registers saved by FXSAVE. Table 11-4 on page 359 shows how the FPR contents are used to find the equivalent FSAVE tag-field value. The *fraction* column refers to fraction portion of the extended-precision significand (bits 62:0). The *integer bit* column refers to the integer-portion of the significand (bit 63). See Chapter 11, “SSE, MMX, and x87 Programming,” on page 335 for more information on floating-point numbering formats.

Table 11-4. Deriving FSAVE Tag Field from FXSAVE Tag Field

Encoded FXSAVE Tag Field	Exponent	Integer Bit[2]	Fraction[1]	Type of Value	Equivalent FSAVE Tag Field
1 (Valid)	All 0s	0	All 0s	Zero	01 (Zero)
		0	Not all 0s	Denormal	10 (Special)

Note:
1. *Bits 62:0 of the significand. Bit 62, the most-significant bit of the fraction, is also called the M bit.*
2. *Bit 63 of the significand, also called the J bit.*

Performance Considerations. When system software supports multi-tasking, it must be able to save the processor state for one task and load the state for another. For performance reasons, the media and/or x87 processor state is usually saved and loaded only when necessary. System software can save and load this state at the time a task switch occurs. However, if the new task does not use the state, loading the state is unnecessary and reduces performance.

The task-switch bit (CR0.TS) is provided as a *lazy* context-switch mechanism that allows system software to save and load the processor state only when necessary. When CR0.TS=1, a device-not-available exception (#NM) occurs when an attempt is made to execute a 128-bit media, 64-bit media, or x87 instruction. System software can use the #NM exception handler to save the state of the previous task, and restore the state of the current task. Before returning from the exception handler to the media or x87 instruction, system software must clear CR0.TS to 0 to allow the instruction to be executed. Using this approach, the processor state is saved only when the registers are used.

In legacy mode, the hardware task-switch mechanism sets CR0.TS=1 during a task switch (see "Task Switched (TS) Bit" on page 44 for more information). In long mode, the hardware task-switching is not supported, and the CR0.TS bit is not set by the processor. Instead, the architecture assumes that system software handles all task-switching and state-saving functions. If CR0.TS is to be used in long mode for controlling the save and restore of media or x87 state, system software must set and clear it explicitly.

12 Task Management

This chapter describes the hardware task-management features. All of the legacy x86 task-management features are supported by the AMD64 architecture in legacy mode, but most features are not available in long mode. Long mode, however, requires system software to initialize and maintain certain task-management *resources*. The details of these resource-initialization requirements for long mode are discussed in “Task-Management Resources” on page 362.

12.1 Hardware Multitasking Overview

A task (also called a *process*) is a program that the processor can execute, suspend, and later resume executing at the point of suspension. During the time a task is suspended, other tasks are allowed to execute. Each task has its own execution space, consisting of:

- Code segment and instruction pointer.
- Data segments.
- Stack segments for each privilege level.
- General-purpose registers.
- rFLAGS register.
- Local-descriptor table.
- Task register, and a link to the previously-executed task.
- I/O-permission and interrupt-permission bitmaps.
- Pointer to the page-translation tables (CR3).

The state information defining this execution space is stored in the task-state segment (TSS) maintained for each task.

Support for hardware multitasking is provided in legacy mode. Hardware multitasking provides automated mechanisms for switching tasks, saving the execution state of the suspended task, and restoring the execution state of the resumed task. When hardware multitasking is used to switch tasks, the processor takes the following actions:

- Suspends execution of the task, allowing any executing instructions to complete and save their results.
- Saves the task execution state in the task TSS.
- Loads the execution state for the new task from its TSS.
- Begins executing the new task at the location specified in the new task TSS.

Software can switch tasks by branching to a new task using the CALL or JMP instructions. Exceptions and interrupts can also switch tasks if the exception or interrupt handlers are themselves separate tasks. IRET can be used to return to an earlier task.

12.2 Task-Management Resources

The hardware-multitasking features are available when protected mode is enabled (CR0.PE=1). Protected-mode software execution, by definition, occurs as part of a task. While system software is not required to use the hardware-multitasking features, it is required to initialize certain task-management resources for at least one task (the current task) when running in protected mode. This single task is needed to establish the protected-mode execution environment. The resources that must be initialized are:

- *Task-State Segment (TSS)*—A segment that holds the processor state associated with a task.
- *TSS Descriptor*—A segment descriptor that defines the task-state segment.
- *TSS Selector*—A segment selector that references the TSS descriptor located in the GDT.
- *Task Register*—A register that holds the TSS selector and TSS descriptor for the current task.

Figure 12-1 on page 363 shows the relationship of these resources to each other in both 64-bit and 32-bit operating environments.

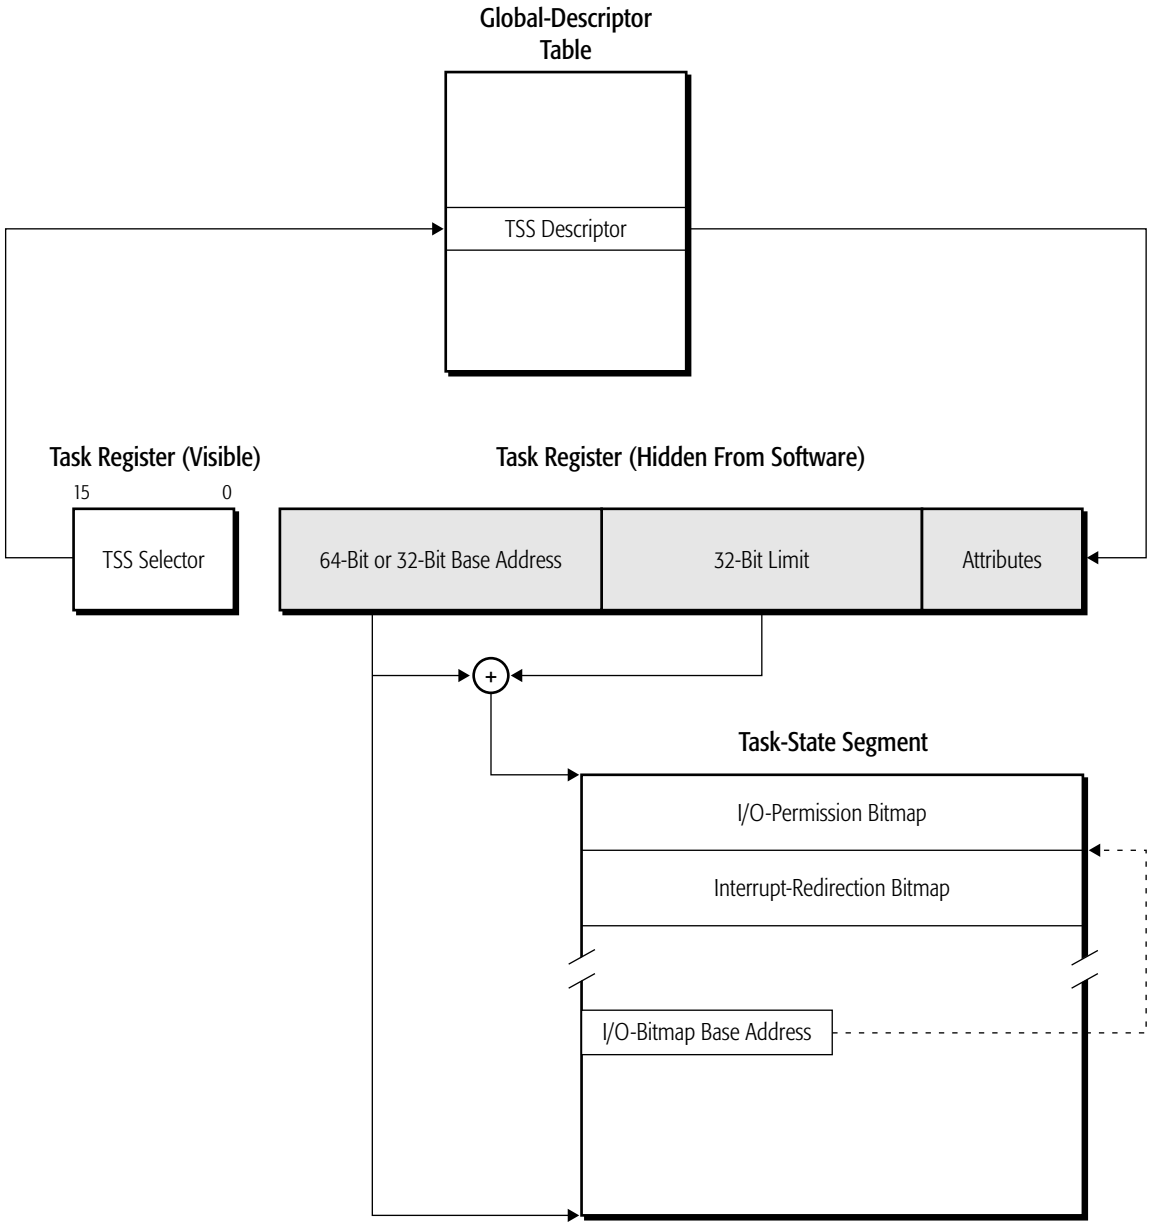

Figure 12-1. Task-Management Resources

A fifth resource is available in legacy mode for use by system software that uses the hardware-multitasking mechanism to manage more than one task:

- *Task-Gate Descriptor*—This form of gate descriptor holds a reference to a TSS descriptor and is used to control access between tasks.

The task-management resources are described in the following sections.

12.2.1 TSS Selector

TSS selectors are selectors that point to task-state segment descriptors in the GDT. Their format is identical to all other segment selectors, as shown in Figure 12-2.

Bits	Mnemonic	Description
15:3		Selector Index
2	TI	Table Indicator
1:0	RPL	Requestor Privilege Level

Figure 12-2. Task-Segment Selector

The selector format consists of the following fields:

Selector Index. Bits 15:3. The selector-index field locates the TSS descriptor in the global-descriptor table.

Table Indicator (TI) Bit. Bit 2. The TI bit must be cleared to 0, which indicates that the GDT is used. TSS descriptors cannot be located in the LDT. If a reference is made to a TSS descriptor in the LDT, a general-protection exception (#GP) occurs.

Requestor Privilege-Level (RPL) Field. Bits 1:0. RPL represents the privilege level (CPL) the processor is operating under at the time the TSS selector is loaded into the task register.

12.2.2 TSS Descriptor

The TSS descriptor is a system-segment descriptor, and it can be located only in the GDT. The format for an 8-byte, legacy-mode and compatibility-mode TSS descriptor can be found in “System Descriptors” on page 94. The format for a 16-byte, 64-bit mode TSS descriptor can be found in “System Descriptors” on page 99.

The fields within a TSS descriptor (all modes) are described in “Descriptor Format” on page 88. The following additional information applies to TSS descriptors:

- *Segment Limit*—When shadow stacks are not enabled (CR4.CET=0), a TSS descriptor must have a segment limit value of at least 67h, which defines a minimum TSS size of 68h (104 decimal) bytes. If shadow stacks are enabled (CR4.CET=1), the TSS segment limit must be at least 06Bh (for a minimum size of 108 decimal bytes), in order to accommodate the 32-bit shadow stack pointer (SSP). If the limit is less than the specified values, an invalid-TSS exception (#TS) occurs during the task switch. When an I/O-permission bitmap, interrupt-redirection bitmap, or additional state

information is included in the TSS, the limit must be set to a value large enough to enclose that information. In this case, if the TSS limit is not large enough to hold the additional information, a #GP exception occurs when an attempt is made to access beyond the TSS limit. No check for the larger limit is performed during the task switch.

- *Type*—Four system-descriptor types are defined as TSS types, as shown in Table 4-5 on page 94. Bit 9 is used as the descriptor busy bit (B). This bit indicates that the task is busy when set to 1, and available when cleared to 0. Busy tasks are the currently running task and any previous (outer) tasks in a nested-task hierarchy. Task recursion is not supported, and a #GP exception occurs if an attempt is made to transfer control to a busy task. See "Nesting Tasks" on page 382 for additional information.

  In long mode, the 32-bit TSS types (available and busy) are redefined as 64-bit TSS types, and only 64-bit TSS descriptors can be used. Loading the task register with an available 64-bit TSS causes the processor to change the TSS descriptor type to indicate a busy 64-bit TSS. Because long mode does not support task switching, the TSS-descriptor busy bit is never cleared by the processor to indicate an available 64-bit TSS.

  Sixteen-bit TSS types are illegal in long mode. A general-protection exception (#GP) occurs if a reference is made to a 16-bit TSS.

12.2.3 Task Register

The *task register* (TR) points to the TSS location in memory, defines its size, and specifies its attributes. As with the other descriptor-table registers, the TR has two portions. A *visible* portion holds the TSS selector, and a *hidden* portion holds the TSS descriptor. When the TSS selector is loaded into the TR, the processor automatically loads the TSS descriptor from the GDT into the hidden portion of the TR.

The TR is loaded with a new selector using the LTR instruction. The TR is also loaded during a task switch, as described in "Switching Tasks" on page 375.

Figure 12-3 shows the format of the TR in legacy mode.

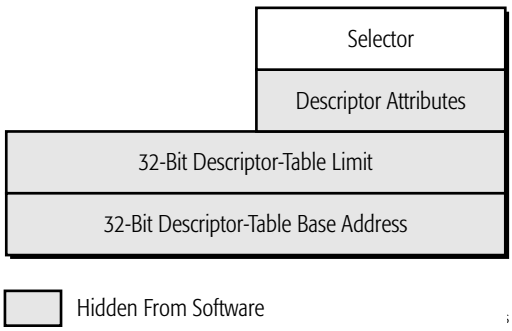

Figure 12-3. TR Format, Legacy Mode

Figure 12-4 shows the format of the TR in long mode (both compatibility mode and 64-bit mode).

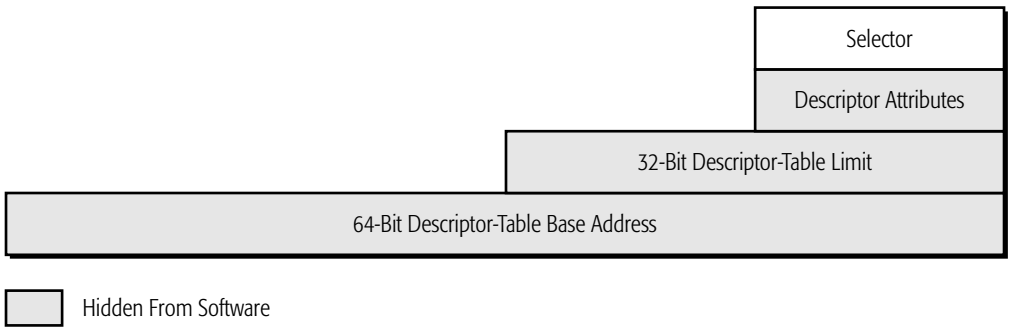

Figure 12-4. TR Format, Long Mode

The AMD64 architecture expands the TSS-descriptor base-address field to 64 bits so that system software running in long mode can access a TSS located anywhere in the 64-bit virtual-address space. The processor ignores the 32 high-order base-address bits when running in legacy mode. Because the TR is loaded from the GDT, the system-segment descriptor format has been expanded to 16 bytes by the AMD64 architecture in support of 64-bit mode. See “System Descriptors” on page 99 for more information on this expanded format. The high-order base-address bits are only loaded from 64-bit mode using the LTR instruction. Figure 12-5 shows the relationship between the TSS and GDT.

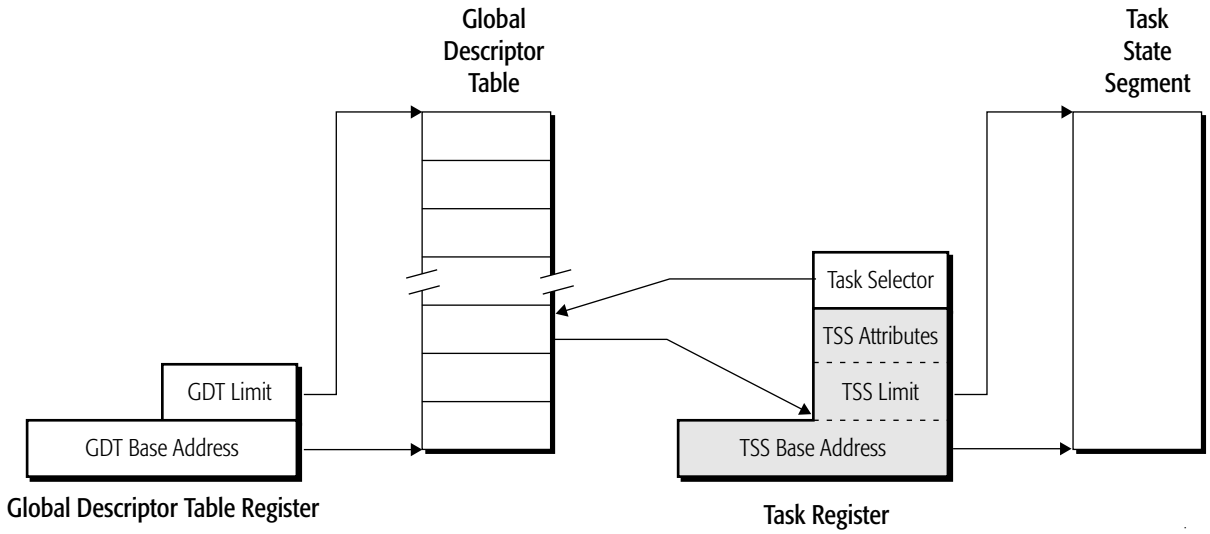

Figure 12-5. Relationship between the TSS and GDT

Long mode requires the use of a 64-bit TSS type, and this type must be loaded into the TR by executing the LTR instruction in *64-bit mode*. Executing the LTR instruction in 64-bit mode loads the TR with the full 64-bit TSS base address from the 16-byte TSS descriptor format (compatibility mode can only load 8-byte system descriptors). A processor running in either compatibility mode or 64-bit mode uses the full 64-bit TR.base address.

12.2.4 Legacy Task-State Segment

The task-state segment (TSS) is a data structure in memory that the processor uses to save and restore the execution state for a task when a task switch occurs. Figure 12-6 on page 368 shows the format of a legacy 32-bit TSS.

Bit Offset 31	16	15	0	Byte Offset

Figure 12-6. Legacy 32-bit TSS

The 32-bit TSS contains three types of fields:

- *Static fields* are read by the processor during a task switch when a new task is loaded, but are not written by the processor when a task is suspended.
- *Dynamic fields* are read by the processor during a task switch when a new task is loaded, and are written by the processor when a task is suspended.
- *Software-defined fields* are read and written by software, but are not read or written by the processor. All but the first 104 bytes of a TSS can be defined for software purposes, minus any additional space required for the optional I/O-permission bitmap and interrupt-redirection bitmap.

TSS fields are not read or written by the processor when the LTR instruction is executed. The LTR instruction loads the TSS descriptor into the TR and marks the task as busy, but it does not cause a task switch.

The TSS fields used by the processor in legacy mode are:

- *Link*—Bytes 01h–00h, dynamic field. Contains a copy of the task selector from the previously-executed task. See “Nesting Tasks” on page 382 for additional information.
- *Stack Pointers*—Bytes 1Bh–04h, static field. Contains the privilege 0, 1, and 2 stack pointers for the task. These consist of the stack-segment selector (SS*n)*, and the stack-segment offset (ESP*n*).
- *CR3*—Bytes 1Fh–1Ch, static field. Contains the page-translation-table base-address (CR3) register for the task.
- *EIP*—Bytes 23h–20h, dynamic field. Contains the instruction pointer (EIP) for the next instruction to be executed when the task is restored.
- *EFLAGS*—Bytes 27h–24h, dynamic field. Contains a copy of the EFLAGS image at the point the task is suspended.
- *General-Purpose Registers*—Bytes 47h–28h, dynamic field. Contains a copy of the EAX, ECX, EDX, EBX, ESP, EBP, ESI, and EDI values at the point the task is suspended.
- *Segment-Selector Registers*—Bytes 59h–48h, dynamic field. Contains a copy of the ES, CS, SS, DS, FS, and GS, values at the point the task is suspended.
- *LDT Segment-Selector Register*—Bytes 63h–60h, static field. Contains the local-descriptor-table segment selector for the task.
- *T (Trap) Bit*—Bit 0 of byte 64h, static field. This bit, when set to 1, causes a debug exception (#DB) to occur on a task switch. See “Breakpoint Instruction (INT3)” on page 398 for additional information.
- *Shadow Stack Pointer (SSP)*—Bytes 6Bh-68h, static field. Contains the 32-bit SSP for the incoming task. Note that the SSP of the outgoing task is not saved in this field.
- *I/O-Permission Bitmap Base Address*—Bytes 67h–66h, static field. This field represents a 16-bit offset into the TSS. This offset points to the beginning of the I/O-permission bitmap, and the end of the interrupt-redirection bitmap.
- *I/O-Permission Bitmap*—Static field. This field specifies protection for I/O-port addresses (up to the 64K ports supported by the processor), as follows:

- Whether the port can be accessed at any privilege level.
- Whether the port can be accessed outside the privilege level established by EFLAGS.IOPL.
- Whether the port can be accessed when the processor is running in virtual-8086 mode.

Because one bit is used per 8-byte I/O-port, this bitmap can take up to 8 Kbytes of TSS space. The bitmap can be located anywhere within the first 64 Kbytes of the TSS, as long as it is above byte 103. The last byte of the bitmap must contain all ones (0FFh). See “I/O-Permission Bitmap” on page 370 for more information.

- *Interrupt-Redirection Bitmap*—Static field. This field defines how each of the 256-possible software interrupts is directed in a virtual-8086 environment. One bit is used for each interrupt, for a total bitmap size of 32 bytes. The bitmap can be located anywhere above byte 103 within the first 64 Kbytes of the TSS. See “Interrupt Redirection of Software Interrupts” on page 281 for information on using this field.

The TSS can be paged by system software. System software that uses the hardware task-switch mechanism must guarantee that a page fault does not occur during a task switch. Because the processor only reads and writes the first 104 TSS bytes during a task switch, this restriction only applies to those bytes. The simplest approach is to align the TSS on a page boundary so that all critical bytes are either present or not present. Then, if a page fault occurs when the TSS is accessed, it occurs before the first byte is read. If the page fault occurs after a portion of the TSS is read, the fault is unrecoverable.

I/O-Permission Bitmap. The I/O-permission bitmap (IOPB) allows system software to grant less-privileged programs access to individual I/O ports, overriding the effect of RFLAGS.IOPL for those devices. When an I/O instruction is executed, the processor checks the IOPB only if the processor is in virtual x86 mode or the CPL is greater than the RFLAGS.IOPL field. Each bit in the IOPB corresponds to a byte I/O port. A word I/O port corresponds to two consecutive IOPB bits, and a doubleword I/O port corresponds to four consecutive IOPB bits. Access is granted to an I/O port of a given size when *all* IOPB bits corresponding to that port are clear. If any bits are set, a #GP occurs.

The IOPB is located in the TSS, as shown by the example in Figure 12-7 on page 371. Each TSS can have a different copy of the IOPB, so access to individual I/O devices can be granted on a task-by-task basis. The I/O-permission bitmap base-address field located at byte 66h in the TSS is an offset into the TSS locating the start of the IOPB. If all 64K IO ports are supported, the IOPB base address must not be greater than 0DFFFh, otherwise accesses to the bitmap cause a #GP to occur. An extra byte must be present after the last IOPB byte. This byte must have all bits set to 1 (0FFh). This allows the processor to read two IOPB bytes each time an I/O port is accessed. By reading two IOPB bytes, the processor can check all bits when unaligned, multi-byte I/O ports are accessed.

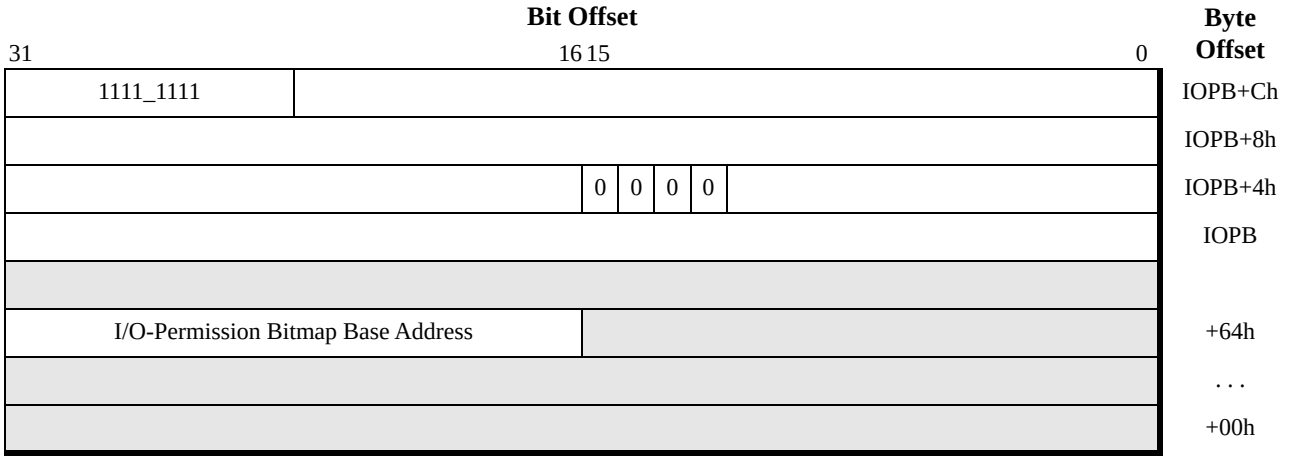

Figure 12-7. I/O-Permission Bitmap Example

Bits in the IOPB sequentially correspond to I/O port addresses. The example in Figure 12-7 shows bits 12 through 15 in the second doubleword of the IOPB cleared to 0. Those bit positions correspond to byte I/O ports 44h through 47h, or alternatively, doubleword I/O port 44h. Because the bits are cleared to zero, software running at any privilege level can access those I/O ports.

By adjusting the TSS limit, it may happen that some ports in the I/O-address space have no corresponding IOPB entry. Ports not represented by the IOPB will cause a #GP exception. Referring again to Figure 12-7, the last IOPB entry is at bit 23 in the fourth IOPB doubleword, which corresponds to I/O port 77h. In this example, all ports from 78h and above will cause a #GP exception, as if their permission bit was set to 1.

12.2.5 64-Bit Task State Segment

Although the hardware task-switching mechanism is not supported in long mode, a 64-bit task state segment (TSS) must still exist. System software must create at least one 64-bit TSS for use after activating long mode, and it must execute the LTR instruction, *in 64-bit mode*, to load the TR register with a pointer to the 64-bit TSS that serves both 64-bit-mode programs and compatibility-mode programs.

The legacy TSS contains several fields used for saving and restoring processor-state information. The legacy fields include general-purpose register, EFLAGS, CR3 and segment-selector register state, among others. Those legacy fields are not supported by the 64-bit TSS. System software must save and restore the necessary processor-state information required by the software-multitasking implementation (if multitasking is supported). Figure 12-8 on page 373 shows the format of a 64-bit TSS.

The 64-bit TSS holds several pieces of information important to long mode that are not directly related to the task-switch mechanism:

- *RSPn*—Bytes 1Bh–04h**.** The full 64-bit canonical forms of the stack pointers (RSP) for privilege levels 0 through 2.

- *ISTn*—Bytes 5Bh–24h**.** The full 64-bit canonical forms of the interrupt-stack-table (IST) pointers. See “Interrupt-Stack Table” on page 276 for a description of the IST mechanism.
- *I/O Map Base Address*—Bytes 67h–66h**.** The 16-bit offset to the I/O-permission bit map from the 64-bit TSS base. The function of this field is identical to that in a legacy 32-bit TSS. See “I/O-Permission Bitmap” on page 370 for more information.

Figure 12-8. Long Mode TSS Format

12.2.6 Task Gate Descriptor (Legacy Mode Only)

Task-gate descriptors hold a selector reference to a TSS and are used to control access between tasks. Unlike a TSS descriptor or other gate descriptors, a task gate can be located in any of the three descriptor tables (GDT, LDT, and IDT). Figure 12-9 shows the format of a task-gate descriptor.

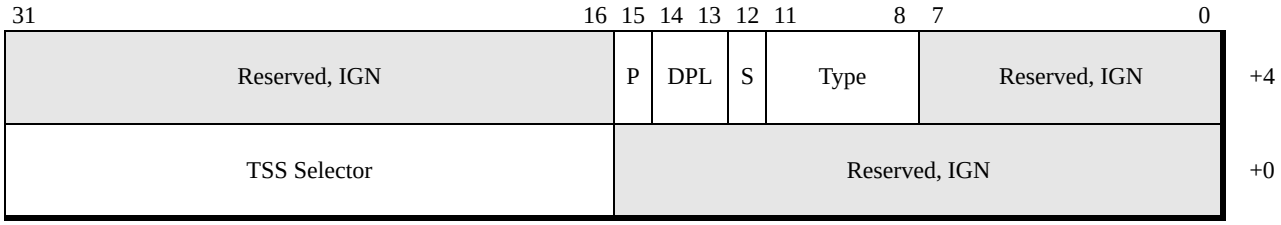

Figure 12-9. Task-Gate Descriptor, Legacy Mode Only

The task-gate descriptor fields are:

- *System (S) and Type*—Bits 12 and 11:8 (respectively) of byte +4. These bits are encoded by software as 00101b to indicate a task-gate descriptor type.
- *Present (P)*—Bit 15 of byte +4. The segment-present bit indicates the segment referenced by the gate descriptor is loaded in memory. If a reference is made to a segment when P=0, a segment-not-present exception (#NP) occurs. This bit is set and cleared by system software and is never altered by the processor.
- *Descriptor Privilege-Level (DPL)*—Bits 14:13 of byte +4. The DPL field indicates the gate-descriptor privilege level. DPL can be set to any value from 0 to 3, with 0 specifying the most privilege and 3 the least privilege.

12.3 Hardware Task-Management in Legacy Mode

This section describes the operation of the task-switch mechanism when the processor is running in legacy mode. None of these features are supported in long mode (either compatibility mode or 64-bit mode).

12.3.1 Task Memory-Mapping

The hardware task-switch mechanism gives system software a great deal of flexibility in managing the sharing and isolation of memory—both virtual (linear) and physical—between tasks.

Segmented Memory. The segmented memory for a task consists of the segments that are loaded during a task switch and any segments that are later accessed by the task code. The hardware task-switch mechanism allows tasks to either share segments with other tasks, or to access segments in isolation from one another. Tasks that share segments actually share a virtual-address (linear-address) space, but they do not necessarily share a physical-address space. When paging is enabled, the virtual-to-physical mapping for each task can differ, as is described in the following section. Shared segments

do share physical memory when paging is disabled, because virtual addresses are used as physical addresses.

A number of options are available to system software that shares segments between tasks:

- Sharing segment descriptors using the GDT. All tasks have access to the GDT, so it is possible for segments loaded in the GDT to be shared among tasks.
- Sharing segment descriptors using a single LDT. Each task has its own LDT, and that LDT selector is automatically saved and restored in the TSS by the processor during task switches. Tasks, however, can share LDTs simply by storing the same LDT selector in multiple TSSs. Using the LDT to manage segment sharing and segment isolation provides more flexibility to system software than using the GDT for the same purpose.
- Copying shared segment descriptors into multiple LDTs. Segment descriptors can be copied by system software into multiple LDTs that are otherwise not shared between tasks. Allowing segment sharing at the segment-descriptor level, rather than the LDT level or GDT level, provides the greatest flexibility to system software.

In all three cases listed above, the actual data and instructions are shared between tasks only when the tasks' virtual-to-physical address mappings are identical.

Paged Memory. Each task has its own page-translation table base-address (CR3) register, and that register is automatically saved and restored in the TSS by the processor during task switches. This allows each task to point to its own set of page-translation tables, so that each task can translate virtual addresses to physical addresses independently. Page translation must be enabled for changes in CR3 values to have an effect on virtual-to-physical address mapping. When page translation is disabled, the tables referenced by CR3 are ignored, and virtual addresses are equivalent to physical addresses.

12.3.2 Switching Tasks

The hardware task-switch mechanism transfers program control to a new task when any of the following occur:

- A CALL or JMP instruction with a selector operand that references a task gate is executed. The task gate can be located in either the LDT or GDT.
- A CALL or JMP instruction with a selector operand that references a TSS descriptor is executed. The TSS descriptor must be located in the GDT.
- A software-interrupt instruction (INT*n*) is executed that references a task gate located in the IDT.
- An exception or external interrupt occurs, and the vector references a task gate located in the IDT.
- An IRET is executed while the EFLAGS.NT bit is set to 1, indicating that a return is being performed from an inner-level task to an outer-level task. The new task is referenced using the selector stored in the current-task link field. See "Nesting Tasks" on page 382 for additional information. The RET instruction *cannot* be used to switch tasks.

When a task switch occurs, the following operations are performed automatically by the processor:

- The processor performs privilege-checking to determine whether the currently-executing program is allowed to access the target task. If this check fails, the task switch is aborted without modifying the processor state, and a general-protection exception (#GP) occurs. The privilege checks performed depend on the cause of the task switch:
  - If the task switch is initiated by a CALL or JMP instruction through a TSS descriptor, the processor checks that both the currently-executing program CPL and the TSS-selector RPL are numerically less-than or equal-to the TSS-descriptor DPL.
  - If the task switch takes place through a task gate, the CPL and task-gate RPL are compared with the task-gate DPL, and no comparison is made using the TSS-descriptor DPL. See “Task Switches Using Task Gates” on page 380.
  - Software interrupts, hardware interrupts, and exceptions all transfer control without checking the task-gate DPL.
  - The IRET instruction transfers control without checking the TSS-descriptor DPL.
- The processor performs limit-checking on the target TSS descriptor to verify that the TSS limit is greater than or equal to:
  - 67h (at least 104 bytes), when shadow stacks are not enabled (CR4.CET=0).
  - 6Bh (at least 108 bytes), when shadow stacks are enabled (CR4.CET=1).

  If this check fails, the task switch is aborted without modifying the processor state, and an invalid-TSS exception (#TS) occurs.
- If shadow stacks are enabled at the current CPL and the task switch was initiated by an IRET instruction, the current SSP must be aligned to 8 bytes. If this check fails, the task switch is aborted without modifying the processor state, and an #TS(current task) exception is generated.
- The current-task state is saved in the TSS. This includes the next-instruction pointer (EIP), EFLAGS, the general-purpose registers, and the segment-selector registers.

  Up to this point, any exception that occurs aborts the task switch without changing the processor state. From this point forward, any exception that occurs does so in the context of the new task. If an exception occurs in the context of the new task during a task switch, the processor finishes loading the new-task state without performing additional checks. The processor transfers control to the #TS handler after this state is loaded, but before the first instruction is executed in the new task. When a #TS occurs, it is possible that some of the state loaded by the processor did not participate in segment access checks. The #TS handler must verify that all segments are accessible before returning to the interrupted task.
- The task register (TR) is loaded with the new-task TSS selector, and the hidden portion of the TR is loaded with the new-task descriptor. The TSS now referenced by the processor is that of the new task.
- The current task is marked as busy. The previous task is marked as available or remains busy, based on the type of linkage. See “Nesting Tasks” on page 382 for more information.
- CR0.TS is set to 1. This bit can be used to save other processor state only when it becomes necessary. For more information, see the next section, “Saving Other Processor State.”

- If shadow stacks are enabled (CR4.CET=1), the following shadow stack actions are performed:

```
saveCsLipSsp = FALSE
checkCsLip   = FALSE
Read CS and EFLAGS from the incoming TSS
newCPL = (EFLAGS.VM == 1) ? 3 : CS.RPL

IF (task switch was initiated by CALL, interrupt or exception)
   {
   IF (ShadowStacksEnabled at current CPL)
     {
     IF ((current CPL == 3) && (newCPL < 3))
        PL3_SSP = SSP     // switching from user to supv
      ELSE
        {
        saveCsLipSsp = TRUE  // all other priv changes
        tempSSP = SSP
        tempLIP = CS.base + EIP
        tempCS  = CS.sel
        }
     }
   } //end task switch initated by CALL,int, or exception

ELSEIF (task switch was initiated by IRET)
   {
   IF (ShadowStacksEnabled at current CPL)
      {
      // pop CS, LIP and SSP from shadow stack
      IF ((newCPL == current CPL) || (newCPL < 3))
        {
        // no priv change, or supv to user/supv
        tempCS  = SSTK_READ_MEM.d [SSP+16]
        tempLIP = SSTK_READ_MEM.d [SSP+8]
        tempSSP = SSTK_READ_MEM.d [SSP]
```

```
        SSP = SSP + 24
        checkCsLip = TRUE
        }
      // check shadow stack token and clear busy bit
       temp_Token = SSTK_READ_MEM.q [SSP]   // read supervisor sstk token
       expected_Token = SSP OR 0x01         // busy bit must be set
       IF (temp_token == expected token)
            SSTK_WRITE_MEM.q [SSP] = SSP    // token OK, clear busy bit
       SSP = 0
      }     // end shadow stacks enabled at current CPL
   } //end task switch initiated by IRET
```

- The new-task state is loaded from the TSS. This includes the next-instruction pointer (EIP), EFLAGS, the general-purpose registers, and the segment-selector registers. The processor clears the segment-descriptor present (P) bits (in the hidden portion of the segment registers) to prevent access into the new segments, until the task switch completes successfully.
- The LDTR and CR3 registers are loaded from the TSS, changing the virtual-to-physical mapping from that of the old task to the new task. Because this is done in the middle of accessing the new TSS, system software must ensure that TSS addresses are translated identically in all tasks.
- The descriptors for all previously-loaded segment selectors are loaded into the hidden portion of the segment registers. This sets or clears the P bits for the segments as specified by the new descriptor values.
- If shadow stacks are enabled (CR4.CET=1), the following shadow stack actions are performed:

```
IF (ShadowStacksEnabled at current CPL)
   {
   IF (EFLAGS.VM == 1)
        EXCEPTION [#TSS(new task selector)]

   IF (task switch was initiated by a CALL, JMP, interrupt or exception)
      {
      newSSP = SSTK_READ_MEM.d [TSS offset 0x68]  // read new SSP
      IF (newSSP[2:0] != 0)                       // must be 8-byte aligned
           EXCEPTION [#TSS(new task selector)]
```

```
      // check token and set busy
      temp_Token = SSTK_READ_MEM.q [newSSP]      // read sstk token
      expected_Token = SSP                       // busy bit must be clear
      IF (temp_token != expected_token)          // token must be valid
            EXCEPTION [#TSS(new task selector)]
      SSTK_WRITE_MEM.q [SSP] = SSP OR 0x01      // valid token, set busy bit
      SSP = newSSP

      IF (saveCsLipSsP == TRUE) // push old CS,LIP,SSP onto new sstk
         {
         SSTK_WRITE_MEM.q [SSP-24] = tempCS
         SSTK_WRITE_MEM.q [SSP-16] = tempLIP
         SSTK_WRITE_MEM.q [SSP-8]  = tempSSP
         SSP = SSP - 24
         }
      } // end task switch initiated by CALL, JMP, interrupt or exception
   } // end shadow stacks enabled at current CPL

ELSEIF (task switch was initiated by an IRET)
   {
   IF (checkCsLip == TRUE)
      {                              // check CS, LIP against shadow stack
      IF (tempCS != CS)
            EXCEPTION [#CP(RETF/IRET)]  // CS must match
      IF (tempLIP != (CS.base + EIP))
            EXCEPTION [#CP(RETF/IRET)]  // LIP must match
      }

   IF ShadowStackEnabled at newCPL
      {
```

```
      IF (!checkCsLip)
         tempSSP = PL3_SSP;
      IF (tempSSP[1:0] != 0)          // SSP must be 4-byte aligned
               EXCEPTION [#CP(RETF/IRET)]
      IF (tempSSP[63:32] != 0)         // and SSP must be <4 GB
               EXCEPTION [#CP(RETF/IRET)]
      SSP = tempSSP
      }  // end shadow stacks enabled at new CPL
   } // end task swtich initiated by IRET
```

If the above steps complete successfully, the processor begins executing instructions in the new task beginning with the instruction referenced by the CS:EIP far pointer loaded from the new TSS. The privilege level of the new task is taken from the new CS segment selector's RPL.

Saving Other Processor State. The processor does not automatically save the registers used by the media or x87 instructions. Instead, the processor sets CR0.TS to 1 during a task switch. Later, when an attempt is made to execute any of the media or x87 instructions while TS=1, a device-not-available exception (#NM) occurs. System software can then save the previous state of the media and x87 registers and clear the CR0.TS bit to 0 before executing the next media/x87 instruction. As a result, the media and x87 registers are saved only when necessary after a task switch.

12.3.3 Task Switches Using Task Gates

When a control transfer to a new task occurs through a task gate, the processor reads the task-gate DPL (DPL_G) from the task-gate descriptor. Two privilege checks, both of which must pass, are performed on DPL_G before the task switch can occur successfully:

- The processor compares the CPL with DPL_G. The CPL must be numerically *less than or equal to* DPL_G for this check to pass. In other words, the following expression must be true: $CPL \leq DPL_G$.
- The processor compares the RPL in the task-gate selector with DPL_G. The RPL must be numerically *less than or equal to* DPL_G for this check to pass. In other words, the following expression must be true: $RPL \leq DPL_G$.

Unlike call-gate control transfers, the processor does not read the DPL from the target TSS descriptor (DPL_S) and compare it with the CPL when a task gate is used.

Figure 12-10 on page 382 shows two examples of task-gate privilege checks. In Example 1, the privilege checks pass:

- The task-gate DPL (DPL_G) is at the lowest privilege (3), specifying that software running at any privilege level (CPL) can access the gate.

- The selector referencing the task gate passes its privilege check because the RPL is numerically less than or equal to DPL_G.

In Example 2, both privilege checks fail:

- The task-gate DPL (DPL_G) specifies that only software at privilege-level 0 can access the gate. The current program does not have enough privilege to access the task gate, because its CPL is 2.
- The selector referencing the task-gate descriptor does not have a high enough privilege to complete the reference. Its RPL is numerically greater than DPL_G.

Although both privilege checks failed in the example, if only one check fails, access into the target task is denied.

Because the legacy task-switch mechanism is not supported in long mode, *software cannot use task gates in long mode*. Any attempt to transfer control to another task using a task gate in long mode causes a general-protection exception (#GP) to occur.

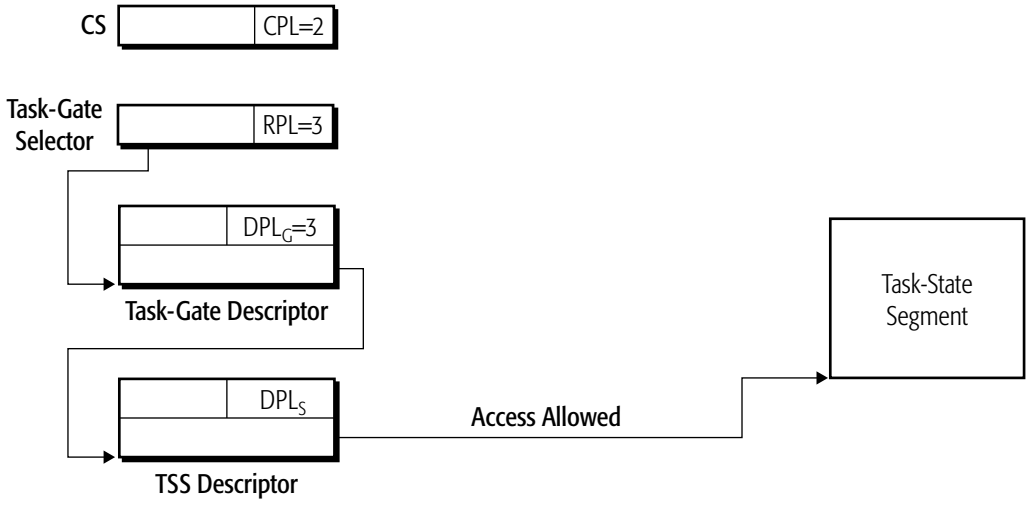

Figure 12-10. Privilege-Check Examples for Task Gates

12.3.4 Nesting Tasks

The hardware task-switch mechanism supports task nesting through the use of EFLAGS *nested-task* (NT) bit and the TSS link-field. The manner in which these fields are updated and used during a task switch depends on how the task switch is initiated:

- The JMP instruction does not update EFLAGS.NT or the TSS link-field. Task nesting is not supported by the JMP instruction.
- The CALL instruction, INT*n* instructions, interrupts, and exceptions can only be performed from outer-level tasks to inner-level tasks. All of these operations set the EFLAGS.NT bit for the new task to 1 during a task switch, and copy the selector for the previous task into the new-task link field.
- An IRET instruction which returns to another task only occurs when the EFLAGS.NT bit for the current task is set to 1, and only can be performed from an inner-level task to an outer-level task. When an IRET results in a task switch, the new task is referenced using the selector stored in the current-TSS link field. The EFLAGS.NT bit for the current task is cleared to 0 during the task switch.

Table 12-1 summarizes the effect various task-switch initiators have on EFLAGS.NT, the TSS link-field, and the TSS-busy bit. (For more information on the busy bit, see the next section, “Preventing Recursion.”)

Table 12-1. Effects of Task Nesting

Task-Switch Initiator	Old Task			New Task		
	EFLAGS.NT	Link (Selector)	Busy	EFLAGS.NT	Link (Selector)	Busy
JMP	—	—	Clear to 0 (was 1)	—	—	Set to 1
CALL INT*n* Interrupt Exception	—		— (Was 1)	Set to 1	Old Task	Set to 1
IRET	Clear to 0 (was 1)	—	Clear to 0 (was 1)	—		

Note:
“—” indicates no change is made.

Programs running at any privilege level can set EFLAGS.NT to 1 and execute the IRET instruction to transfer control to another task. System software can keep control over improperly nested-task switches by initializing the link field of all TSSs that it creates. That way, improperly nested-task switches always transfer control to a known task.

Preventing Recursion. Task recursion is not allowed by the hardware task-switch mechanism. If recursive-task switches were allowed, they would replace a previous task-state image with a newer image, discarding the previous information. To prevent recursion from occurring, the processor uses the busy bit located in the TSS-descriptor type field (bit 9 of byte +4). Use of this bit depends on how the task switch is initiated:

- The JMP instruction clears the busy bit in the old task to 0 and sets the busy bit in the new task to 1. A general-protection exception (#GP) occurs if an attempt is made to JMP to a task with a set busy bit.
- The CALL instruction, INT*n* instructions, interrupts, and exceptions set the busy bit in the new task to 1. The busy bit in the old task remains set to 1, preventing recursion through task-nesting levels. A general-protection exception (#GP) occurs if an attempt is made to switch to a task with a set busy bit.
- An IRET to another task (EFLAGS.NT must be 1) clears the busy bit in the old task to 0. The busy bit in the new task is not altered, because it was already set to 1.

Table 12-1 on page 383 summarizes the effect various task-switch initiators have on the TSS-busy bit.

13 Software Debug and Performance Resources

Testing, debug, and performance optimization consume a significant portion of the time needed to develop a new computer or software product and move it successfully into production. To stay competitive, product developers need tools that allow them to rapidly detect, isolate, and correct problems before a product is shipped. The goal of the debug and performance features incorporated into processor implementations of the AMD64 architecture is to support the tool chain solutions used in software and hardware product development.

The debug and performance resources that can be supported by AMD64 architecture implementations include:

- *Software Debug*—Software-debug facilities include the debug registers (DR0–DR7), debug exception, and breakpoint exception. Additional features are provided using model-specific registers (MSRs). These registers are used to set breakpoints on branches, interrupts, and exceptions and to single step from one branch to the next. The software-debug capability is described in the following section.
- *Performance Monitoring Counters*—Performance monitoring counters (PMCs) are provided to count specific processor hardware events. A set of control registers allow the selection of events to be monitored and a corresponding set of counter registers track the frequency of monitored events. These counters are described in Section 13.2 “Performance Monitoring Counters” on page 400.
- *Instruction-Based Sampling*— Instruction-based sampling is a hardware-based facility that enables system software to capture specific data concerning instruction fetch and instruction execution operation based on random sampling. This facility is described in Section 13.3 “Instruction-Based Sampling” on page 409.
- *Lightweight Profiling*—AMD64 architecture provides instructions that allow user-level programs to manage the gathering of instruction statistics using very little overhead. This facility is described in Section 13.4 “Lightweight Profiling” on page 422.

Although a subset of the facilities listed are available in all processor implementations, the remainder are optional. Support for optional facilities is indicated via CPUID feature bits. The means of determining support for each architected facility is described along with the facility in the sections that follow.

A given processor product may include additional debug and performance monitoring capabilities beyond those which are architecturally-defined. For details see the *BIOS and Kernel Developer’s Guide (BKDG)* or *Processor Programming Reference Manual (PPR)* applicable to your product.

13.1 Software-Debug Resources

Software can program breakpoints into the debug registers, causing a debug exception (#DB) when matches occur on instruction-memory addresses, data-memory addresses, or I/O addresses. The breakpoint exception (#BP) is also supported to allow software to set breakpoints by placing INT3 instructions in the instruction memory for a program. Program control is transferred to the breakpoint exception (#BP) handler when an INT3 instruction is executed.

In addition to the debug features supported by the debug registers (DR0–DR7), the processor also supports features supported by model-specific registers (MSRs). Together, these capabilities provide a rich set of breakpoint conditions, including:

- *Breakpoint On Address Match*—Breakpoints occur when the address stored in a address-breakpoint register matches the address of an instruction or data reference. Up to four address-match breakpoint conditions can be set by software.
- *Single Step All Instructions*—Breakpoints can be set to occur on every instruction, allowing a debugger to examine the contents of registers as a program executes.
- *Single Step Control Transfers*—Breakpoints can be set to occur on control transfers, such as calls, jumps, interrupts, and exceptions. This can allow a debugger to narrow a problem search to a specific section of code before enabling single stepping of all instructions.
- *Breakpoint On Any Instruction*—Breakpoints can be set on any specific instruction using either the address-match breakpoint condition or using the INT3 instruction to force a breakpoint when the instruction is executed.
- *Breakpoint On Task Switch*—Software forces a #DB exception to occur when a task switch is performed to a task with the T bit in the TSS set to 1. Debuggers can use this capability to enable or disable debug conditions for a specific task.

Problem areas can be identified rapidly using the information supplied by the debug registers when breakpoint conditions occur:

- Special conditions that cause a #DB exception are recorded in the DR6 debug-status register, including breakpoints due to task switches and single stepping. The DR6 register also identifies which address-breakpoint register (DR0–DR3) caused a #DB exception due to an address match. When combined with the DR7 debug-control register settings, the cause of a #DB exception can be identified.
- To assist in analyzing the instruction sequence a processor follows in reaching its current state, the source and destination addresses of control-transfer events are saved by the processor. These include branches (calls and jumps), interrupts, and exceptions. Debuggers can use this information to narrow a problem search to a specific section of code before single stepping all instructions.

13.1.1 Debug Registers

The AMD64 architecture supports the legacy debug registers, DR0–DR7. These registers are expanded to 64 bits by the AMD64 architecture. In legacy mode and in compatibility mode, only the lower 32 bits are used. In these modes, writes to a debug register fill the upper 32 bits with zeros, and

reads from a debug register return only the lower 32 bits. In 64-bit mode, all 64 bits of the debug registers are read and written. Operand-size prefixes are ignored.

The debug registers can be read and written only when the current-protection level (CPL) is 0 (most privileged). Attempts to read or write the registers at a lower-privilege level (CPL>0) cause a general-protection exception (#GP).

Several debug registers described below are model-specific registers (MSRs). See “Software-Debug MSRs” on page 672 for a listing of the debug-MSR numbers and their reset values. Some processor implementations include additional MSRs used to support implementation-specific software debug features. For more information on these registers and their capabilities, see the *BIOS and Kernel Developer’s Guide (BKDG)* or *Processor Programming Reference Manual (PPR)* applicable to your product.

13.1.1.1 Address-Breakpoint Registers (DR0-DR3)

Figure 13-1 shows the format of the four address-breakpoint registers, DR0-DR3. Software can load a virtual (linear) address into any of the four registers, and enable breakpoints to occur when the address matches an instruction or data reference. The MOV DR*n* instructions *do not* check that the virtual addresses loaded into DR0–DR3 are in canonical form. Breakpoint conditions are enabled using the debug-control register, DR7 (see “Debug-Control Register (DR7)” on page 389).

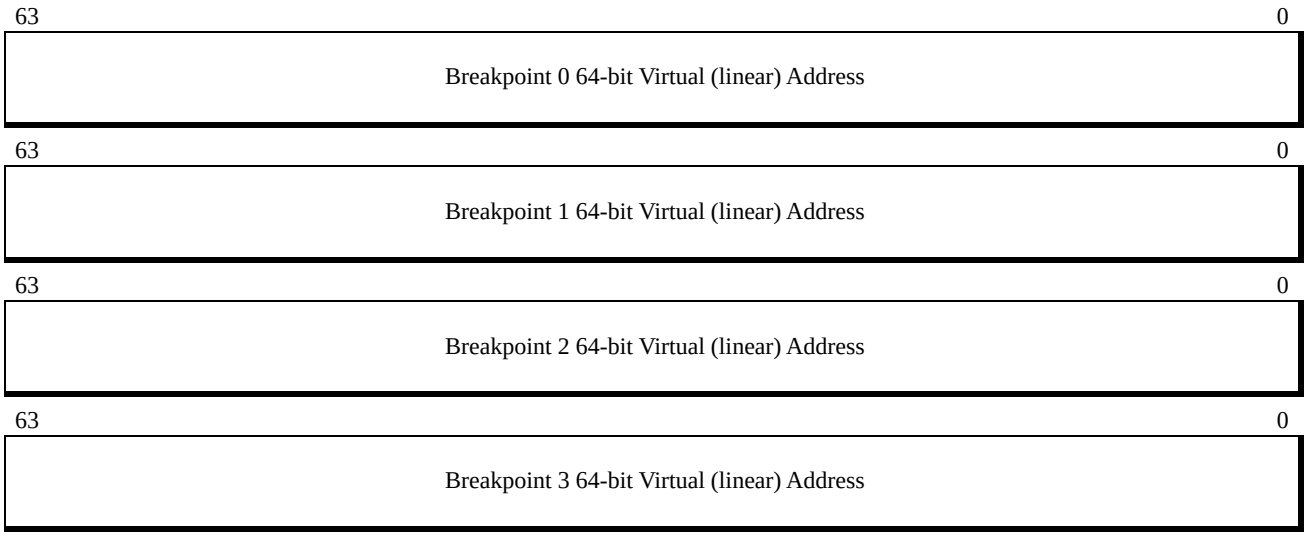

Figure 13-1. Address-Breakpoint Registers (DR0–DR3)

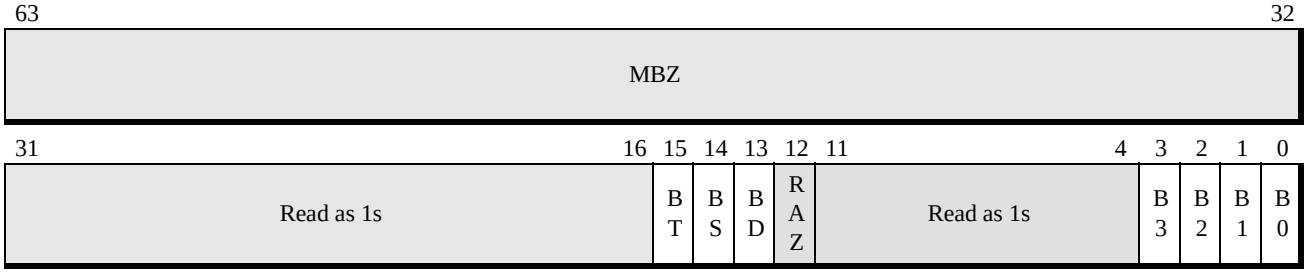
13.1.1.2 Reserved Debug Registers (DR4, DR5)

The DR4 and DR5 registers are reserved and should not be used by software. These registers are aliased to the DR6 and DR7 registers, respectively. When the debug extensions are enabled (CR4[DE] = 1) attempts to access these registers cause an invalid-opcode exception (#UD).

13.1.1.3 Debug-Status Register (DR6)

Figure 13-2 on page 388 shows the format of the debug-status register, DR6. Debug status is loaded into DR6 when an enabled debug condition is encountered that causes a #DB exception.



Bits	Mnemonic	Description	Access type
63:16	—	Reserved	MBZ
15	BT	Breakpoint Task Switch	R/W
14	BS	Breakpoint Single Step	R/W
13	BD	Breakpoint Debug Access Detected	R/W
12	—	Reserved	RAZ
11:4	—	Reserved	RAI
3	B3	Breakpoint #3 Condition Detected	R/W
2	B2	Breakpoint #2 Condition Detected	R/W
1	B1	Breakpoint #1 Condition Detected	R/W
0	B0	Breakpoint #0 Condition Detected	R/W

Figure 13-2. Debug-Status Register (DR6)

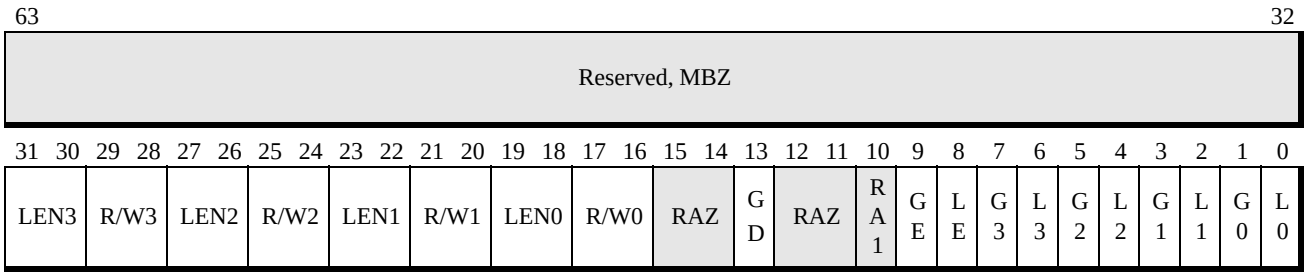
Bits 15:13 of the DR6 register are not cleared by the processor and must be cleared by software after the contents have been read. Register fields are:

- *Breakpoint-Condition Detected (B3–B0)*—Bits 3:0. The processor updates these four bits on every debug breakpoint or general-detect condition. A bit is set to 1 if the corresponding address-breakpoint register detects an enabled breakpoint condition, as specified by the DR7 L*n*, G*n*, R/W*n* and LEN*n* controls, and is cleared to 0 otherwise. For example, B1 (bit 1) is set to 1 if an address-breakpoint condition is detected by DR1.
- *Debug-Register-Access Detected (BD)*—Bit 13. The processor sets this bit to 1 if software accesses any debug register (DR0–DR7) while the general-detect condition is enabled (DR7[GD] = 1).
- *Single Step (BS)*—Bit 14. The processor sets this bit to 1 if the #DB exception occurs as a result of single-step mode (rFLAGS[TF] = 1). Single-step mode has the highest-priority among debug exceptions. Other status bits within the DR6 register can be set by the processor along with the BS bit.
- *Task-Switch (BT)*—Bit 15. The processor sets this bit to 1 if the #DB exception occurred as a result of task switch to a task with a TSS T-bit set to 1.

All remaining bits in the DR6 register are reserved. Reserved bits 31:16 and 11:4 must all be set to 1, while reserved bit 12 must be cleared to 0. In 64-bit mode, the upper 32 bits of DR6 are reserved and must be written with zeros. Writing a 1 to any of the upper 32 bits results in a general-protection exception, #GP(0).

13.1.1.4 Debug-Control Register (DR7)

Figure 13-3 shows the format of the debug-control register, DR7. DR7 is used to establish the breakpoint conditions for the address-breakpoint registers (DR0–DR3) and to enable debug exceptions for each address-breakpoint register individually. DR7 is also used to enable the general-detect breakpoint condition.



Bits	Mnemonic	Description	Access type
63:32	—	Reserved	MBZ
31:30	LEN3	Length of Breakpoint #3	R/W
29:28	R/W3	Type of Transaction(s) to Trap	R/W
27:26	LEN2	Length of Breakpoint #2	R/W
25:24	R/W2	Type of Transaction(s) to Trap	R/W
23:22	LEN1	Length of Breakpoint #1	R/W
21:20	R/W1	Type of Transaction(s) to Trap	R/W
19:18	LEN0	Length of Breakpoint #0	R/W
17:16	R/W0	Type of Transaction(s) to Trap	R/W
15:14	—	Reserved	RAZ
13	GD	General Detect Enabled	R/W
12:11	—	Reserved	RAZ
10	—	Reserved	RA1
9	GE	Global Exact Breakpoint Enabled	R/W
8	LE	Local Exact Breakpoint Enabled	R/W
7	G3	Global Exact Breakpoint #3 Enabled	R/W
6	L3	Local Exact Breakpoint #3 Enabled	R/W
5	G2	Global Exact Breakpoint #2 Enabled	R/W
4	L2	Local Exact Breakpoint #2 Enabled	R/W
3	G1	Global Exact Breakpoint #1 Enabled	R/W
2	L1	Local Exact Breakpoint #1 Enabled	R/W
1	G0	Global Exact Breakpoint #0 Enabled	R/W
0	L0	Local Exact Breakpoint #0 Enabled	R/W

Figure 13-3. Debug-Control Register (DR7)

The fields within the DR7 register are all read/write. These fields are:

- *Local-Breakpoint Enable (L3–L0)*—Bits 6, 4, 2, and 0 (respectively). Software individually sets these bits to 1 to enable debug exceptions to occur when the corresponding address-breakpoint register (DR*n*) detects a breakpoint condition while executing the *current* task. For example, if L1 (bit 2) is set to 1 and an address-breakpoint condition is detected by DR1, a #DB exception occurs. These bits are cleared to 0 by the processor when a hardware task-switch occurs.
- *Global-Breakpoint Enable (G3–G0)*—Bits 7, 5, 3, and 1 (respectively). Software sets these bits to 1 to enable debug exceptions to occur when the corresponding address-breakpoint register (DR*n*) detects a breakpoint condition while executing *any* task. For example, if G1 (bit 3) is set to 1 and an address-breakpoint condition is detected by DR1, a #DB exception occurs. These bits are never cleared to 0 by the processor.
- *Local-Enable (LE)*—Bit 8. Software sets this bit to 1 in legacy implementations to enable exact breakpoints while executing the *current* task. This bit is ignored by implementations of the AMD64 architecture. All breakpoint conditions, except certain string operations preceded by a repeat prefix, are exact.
- *Global-Enable (GE)*—Bit 9. Software sets this bit to 1 in legacy implementations to enable exact breakpoints while executing *any* task. This bit is ignored by implementations of the AMD64 architecture. All breakpoint conditions, except certain string operations preceded by a repeat prefix, are exact.
- *General-Detect Enable (GD)*—Bit 13. Software sets this bit to 1 to cause a debug exception to occur when an attempt is made to execute a MOV DR*n* instruction to any debug register (DR0–DR7). This bit is cleared to 0 by the processor when the #DB handler is entered, allowing the handler to read and write the DR*n* registers. The #DB exception occurs before executing the instruction, and DR6[BD] is set by the processor. Software debuggers can use this bit to prevent the currently-executing program from interfering with the debug operation.
- *Read/Write (R/W3–R/W0)*—Bits 29:28, 25:24, 21:20, and 17:16 (respectively). Software sets these fields to control the breakpoint conditions used by the corresponding address-breakpoint registers (DR*n*). For example, control-field R/W1 (bits 21:20) controls the breakpoint conditions for the DR1 register. The R/W*n* control-field encodings specify the following conditions for an address-breakpoint to occur:
  - 00—Only on instruction execution.
  - 01—Only on data write.
  - 10—This encoding is further qualified by CR4[DE] as follows:
    . CR4[DE] = 0—Condition is undefined.
    . CR4[DE] = 1—Only on I/O read or I/O write.
  - 11—Only on data read or data write.
- *Length (LEN3–LEN0)*—Bits 31:30, 27:26, 23:22, and 19:18 (respectively). Software sets these fields to control the range used in comparing a memory address with the corresponding address-breakpoint register (DR*n*). For example, control-field LEN1 (bits 23:22) controls the breakpoint-comparison range for the DR1 register.

The value in DR*n* defines the low-end of the address range used in the comparison. LEN*n* is used to mask the low-order address bits in the corresponding DR*n* register so that they are not used in the address comparison. To work properly, breakpoint boundaries must be aligned on an address corresponding to the range size specified by LEN*n*. The LEN*n* control-field encodings specify the following address-breakpoint-comparison ranges:

- 00—1 byte.
- 01—2 byte, must be aligned on a word boundary.
- 10—8 byte, must be aligned on a quadword boundary. (Long mode only; otherwise undefined.)
- 11—4 byte, must be aligned on a doubleword boundary.

If the R/W*n* field is used to specify instruction breakpoints (R/W*n*=00), the corresponding LEN*n* field must be set to 00. Setting LEN*n* to any other value produces undefined results.

All remaining bits in the DR7 register are reserved. Reserved bits 15:14 and 12:11 must all be cleared to 0, while reserved bit 10 must be set to 1. In 64-bit mode, the upper 32 bits of DR7 are reserved and must be written with zeros. Writing a 1 to any of the upper 32 bits results in a general-protection #GP(0) exception.

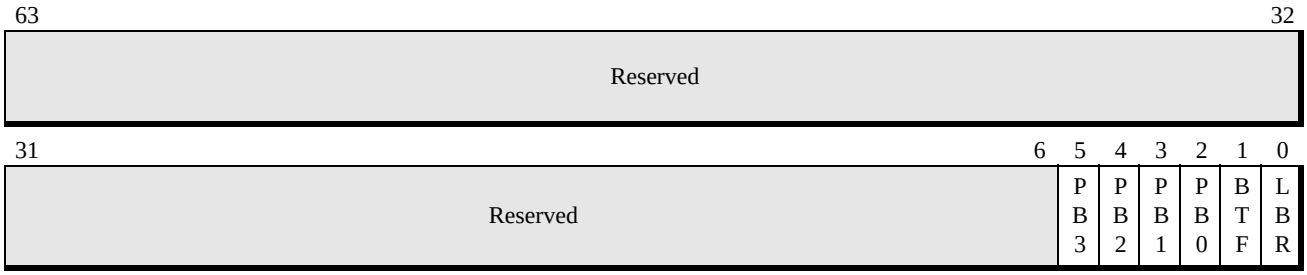
13.1.1.5 64-Bit-Mode Extended Debug Registers

In 64-bit mode, additional encodings for debug registers are available. The R bit of the REX prefix is used to modify the ModRM *reg* field when that field encodes a control register. These additional encodings enable the processor to address DR8–DR15.

Access to the DR8–DR15 registers is implementation-dependent. The architecture does not require any of these extended debug registers to be implemented. Any attempt to access an unimplemented register results in an invalid-opcode exception (#UD).

13.1.1.6 Debug-Control MSR (DebugCtl)

Figure 13-4 on page 392 shows the format of the debug-control MSR (DebugCtl). DebugCtl provides additional debug controls over control-transfer recording and single stepping, and external-breakpoint reporting and trace messages. DebugCtl is read and written using the RDMSR and WRMSR instructions.



Bits	Mnemonic	Description	R/W
63:6	Reserved		
5	PB3	Performance Monitoring Pin Control	R/W
4	PB2	Performance Monitoring Pin Control	R/W
3	PB1	Performance Monitoring Pin Control	R/W
2	PB0	Performance Monitoring Pin Control	R/W
1	BTF	Branch Single Step	R/W
0	LBR	Last-Branch Record	R/W

Figure 13-4. Debug-Control MSR (DebugCtl)

The fields within the DebugCtl register are:

- *Last-Branch Record (LBR)*—Bit 0, read/write. Software sets this bit to 1 to cause the processor to record the source and target addresses of the last control transfer taken before a debug exception occurs. The recorded control transfers include branch instructions, interrupts, and exceptions. See “Control-Transfer Breakpoint Features” on page 398 for more details on the registers. See Figure 13-5 on page 393 for the format of the control-transfer recording MSRs.
- *Branch Single Step (BTF)*—Bit 1, read/write. Software uses this bit to change the behavior of the rFLAGS[TF] bit. When this bit is cleared to 0, the rFLAGS[TF] bit controls instruction single stepping, (normal behavior). When this bit is set to 1, the rFLAGS[TF] bit controls single stepping on control transfers. The single-stepped control transfers include branch instructions, interrupts, and exceptions. Control-transfer single stepping requires both BTF = 1 and rFLAGS[TF] = 1. See “Control-Transfer Breakpoint Features” on page 398 for more details on control-transfer single stepping.
- *Performance-Monitoring/Breakpoint Pin-Control (PBi)*—Bits 5:2, read/write. Software uses these bits to control the type of information reported by the four external performance-monitoring/breakpoint pins on the processor. When a PB*i* bit is cleared to 0, the corresponding external pin (BP*i*) reports performance-monitor information. When a PB*i* bit is set to 1, the corresponding external pin (BP*i*) reports breakpoint information.

All remaining bits in the DebugCtl register are reserved.

13.1.1.7 Control-Transfer Recording MSRs

Figure 13-5 on page 393 shows the format of the 64-bit control-transfer recording MSRs: LastBranchToIP, LastBranchFromIP, LastIntToIP, and LastIntFromIP. These registers are loaded automatically by the processor when the DebugCtl[LBR] bit is set to 1. These MSRs are read-only.

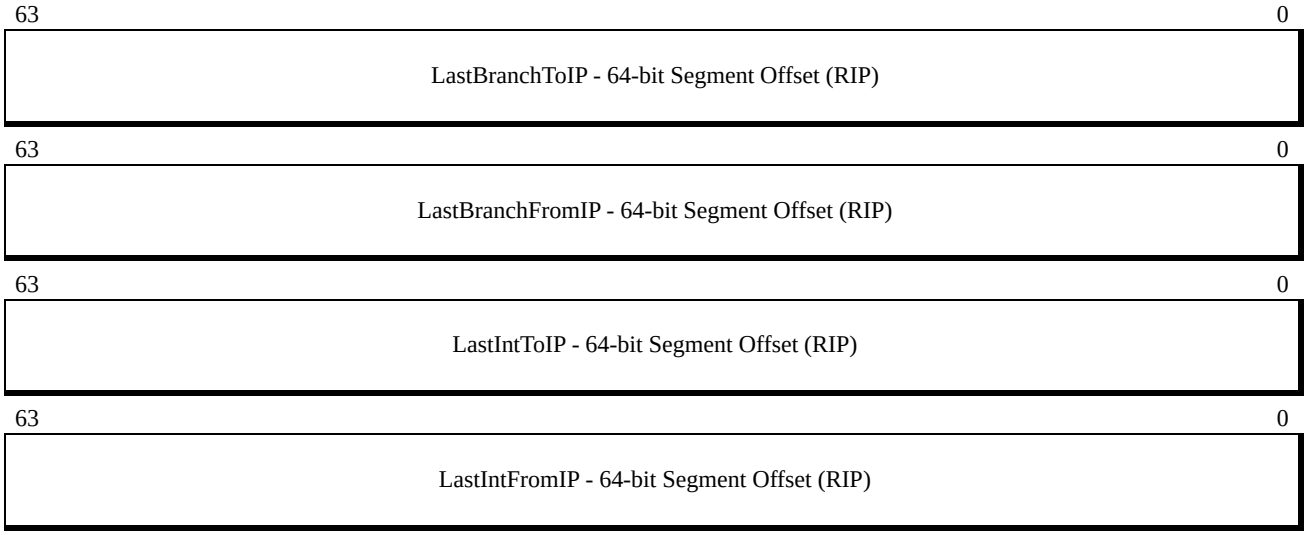


Figure 13-5. Control-Transfer Recording MSRs

13.1.2 Setting Breakpoints

Breakpoints can be set to occur on either instruction addresses or data addresses using the breakpoint-address registers, DR0–DR3 (DR*n*). The values loaded into these registers represent the breakpoint-location virtual address. The debug-control register, DR7, is used to enable the breakpoint registers and to specify the type of access and the range of addresses that can trigger a breakpoint.

Software enables the DR*n* registers using the corresponding local-breakpoint enable (L*n*) or global-breakpoint enable (G*n*) found in the DR7 register. L*n* is used to enable breakpoints only while the current task is active, and it is cleared by the processor when a task switch occurs. G*n* is used to enable breakpoints for all tasks, and it is never cleared by the processor.

The R/W*n* fields in DR7, along with the CR4[DE] bit, specify the type of access required to trigger a breakpoint when an address match occurs on the corresponding DR*n* register. Breakpoints can be set to occur on instruction execution, data reads and writes, and I/O reads and writes. The R/W*n* and CR4[DE] encodings used to specify the access type are described on page 390 of “Debug-Control Register (DR7).”

The LEN*n* fields in DR7 specify the size of the address range used in comparison with data or instruction addresses. LEN*n* is used to mask the low-order address bits in the corresponding DR*n* register so that they are not used in the address comparison. Breakpoint boundaries must be aligned on an address corresponding to the range size specified by LEN*n*. Assuming the access type matches the

type specified by R/W*n*, a breakpoint occurs if any accessed byte falls within the range specified by LEN*n*. For instruction breakpoints, LEN*n* must specify a single-byte range. The LEN*n* encodings used to specify the address range are described on page 390 of "Debug-Control Register (DR7)."

Table 13-1 shows several examples of data accesses, and whether or not they cause a #DB exception to occur based on the breakpoint address in DR*n* and the breakpoint-address range specified by LEN*n*. In this table, R/W*n* always specifies read/write access.

Table 13-1. Breakpoint-Setting Examples

Data-Access Address (hexadecimal)	Access Size (bytes)	Byte-Addresses in Data-Access (hexadecimal)	Breakpoint-Address Range (hexadecimal)	Result
DR*n*=F000, LEN*n*=00 (1 Byte)				
EFFB	8	EFFB, EFFC, EFFD, EFFE, EFFF, F000, F001	F000	#DB
EFFE	2	EFFE, EFFF		—
	4	EFFE, EFFF, F000, F001		#DB
F000	1	F000		
F001	2	F001, F002		—
F005	4	F005, F006, F007, F008		
DR*n*=F004, LEN*n*=11 (4 Bytes)				
EFFB	8	EFFB, EFFC, EFFD, EFFE, EFFF, F000, F001	F004–F007	—
EFFE	2	EFFE, EFFF		
	4	EFFE, EFFF, F000, F001		
F000	1	F000		
F001	2	F001, F002		
F005	4	F005, F006, F007, F008		#DB
DR*n*=F005, LEN*n*=10 (8 Bytes)				
EFFB	8	EFFB, EFFC, EFFD, EFFE, EFFF, F000, F001	F000–F007	#DB
EFFE	2	EFFE, EFFF		—
	4	EFFE, EFFF, F000, F001		#DB
F000	1	F000		
F001	2	F001, F002		
F005	4	F005, F006, F007, F008		

Note:
"—" indicates no #DB occurs.

13.1.3 Using Breakpoints

A debug exception (#DB) occurs when an enabled-breakpoint condition is encountered during program execution. The debug-handler must check the debug-status register (DR6), the conditions enabled by the debug-control register (DR7), and the debug-control MSR (DebugCtl), to determine the #DB cause. The #DB exception corresponds to interrupt vector 1. See "#DB—Debug Exception (Vector 1)" on page 239.

Instruction breakpoints and general-detect conditions cause the #DB exception to occur *before* the instruction is executed, while all other breakpoint and single-stepping conditions cause the #DB exception to occur *after* the instruction is executed. Table 13-2 summarizes where the #DB exception occurs based on the breakpoint condition.

Table 13-2. Breakpoint Location by Condition

Breakpoint Condition	Breakpoint Location
Instruction	Before Instruction is Executed
General Detect	
Data Write Only	After Instruction is Executed[1]
Data Read or Data Write	
I/O Read or I/O Write	
Single Step[1]	After Instruction is Executed
Task Switch	

Note:
1. *Repeated operations (REP prefix) can breakpoint between iterations.*

Instruction breakpoints and general-detect conditions have a lower interrupt-priority than the other breakpoint and single-stepping conditions (see "Priorities" on page 255). Data-breakpoint conditions on the *previous* instruction occur before an instruction-breakpoint condition on the *next* instruction. However, if instruction and data breakpoints can occur as a result of executing a *single* instruction, the instruction breakpoint occurs first (before the instruction is executed), followed by the data breakpoint (after the instruction is executed).

13.1.3.1 Instruction Breakpoints

Instruction breakpoints are set by loading a breakpoint-address register (DR*n*) with the desired instruction virtual-address, and then setting the corresponding DR7 fields as follows:

- L*n* or G*n* is set to 1 to enable the breakpoint for either the local task or all tasks, respectively.
- R/W*n* is set to 00b to specify that the contents of DR*n* are to be compared only with the virtual address of the next instruction to be executed.
- LEN*n* must be set to 00b.

When a #DB exception occurs due to an instruction breakpoint-address in DR*n*, the corresponding B*n* field in DR6 is set to 1 to indicate that a breakpoint condition occurred. The breakpoint occurs before

the instruction is executed, and the breakpoint-instruction address is pushed onto the debug-handler stack. If multiple instruction breakpoints are set, the debug handler can use the B*n* field to identify which register caused the breakpoint.

Returning from the debug handler causes the breakpoint instruction to be executed. Before returning from the debug handler, the rFLAGS[RF] bit should be set to 1 to prevent a reoccurrence of the #DB exception due to the instruction-breakpoint condition. The processor ignores instruction-breakpoint conditions when rFLAGS[RF] = 1, until after the next instruction (in this case, the breakpoint instruction) is executed. After the next instruction is executed, the processor clears rFLAGS[RF].

13.1.3.2 Data Breakpoints

Data breakpoints are set by loading a breakpoint-address register (DR*n*) with the desired data virtual-address, and then setting the corresponding DR7 fields as follows:

- L*n* or G*n* is set to 1 to enable the breakpoint for either the local task or all tasks, respectively.
- R/W*n* is set to 01b to specify that the data virtual-address is compared with the contents of DR*n* only during a memory-write. Setting this field to 11b specifies that the comparison takes place during both memory reads and memory writes.
- LEN*n* is set to 00b, 01b, 11b, or 10b to specify an address-match range of one, two, four, or eight bytes, respectively. Long mode must be active to set LEN*n* to 10b.

When a #DB exception occurs due to a data breakpoint address in DR*n*, the corresponding B*n* field in DR6 is set to 1 to indicate that a breakpoint condition occurred. The breakpoint occurs after the data-access instruction is executed, which means that the original data is overwritten by the data-access instruction. If the debug handler needs to report the previous data value, it must save that value before setting the breakpoint.

Because the breakpoint occurs after the data-access instruction is executed, the address of the instruction following the data-access instruction is pushed onto the debug-handler stack. Repeated string instructions, however, can trigger a breakpoint before all iterations of the repeat loop have completed. When this happens, the address of the string instruction is pushed onto the stack during a #DB exception if the repeat loop is not complete. A subsequent IRET from the #DB handler returns to the string instruction, causing the remaining iterations to be executed. Most implementations cannot report breakpoints exactly for repeated string instructions, but instead report the breakpoint on an iteration later than the iteration where the breakpoint occurred.

13.1.3.3 I/O Breakpoints

I/O breakpoints are set by loading a breakpoint-address register (DR*n*) with the I/O-port address to be trapped, and then setting the corresponding DR7 fields as follows:

- L*n* or G*n* is set to 1 to enable the breakpoint for either the local task or all tasks, respectively.
- R/W*n* is set to 10b to specify that the I/O-port address is compared with the contents of DR*n* only during execution of an I/O instruction. This encoding of R/W*n* is valid only when debug extensions are enabled (CR4[DE] = 1).

- LEN*n* is set to 00b, 01b, or 11b to specify the breakpoint occurs on a byte, word, or doubleword I/O operation, respectively.

The I/O-port address specified by the I/O instruction is zero extended by the processor to 64 bits before comparing it with the DR*n* registers.

When a #DB exception occurs due to an I/O breakpoint in DR*n*, the corresponding B*n* field in DR6 is set to 1 to indicate that a breakpoint condition occurred. The breakpoint occurs after the instruction is executed, which means that the original data is overwritten by the breakpoint instruction. If the debug handler needs to report the previous data value, it must save that value before setting the breakpoint.

Because the breakpoint occurs after the instruction is executed, the address of the instruction following the I/O instruction is pushed onto the debug-handler stack, in most cases. In the case of INS and OUTS instructions that use the repeat prefix, however, the breakpoint occurs after the first iteration of the repeat loop. When this happens, the I/O-instruction address can be pushed onto the stack during a #DB exception if the repeat loop is not complete. A subsequent return from the debug handler causes the next I/O iteration to be executed. If the breakpoint condition is still set, the #DB exception reoccurs after that iteration is complete.

13.1.3.4 Task-Switch Breakpoints

Breakpoints can be set in a task TSS to raise a #DB exception after a task switch. Software enables a task breakpoint by setting the T bit in the TSS to 1. When a task switch occurs into a task with the T bit set, the processor completes loading the new task state. Before the first instruction is executed, the #DB exception occurs, and the processor sets DR6[BT] to 1, indicating that the #DB exception occurred as a result of task breakpoint.

The processor does not clear the T bit in the TSS to 0 when the #DB exception occurs. Software must explicitly clear this bit to disable the task breakpoint. Software should never set the T-bit in the debug-handler TSS if a separate task is used for #DB exception handling, otherwise the processor loops on the debug handler.

13.1.3.5 General-Detect Condition

General-detect is a special debug-exception condition that occurs when software running at any privilege level attempts to access any of the DR*n* registers while DR7[GD] is set to 1. When a #DB exception occurs due to the general-detect condition, the processor clears DR7[GD] and sets DR6[BD] to 1. Clearing DR7[GD] allows the debug handler to access the DR*n* registers without causing infinite #DB exceptions.

A debugger enables general detection to prevent other software from accessing and interfering with the debug registers while they are in use by the debugger. The exception is taken before executing the MOV DR*n* instruction so that the DR*n* contents are not altered.

13.1.4 Single Stepping

Single-step breakpoints are enabled by setting the rFLAGS[TF] bit to 1. TF may be set by the IRET, POPF or SYSRET instructions, with an IRET executed by a debugger being the typical use case. When IRET sets TF, it causes a #DB exception to be taken immediately *after* the *target* of the IRET is executed, returning control to the debugger and thereby single-stepping the target instruction. Setting TF with a POPF instruction also causes a one-instruction delayed #DB exception. When TF is set by SYSRET however, a #DB exception is taken *before* the target instruction executes, hence SYSRET does not provide the single-stepping behavior of IRET.

When a #DB exception occurs due to single stepping, the processor clears rFLAGS[TF] before entering the debug handler, so that the debug handler itself is not single stepped. The processor also sets DR6[BS] to 1, which indicates that the #DB exception occurred as a result of single stepping. The rFLAGS image pushed onto the debug-handler stack has the TF bit set, and single stepping resumes when a subsequent IRET pops the stack image into the rFLAGS register.

Single-step breakpoints have a higher priority than external interrupts. If an external interrupt occurs during single stepping, control is transferred to the #DB handler first, causing the rFLAGS[TF] bit to be cleared. Next, before the first instruction in the debug handler is executed, the processor transfers control to the pending-interrupt handler. This allows external interrupts to be handled outside of single-step mode.

The INT*n*, INT3, and INTO instructions clear the rFLAGS[TF] bit when they are executed. If a debugger is used to single-step software that contains these instructions, it must emulate them instead of executing them.

The single-step mechanism can also be set to single step only control transfers, rather than single step every instruction. See “Single Stepping Control Transfers” on page 399 for additional information.

13.1.5 Breakpoint Instruction (INT3)

The INT3 instruction, or the INT*n* instruction with an operand of 3, can be used to set breakpoints that transfer control to the breakpoint-exception (#BP) handler rather than the debug-exception handler. When a debugger uses the breakpoint instructions to set breakpoints, it does so by replacing the first bytes of an instruction with the breakpoint instruction. The debugger replaces the breakpoint instructions with the original-instruction bytes to clear the breakpoint.

INT3 is a single-byte instruction while INT*n* with an operand of 3 is a two-byte instruction. The instructions have slightly different effects on the breakpoint exception-handler stack. See “#BP—Breakpoint Exception (Vector 3)” on page 240 for additional information on this exception.

13.1.6 Control-Transfer Breakpoint Features

A control transfers is accomplished by using one of following instructions:

- JMP, CALL, RET
- J*cc*, J*r*CXZ, LOOP*cc*

- JMPF, CALLF, RETF
- INT*n*, INT 3, INTO, ICEBP
- Exceptions, IRET
- SYSCALL, SYSRET, SYSENTER, SYSEXIT
- INTR, NMI, SMI, RSM

13.1.6.1 Recording Control Transfers

Software enables control-transfer recording by setting DebugCtl[LBR] to 1. When this bit is set, the processor updates the recording MSRs automatically when control transfers occur:

- *LastBranchFromIP and LastBranchToIP Registers*—On branch instructions, the LastBranchFromIP register is loaded with the segment offset of the branch instruction, and the LastBranchToIP register is loaded with the first instruction to be executed after the branch. On interrupts and exceptions, the LastBranchFromIP register is loaded with the segment offset of the interrupted instruction, and the LastBranchToIP register is loaded with the offset of the interrupt or exception handler.
- *LastIntFromIP and LastIntToIP Registers*—The processor loads these from the LastBranchFromIP register and the LastBranchToIP register, respectively, when most interrupts and exceptions are taken. These two registers are not updated, however, when #DB or #MC exceptions are taken, or the ICEBP instruction is executed.

The processor automatically disables control-transfer recording when a debug exception (#DB) occurs by clearing DebugCtl[LBR] to 0. The contents of the control-transfer recording MSRs are not altered by the processor when the #DB occurs. Before exiting the debug-exception handler, software can set DebugCtl[LBR] to 1 to re-enable the recording mechanism.

Debuggers can trace a control transfer backward from a bug to its source using the recording MSRs and the breakpoint-address registers. The debug handler does this by updating the breakpoint registers from the recording MSRs after a #DB exception occurs, and restarting the program. The program takes a #DB exception on the previous control transfer, and this process can be repeated. The debug handler cannot simply copy the contents of the recording MSR into the breakpoint-address register. The recording MSRs hold segment offsets, while the debug registers hold virtual (linear) addresses. The debug handler must calculate the virtual address by reading the code-segment selector (CS) from the interrupt-handler stack, then reading the segment-base address from the CS descriptor, and adding that base address to the offset in the recording MSR. The calculated virtual-address can then be used as a breakpoint address.

13.1.6.2 Single Stepping Control Transfers

Software can enable control-transfer single stepping by setting DebugCtl[BTF] to 1 and rFLAGS[TF] to 1. The processor automatically disables control-transfer single stepping when a debug exception (#DB) occurs by clearing DebugCtl[BTF]. rFLAGS[TF] is also cleared when a #DB exception occurs. Before exiting the debug-exception handler, software must set both DebugCtl[BTF] and rFLAGS[TF] to 1 to restart single stepping.

When enabled, this single-step mechanism causes a #DB exception to occur on every branch instruction, interrupt, or exception. Debuggers can use this capability to perform a “coarse” single step across blocks of code (bound by control transfers), and then, as the problem search is narrowed, switch into a “fine” single-step mode on every instruction (DebugCtl[BTF] = 0 and rFLAGS[TF] = 1).

Debuggers can use both the single-step mechanism and recording mechanism to support full backward and forward tracing of control transfers.

13.1.7 Debug Breakpoint Address Masking

The Breakpoint Address Extension feature extends the DR[0-3] breakpoint capabilities. Processors with this extension support address mask registers corresponding to each of the DR[0-3] breakpoint registers, in the form of DR[0-3]_ADDR_MASK MSRs. These masks may be used to increase the range of breakpoints by excluding address bits from the breakpoint match. Each bit set to one excludes the corresponding address bit from the breakpoint comparison. Mask bits 11:0 may be used to expand instruction fetch breakpoint ranges up to a 4KB page, while mask bits 31:12 have no effect on instruction breakpoints. For DR0 only, the full mask field (31:0) may be used to qualify data breakpoint matches. This extension is signified by CPUID Fn8000_0001_ECX[26]=1.

An additional extension expands the data breakpoint masking capability of DR0 to the other breakpoint registers, and extends instruction breakpoint masking to bits 31:0 for all registers. This is signified by CPUID Fn8000_0001_ECX[30]=1.

13.2 Performance Monitoring Counters

The AMD64 architecture supports a set of hardware-based performance-monitoring counters (PMCs) that can be utilized to measure the frequency or duration of certain hardware events. MSRs allow the selection of events to be monitored and include a set of corresponding counter registers that accumulate a count of monitored events.

Software tools can use these counters to identify performance bottlenecks, such as sections of code that have high cache-miss rates or frequently mispredicted branches. This information can then be used as a guide for improving overall performance or eliminating performance problems through software optimizations or hardware-design improvements.

Software performance analysis tools often require a means to time-stamp an event or measure elapsed time between two events. The time-stamp counter provides this capability. See Section 13.2.4 “Time-Stamp Counter” on page 407.

The registers used in support of performance monitoring are model-specific registers (MSRs). See “Model-Specific Registers (MSRs)” on page 59 for a general discussion of MSRs and “Performance-Monitoring MSRs” on page 673 for a listing of the performance-monitoring MSR numbers and their reset values.

13.2.1 Performance Counter MSRs

The legacy architecture defines four performance counters (PerfCtr*n*) and corresponding event-select registers (PerfEvtSel*n*). Extensions add northbridge and L2 cache performance monitoring counters. Each *PerfCtr register counts events selected by the corresponding *PerfEvtSel register.

An architectural extension augments the number of performance and event-select registers by adding two more processor counter / event-select pairs. Further extensions add four counter / event-select pairs dedicated to counting northbridge (NB) events and four counter / event-select pairs dedicated to counting L2 cache (L2I) events.

Core logic includes instruction execution pipelines, execution units, and caches closest to the execution hardware. The NB includes logic that routes data traffic between caches, external I/O devices, and a system memory controller which reads and writes system memory (usually implemented as external DRAM). The L2 cache is a cache that is further away from the processor core than the L1 cache or caches. This cache is normally larger than the L1 cache(s) and requires more processor cycles to access. An L2 cache may be shared between physical processor cores.

All implementations support the base set of four performance counter / event-select pairs. Support for the extended performance monitoring registers and the performance-related events selectable via the *PerfEvtSel registers vary by implementation and are described in the *BIOS and Kernel Developer's Guide (BKDG)* or *Processor Programming Reference Manual (PPR)* for that processor.

Core performance counters are used to count processor core events, such as data-cache misses, or the duration of events, such as the number of clocks it takes to return data from memory after a cache miss. During event counting, hardware increments a counter each time it detects an occurrence of a specified event. During duration measurement, hardware counts the number of processor clock cycles required to complete a specific hardware function.

NB performance counters are used to count events that occur within the northbridge. The L2I performance counters are used to count events associated with accessing the L2 cache.

Performance counters and event-select registers are implemented as machine-specific registers (MSRs). The base set of four PerfCtr and PerfEvtSel registers are accessed via a legacy set of MSRs and the extended set of six core PerfCtr / PerfEvtSel registers are accessed via a different set. Extended core PerfCtr / PerfEvtSel registers 0–3 alias the legacy set.

Support for the extended set of core PerfCtr registers and associated PerfEvtSel registers, as well as the sets of northbridge and L2 cache counter / event-select pairs are indicated by CPUID feature bits. See "Detecting Hardware Support for Performance Counters" on page 407. The MSR address assignments for the legacy and extended performance / event-select pairs are listed in Appendix A, Section A.6, "Performance-Monitoring MSRs" on page 673.

The length, in bits, of the performance counters is implementation-dependent, but the maximum length supported is 64 bits. Figure 13-6 shows the format of the performance counter registers.

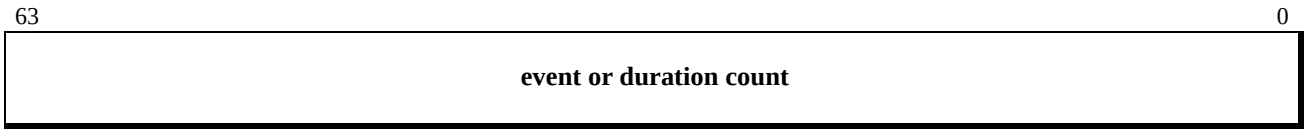

Figure 13-6. Performance Counter Format

For a given processor, all implemented performance counter registers can be read and written by system software running at CPL = 0 using the RDMSR and WRMSR instructions, respectively. The architecture also provides an instruction, RDPMC, which may be employed by user-mode software to read the architected core, northbridge, and L2 performance counters.

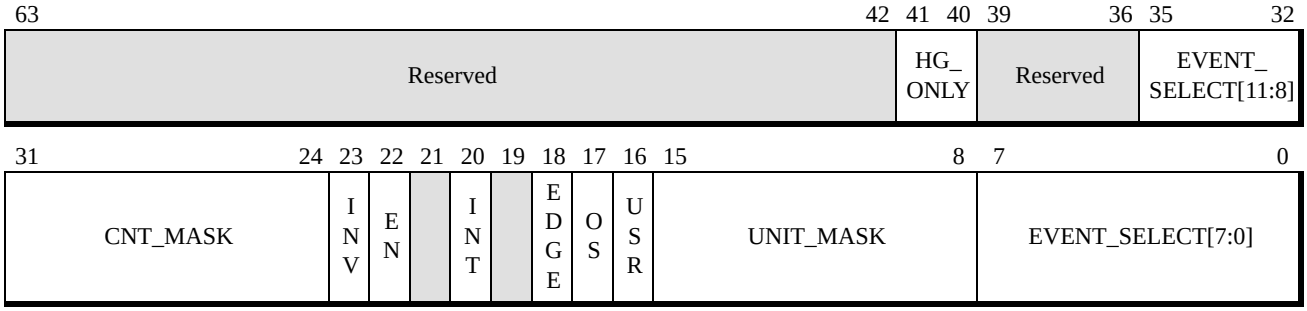
The RDPMC instruction loads the contents of the architected performance counter register specified by the index value contained in the ECX register, into the EDX register and the EAX register. The high 32 bits are returned in EDX, and the low 32 bits are returned in EAX. RDPMC can be executed only at CPL = 0, unless system software enables use of the instruction at all privilege levels. RDPMC can be enabled for use at all privilege levels by setting CR4[PCE] (the *performance-monitor counter-enable* bit) to 1. When CR4[PCE] = 0 and CPL > 0, attempts to execute RDPMC result in a general-protection exception (#GP). For more information on the RDPMC instruction, see the instruction reference page in Volume 3 of this manual.

Writing the performance counters can be useful if software wants to count a specific number of events, and then trigger an interrupt when that count is reached. An interrupt can be triggered when a performance counter overflows (see “Counter Overflow” on page 407 for additional information). Software should use the WRMSR instruction to load the count as a two’s-complement negative number into the performance counter. This causes the counter to overflow after counting the appropriate number of times.

The performance counters are not guaranteed to produce identical measurements each time they are used to measure a particular instruction sequence, and they should not be used to take measurements of very small instruction sequences. The RDPMC instruction is not serializing, and it can be executed out-of-order with respect to other instructions around it. Even when bound by serializing instructions, the system environment at the time the instruction is executed can cause events to be counted before the counter value is loaded into EDX:EAX. The following sections describe the core performance event-select and the northbridge performance event-select registers.

Core Performance Event-Select Registers

The core performance event-select registers (PerfEvtSel*n*) are 64-bit registers used to specify the events counted by the core performance counters, and to control other aspects of their operation. Each performance counter supported by the implementation has a corresponding event-select register that controls its operation. Figure 13-7 below shows the format of the core PerfEvtSel register.



Bits	Mnemonic	Description	R/W
63:42	—	Reserved	
41:40	HG_ONLY	Host/Guest Only	R/W
39:36	—	Reserved	
35:32	EVENT_SELECT[11:8]	Event select bits 11:8	R/W
31:24	CNT_MASK	Counter Mask	R/W
23	INV	Invert Comparison	R/W
22	EN	Counter Enable	R/W
21	—	Reserved	
20	INT	Interrupt Enable	R/W
19	—	Reserved	
18	EDGE	Edge Detect	R/W
17	OS	Operating-System Mode	R/W
16	USR	User Mode	R/W
15:8	UNIT_MASK	Unit Mask	R/W
7:0	EVENT_SELECT[7:0]	Event select bits 7:0	R/W

Figure 13-7. Core Performance Event-Select Register (PerfEvtSel*n*)

The fields shown in Figure 13-7 above are further described below:

- HG_ONLY (Host/Guest Only): read/write. This field qualifies events to be counted based on virtualization operating mode (guest or host). The following table defines how HG_ONLY qualifies the counting of events:

Table 13-3. Host/Guest Only Bits

Host Mode (Bit 41)	Guest Mode (Bit 40)	Events Counted
0	0	All events, irrespective of guest or host mode
0	1	Guest events, if EFER[SVME] = 1
1	0	Host events, if EFER[SVME] = 1
1	1	Guest and host events, if EFER[SVME] = 1

- EVENT_SELECT[11:8] (Event Select): read/write. This field extends the EVENT_SELECT field from 8 bits to 12 bits. See EVENT_SELECT[7:0] below.

- CNT_MASK (Counter Mask): read/write. Used with INV bit to control the counting of multiple events that occur within one clock cycle. The table below describes this:

Table 13-4. Count Control Using CNT_MASK and INV

CNT_MASK	INV	Increment Value
00h	–	Corresponding PerfCtr[*n*] register is incremented by the number of events occurring in a clock cycle. If the number of events is equal to or greater than 32, the count register is incremented by 32.
FFh:01h[1]	0	Corresponding PerfCtr[*n*] register is incremented by 1, if the number of events occurring in a clock cycle is greater than or equal to the CNT_MASK value.
	1	Corresponding PerfCtr[*n*]register is incremented by 1, if the number of events occurring in a clock cycle is less than the CNT_MASK value.
Note 1: Maximum CNT_MASK value (in the range FFh:01h is implementation dependent. Consult applicable BIOS and Kernel Developer's Guide (BKDG) or Processor Programming Reference Manual (PPR) .		

- INV (Invert Comparison): read/write. Used with CNT_MASK field to control the counting of multiple events within one clock cycle. See table above.
- EN (Counter Enable): read/write. Software sets this bit to 1 to enable the PerfEvtSel*n* register, and counting in the corresponding PerfCtr*n* register. Clearing this bit to 0 disables the register pair.
- INT (Interrupt Enable): read/write. Software sets this bit to 1 to enable an interrupt to occur when the performance counter overflows (see "Counter Overflow" on page 407 for additional information). Clearing this bit to 0 disables the triggering of the interrupt.
- EDGE (Edge Detect): read/write. Software sets this bit to 1 to count the number of edge transitions from the negated to asserted state. This feature is useful when coupled with event-duration monitoring, as it can be used to calculate the average time spent in an event. Clearing this bit to 0 disables edge detection.
- OS (Operating-System Mode) and USR (User Mode): read/write. Software uses these bits to control the privilege level at which event counting is performed according to Table 13-5.

Table 13-5. Operating-System Mode and User Mode Bits

OS (Bit 17)	USR (Bit 16)	Event Counting
0	0	No counting.
0	1	Only at CPL > 0.
1	0	Only at CPL = 0.
1	1	At all privilege levels.

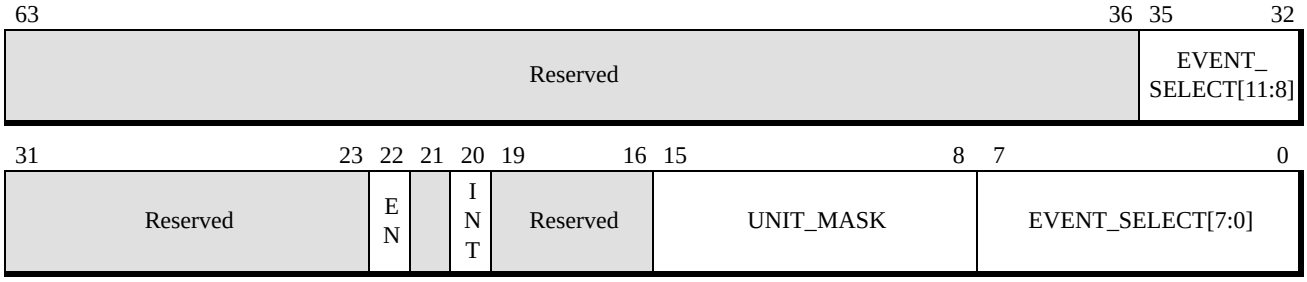
- UNIT_MASK (Unit Mask): read/write. This field further specifies or qualifies the event specified by the EVENT_SELECT field. Depending on implementation, it may be used to specify a sub-event within the class specified by the EVENT_SELECT field or it may act as bit mask and be used to specify a number of events within the class to be monitored simultaneously.

- EVENT_SELECT[7:0] (Event Select [7:0]): read/write. This field concatenated with EVENT_SELECT[11:8] specifies the event or event duration to be counted by the corresponding PerfCtr[*n*] register. The events that can be monitored are implementation dependent. In some implementations, support for a specific EVENT_SELECT value may restricted to a subset of the available performance counters. For more information, see the *BIOS and Kernel Developer's Guide (BKDG)* or *Processor Programming Reference Manual (PPR)* applicable to your product.

The core performance event-select registers can be read and written only by system software running at CPL = 0 using the RDMSR and WRMSR instructions, respectively. Any attempt to read or write these registers at CPL > 0 causes a general-protection exception to occur.

Northbridge (NB) Performance Event-Select Registers

The NB performance event-select registers (NB_PerfEvtSel*n*) are 64-bit registers used to specify the events counted by the northbridge performance counters, and to control other aspects of their operation. Each performance counter supported by the implementation has a corresponding event-select register that controls its operation. Figure 13-8 below shows the format of the NB_PerfEvtSel*n* register.



Bits	Mnemonic	Description	R/W
63:36	—	Reserved	
35:32	EVENT_SELECT[11:8]	Event select bits [11:8]	R/W

7:0	EVENT_SELECT[7:0]	Event select bits [7:0]	R/W

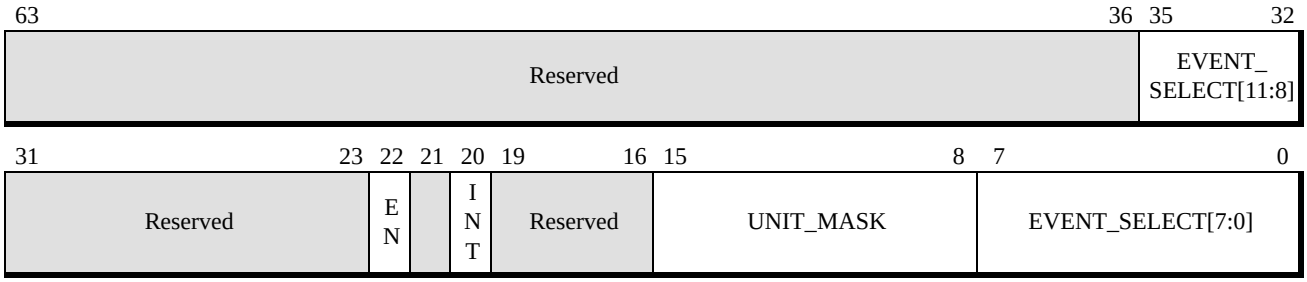
Figure 13-8. Northbridge Performance Event-Select Register (NB_PerfEvtSel*n*)

The northbridge performance event-select registers can be read and written only by system software running at CPL = 0 using the RDMSR and WRMSR instructions, respectively. Any attempt to read or write these registers at CPL > 0 causes a general-protection exception to occur.

For more information on the defined fields within the NB_PerfEvtSel*n* registers, see the *BIOS and Kernel Developer's Guide (BKDG)* or *Processor Programming Reference Manual (PPR)* applicable to your product.

L2 Cache (L2I) Performance Event-Select Registers

The L2 cache performance event-select registers (L2I_PerfEvtSel*n*) are 64-bit registers used to specify the events counted by the L2 cache performance counters, and to control other aspects of their operation. Each performance counter supported by the implementation has a corresponding event-select register that controls its operation. Figure 13-9 below shows the format of the L2I_PerfEvtSel*n* register.



Bits	Mnemonic	Description	R/W
63:36	—	Reserved	
35:32	EVENT_SELECT[11:8]	Event select bits [11:8]	R/W
31:23	—	Reserved	
22	EN	Counter Enable	R/W
21	—	Reserved	
20	INT	Interrupt Enable	R/W
19:16	—	Reserved	
15:8	UNIT_MASK	Unit Mask	R/W
7:0	EVENT_SELECT[7:0]	Event select bits [7:0]	R/W

Figure 13-9. L2 Cache Performance Event-Select Register (L2I_PerfEvtSel*n*)

The L2 cache performance event-select registers can be read and written only by system software running at CPL = 0 using the RDMSR and WRMSR instructions, respectively. Any attempt to read or write these registers at CPL > 0 causes a general-protection exception to occur.

For more information on the defined fields within the L2I_PerfEvtSel*n* registers, see the *BIOS and Kernel Developer's Guide (BKDG)* or *Processor Programming Reference Manual (PPR)* applicable to your product.

Instructions Retired Performance counter

This is a dedicated counter that is always counting instructions retired. It exists at MSR address C000_00E9. It is enabled by setting a 1 to HWCR[30] and its support is indicated by CPUID Fn8000_0008_EBX[1].

13.2.2 Detecting Hardware Support for Performance Counters

Support for extended core, northbridge, and L2 cache performance counters is implementation-dependent. Support on a given processor implementation can be verified using the CPUID instruction.

CPUID Fn8000_0001_ECX[PerfCtrExtCore] = 1 indicates support for the six architecturally defined extended core performance counters and their associated event-select registers. CPUID Fn8000_0001_ECX[PerfCtrExtNB] = 1 indicates support for the four architecturally defined northbridge performance counter / event-select pairs and CPUID Fn8000_0001_ECX[PerfCtrExtL2I] = 1 indicates support for the four architecturally defined L2 cache performance counter / event-select pairs.

See Section 3.3, “Processor Feature Identification,” on page 71 for more information on using the CPUID instruction.

A given processor may implement other performance measurement MSRs with similar capabilities even if one of the optional architected facilities are not.

13.2.3 Using Performance Counters

13.2.3.1 Starting and Stopping

Performance measurement using the PerfCtr*n*, NB_PerfCtr*n*, and L2I_PerfCtr*n* registers is initiated by setting the corresponding *PerfEvtSel*n*[EN] bit to 1. Counting is stopped by clearing the *PerfEvtSel*n*[EN] bit. Software must initialize the remaining *PerfEvtSel*n* fields with the appropriate setup information before or at the same time EN is set. Counting begins when the WRMSR instruction that sets *PerfEvtSel*n*[EN] to 1 completes execution. Counting stops when the WRMSR instruction that clears the EN bit completes execution.

13.2.3.2 Counter Overflow

Some processor implementations support an interrupt-on-overflow capability that allows an interrupt to occur when one of the *PerfCtr*n* registers overflows. The source and type of interrupt is implementation dependent. Some implementations cause a debug interrupt to occur, while others make use of the local APIC to specify the interrupt vector and trigger the interrupt when an overflow occurs. Software enables or disables the triggering of an interrupt on counter overflow by setting or clearing the *PerfEvtSel*n*[INT] bit.

If system software makes use of the interrupt-on-overflow capability, an interrupt handler must be provided that can record information relevant to the counter overflow. Before returning from the interrupt handler, the performance counter can be re-initialized to its previous state so that another interrupt occurs when the appropriate number of events are counted.

13.2.4 Time-Stamp Counter

The time-stamp counter (TSC) is used to count processor-clock cycles. The TSC is cleared to 0 after a processor reset. After a reset, the TSC is incremented at a rate corresponding to the baseline frequency

of the processor (which may differ from actual processor frequency in low power modes of operation). Each time the TSC is read, it returns a monotonically-larger value than the previous value read from the TSC. When the TSC contains all ones, it wraps to zero. The TSC in a 1-GHz processor counts for almost 600 years before it wraps. Figure 13-10 shows the format of the 64-bit time-stamp counter (TSC).

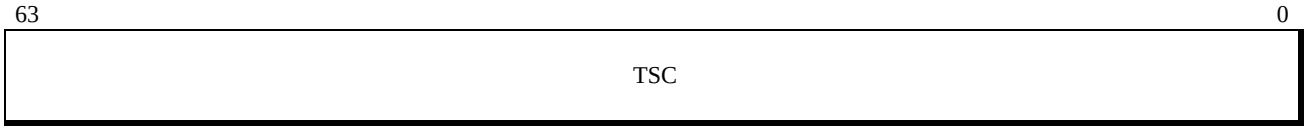


Figure 13-10. Time-Stamp Counter (TSC)

The TSC is a model-specific register that can also be read using one of the special *read time-stamp counter* instructions, RDTSC (Read Time-Stamp Counter) or RDTSCP (Read Time-Stamp Counter and Processor ID). The RDTSC and RDTSCP instructions load the contents of the TSC into the EDX register and the EAX register. The high 32 bits are loaded into EDX, and the low 32 bits are loaded into EAX. The RDTSC and RDTSCP instructions can be executed at any privilege level and from any processor mode. However, system software can disable the RDTSC or RDTSCP instructions for programs that run at CPL > 0 by setting CR4[TSD] (the *time-stamp disable* bit) to 1. When CR4[TSD] = 1 and CPL > 0, attempts to execute RDSTC or RDSTCP result in a general-protection exception (#GP).

The TSC register can be read and written using the RDMSR and WRMSR instructions, respectively. The programmer should use the CPUID instruction to determine whether these features are supported. If EDX bit 4 (as returned by CPUID function 1) is set, then the processor supports TSC, the RDTSC instruction and CR4[TSD]. If EDX bit 27 returned by CPUID function 8000_0001h is set, then the processor supports the RDTSCP instruction.

The TSC register can be used by performance-analysis applications, along with the performance-monitoring registers, to help determine the relative frequency of an event or its duration. Software can also use the TSC to time software routines to help identify candidates for optimization. In general, the TSC should not be used to take very short time measurements, because the resulting measurement is not guaranteed to be identical each time it is made. The RDTSC instruction (unlike the RDTSCP instruction) is not serializing, and can be executed out-of-order with respect to other instructions around it. Even when bound by serializing instructions, the system environment at the time the instruction is executed can cause additional cycles to be counted before the TSC value is loaded into EDX:EAX.

When using the TSC to measure elapsed time, programmers must be aware that for some implementations, the rate at which the TSC is incremented varies based on the processor power management state (Pstate). For other implementations, the TSC increment rate is fixed and is not subject to power-management related changes in processor frequency. CPUID Fn 8000_0007h_EDX[TscInvariant] = 1 indicates that the TSC increment rate is a constant.

For more information on using the CPUID instruction to obtain processor implementation information, see Section 3.3, “Processor Feature Identification,” on page 71.

13.3 Instruction-Based Sampling

Instruction-Based Sampling (IBS) is a hardware facility that can be used to gather specific metrics related to processor instruction fetch and instruction execution activity. Data capture is performed by hardware at a sampling interval specified by values programmed in IBS sampling control registers. The IBS facility can be utilized by software to perform code profiling based on statistical sampling.

There are two independent data gathering components of IBS: instruction fetch sampling and instruction execution sampling. Instruction fetch sampling provides information about instruction address translation look-aside buffer (ITLB) and instruction cache behavior for a randomly selected fetch block, under the control of the IBS Fetch Control Register. Instruction execution sampling provides information about instruction execution behavior by tracking the execution of a single operation (op) that is randomly selected, under the control of the IBS Execution Control Register.

When the programmed interval for fetch sampling has expired, the fetch sampling component of IBS selects and tags the next fetch block. IBS hardware records specific performance information about the tagged fetch. In a similar manner, when the programmed interval for op sampling has expired, the op sampling component of IBS selects and tags the next op being dispatched for execution.

When data collection for the tagged fetch or op is complete, the hardware signals an interrupt. An interrupt handler can then read the performance information that was captured for the fetch or op in IBS MSRs, save it, and re-enable the hardware to take the next sample.

More information about the IBS facility and how software can use it to perform code profiling can be found in the *Software Optimization Guide* for your specific product. The *Software Optimization Guide for AMD Family 15h Processors* is order #47414.

Support for the IBS feature is indicated by the CPUID Fn 8000_0001h_ECX[IBS]. For more information on using the CPUID instruction to obtain processor implementation information, see Section 3.3, “Processor Feature Identification,” on page 71.

13.3.1 IBS Fetch Sampling

When a processor fetches an instruction, it is actually reading a contiguous range of instruction bytes that contains the instruction from memory or from cache. This range of bytes loaded by the processor in one operation is called a *fetch block*. The size and address-alignment characteristics of the fetch block are implementation-dependent. In the following discussion, the term *instruction fetch* or simply *fetch* refers to this operation of reading a fetch block.

Instruction fetch sampling records the following performance information for each tagged fetch:

- If the fetch completed or was aborted
- The number of core clock cycles spent on the fetch

- If the fetch hit or missed the instruction cache
- If the instruction fetch hit or missed the instruction TLBs
- The fetch address translation page size
- The linear and physical address associated with the fetch

IBS selects and tags a fetch at a programmable rate. When enabled by the IBS Fetch Control Register (IbsFetchEn = 1 and IbsFetchVal = 0), an internal 20-bit fetch interval counter increments for every attempted fetch operation. When the value in bits 19:4 of the fetch counter equal the value in the IbsFetchMaxCnt field of the IBS Fetch Control Register, the next fetch block is tagged for data collection.

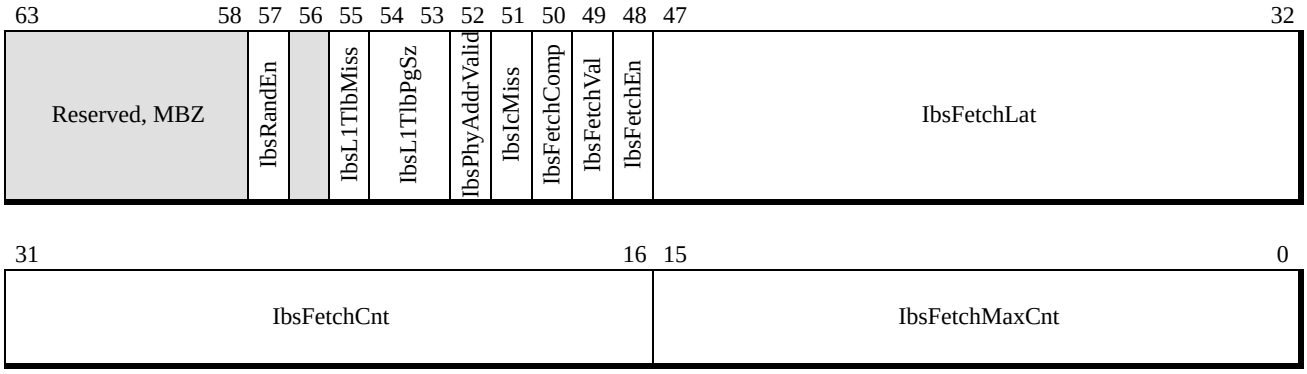
When the tagged fetch completes or is aborted, the status of the fetch is written to the IBS Fetch Control Register and the associated linear address and physical address are written in the IBS Fetch Linear Address Register and IBS Fetch Physical Address Register, respectively. The IbsFetchVal bit is set in the IBS Fetch Control Register and an interrupt is generated as specified by the local APIC.

The interrupt service routine saves the performance information stored in the IBS fetch registers. Software can then initiate another sample by resetting the IbsFetchVal bit in the IBS Fetch Control Register. Hardware initializes bits 19:4 of the internal fetch interval counter with the value in the IbsFetchCnt field. If the IbsFetchCtl[IbsRandEn] bit is set, bits 3:0 of the fetch interval counter are re-initialized by hardware with a pseudo-random value; otherwise bits 3:0 are cleared.

13.3.2 IBS Fetch Sampling Registers

The IBS fetch sampling registers consist of the status and control register (IBS Fetch Control Register) and the associated fetch address registers (IBS Fetch Linear Address Register and IBS Fetch Physical Address Register). The IBS fetch sampling registers are accessed using the RDMSR and WRMSR instructions.

IBS Fetch Control Register



Bit(s)	Field Mnemonic	Descriptive Name	R/W
63:58	—	Reserved, MBZ	
57	IbsRandEn	IBS Randomize Tagging Enable	R/W
56	—	Reserved	
55	IbsL1TlbMiss	IBS Fetch L1 TLB Miss	R/W
54:53	IbsL1TlbPgSz	IBS Fetch L1 TLB Page Size	R/W
52	IbsPhyAddrValid	IBS Fetch Physical Address Valid	R/W
51	IbsIcMiss	IBS Instruction Cache Miss	R/W
50	IbsFetchComp	IBS Fetch Complete	R/W
49	IbsFetchVal	IBS Fetch Valid	R/W
48	IbsFetchEn	IBS Fetch Enable	R/W
47:32	IbsFetchLat	IBS Fetch Latency	R/W
31:16	IbsFetchCnt	IBS Fetch Count	R/W
15:0	IbsFetchMaxCnt	IBS Fetch Maximum Count	R/W

Figure 13-11. IBS Fetch Control Register(IbsFetchCtl)

The fields shown in Figure 13-11 are further described below:

- IbsRandEn (IBS Randomize Tagging Enable)—Bit 57, read/write. Software sets this bit to 1 to add variability to the interval at which fetch operations are selected for tagging. When set, bits 3:0 of the fetch interval counter are set to a pseudo-random value when the IbsFetchCtl register is written. Clearing this bit causes bits 3:0 of the fetch interval counter to be reset to zero.
- IbsL1TlbMiss (IBS Fetch L1 TLB Miss)—Bit 55, read/write. This bit is set if the tagged fetch missed in the L1 TLB.
- IbsL1TlbPgSz[1:0] (IBS Fetch L1 TLB Page Size)—Bits 54:53, read/write. This field indicates the page size of the translation in the L1 TLB for the tagged fetch. This field is valid only if IbsPhyAddrVal = 1. The table below defines the encoding of this two-bit field:

Value	Page Size
00b	4 Kbyte
01b	2 Mbyte
10b	1 Gbyte
11b	Reserved

  Some implementations might not support all page sizes. Note: The page size in the L1 TLB might not match the page size in the page table.
- IbsPhyAddrValid (IBS Fetch Physical Address Valid)—Bit 52, read/write. This bit is set if the physical address of the tagged fetch is valid. When this bit is set, the IbsL1TlbPgSz field and the contents of the IBS Fetch Physical Address Register (see definition of this register below) are both valid.
- IbsIcMiss (IBS Instruction Cache Miss)—Bit 51, read/write. This bit is set if the tagged fetch missed in the instruction cache.

- IbsFetchComp (IBS Fetch Complete)—Bit 50, read/write. This bit is set if the tagged fetch completes and data is available for use by the instruction decoder.
- IbsFetchVal (IBS Fetch Valid)—Bit 49, read/write. This bit is set if the tagged fetch either completes or is aborted. When the bit is set, captured data for the tagged fetch is available and the fetch interval counter stops. An interrupt is generated as specified by the local APIC. The interrupt handler should read and save the captured performance data before clearing the bit.
- IbsFetchEn (IBS Fetch Enable)—Bit 48, read/write. Software sets this bit to enable fetch sampling. Clearing this bit to 0 disables fetch sampling.
- IbsFetchLat[15:0] (IBS Fetch Latency)—Bits 47:32, read/write. This 16-bit field indicates the number of core clock cycles from the initiation of the fetch to the delivery of the instruction bytes to the core. If the fetch is aborted before it completes, this field returns the number of clock cycles from the initiation of the fetch to its abortion.
- IbsFetchCnt[15:0] (IBS Fetch Count)—Bits 31:16, read/write. This 16-bit field returns the current value of bits 19:4 of the fetch interval counter on a read. Bits 19:4 of the fetch interval counter are set to this value on a write.
- IbsFetchMaxCnt[15:0] (IBS Fetch Maximum Count)—Bits 15:0, read/write. This 16-bit field specifies the maximum count value of bits 19:4 of the fetch interval counter. When the value in bits 19:4 of the fetch counter equals the value in this field, the next fetch block is tagged for profiling.

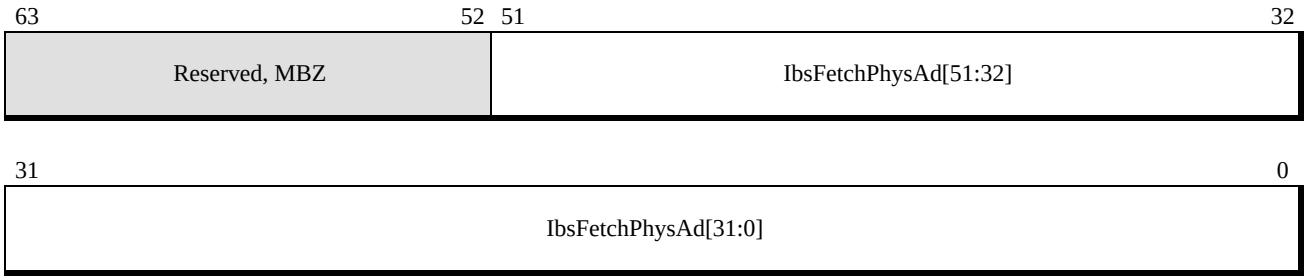
IBS Fetch Linear Address Register

Bit(s)	Field Mnemonic	Descriptive Name	R/W
63:0	IbsFetchLinAd	IBS Fetch Linear Address	RO

Figure 13-12. IBS Fetch Linear Address Register (IbsFetchLinAd)

This is a read-only register. Reading the IbsFetchLinAd MSR returns the 64-bit linear address of the tagged fetch. This address may correspond to the first byte of an AMD64 instruction or the start of the fetch block. The address is valid only if the IbsFetchVal bit is set. The address is in canonical form.

IBS Fetch Physical Address Register



Bit(s)	Field Mnemonic	Descriptive Name	R/W
63:52	—	Reserved, MBZ	n/a
51:0	IbsFetchPhysAd	IBS Fetch Physical Address	RO

Figure 13-13. IBS Fetch Physical Address Register (IbsFetchPhysAd)

This is a read-only register. Reading the IbsFetchPhysAd MSR returns the 52-bit physical address of the tagged fetch. This address may correspond to the first byte of an AMD64 instruction or the start of the fetch block. The address is valid only if both the IbsPhyAddrValid and the IbsFetchVal bits of the IbsFetchCtl register are set. Otherwise, the contents of this register are undefined. The indicated size of 52 bits is an architectural limit. Specific processors may implement fewer bits.

13.3.3 IBS Execution Sampling

Instruction execution performance is measured by tagging an op associated with an instruction. The tagged op joins other ops in a queue waiting to be dispatched and executed. Instructions that decode to more than one op may return different performance data depending upon which op associated with the instruction is tagged. IBS returns the following performance information for each retired tagged op:

- Branch status for branch ops.
- For a load or store op:
  - Whether the load or store missed in the data cache.
  - Whether the load or store address hit or missed in the TLBs.
  - The linear and physical address of the data operand associated with the load or store operation.
  - Source information for cache, DRAM, MMIO, or I/O accesses.

IBS selects and tags an op at a programmable rate. When enabled by the IBS Execution Control Register (IbsOpEn = 1 and IbsOpVal = 0), an internal 27-bit op interval counter increments either once for every core clock cycle, if IbsOpCntCtl is cleared, or once for every dispatched op, if IbsOpCntCtl is set.

When the value in bits 26:4 of the op counter equals the value in the IbsOpMaxCnt field of the IBS Execution Control Register, an op is tagged in the next cycle. When the op is retired, the execution status of the op is written to the IBS execution registers, and IbsOpVal bit of the IBS Execution Control

Register is set. When this is complete, an interrupt is signalled to the local APIC. The local APIC should be programmed to deliver this interrupt to the processor core.

The interrupt service routine must save the performance information stored in IBS execution registers. Software can then initiate another sample by resetting the IbsOpVal bit in the IBS Execution Control Register.

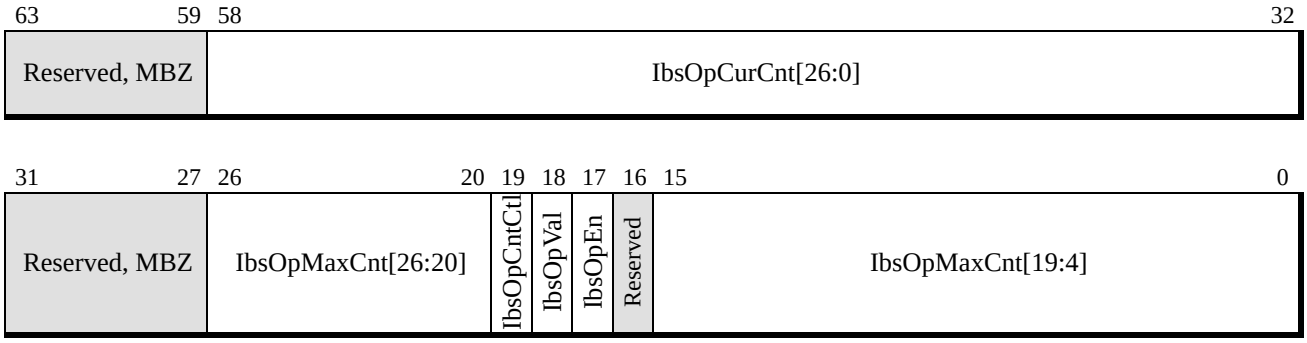
Aborted ops do not produce an IBS execution sample. If the tagged op aborts (i.e., does not retire), hardware resets bits 26:7 of the op interval counter to zero, and bits 6:0 to a random value. The op counter continues to increment and another op is selected when the value in bits 26:4 of the op interval counter equals the value in the IbsOpMaxCnt field.

Randomization of sampling interval: A degree of randomization of the sampling interval is necessary to ensure fairness in sampling, especially for loop-intensive code. For execution sampling this must be done by software. This is accomplished when writing the IbsOpCtl register to clear the IbsOpVal bit and initiate a new sampling interval. At that time software can provide a small random number (4-6 bits) in the IbsOpCurCnt field to offset the starting count, thereby randomizing the point at which the count reaches the IbsOpMaxCnt value and triggers a sample.

13.3.4 IBS Execution Sampling Registers

The IBS execution sampling registers consist of the control register (IBS Execution Control Register), the linear address register (IBS Op Linear Address Register), and three execution data registers (IBS Op Data 1–3). The IBS execution sampling registers are accessed using the RDMSR and WRMSR instructions.

IBS Execution Control Register (IbsOpCtl)



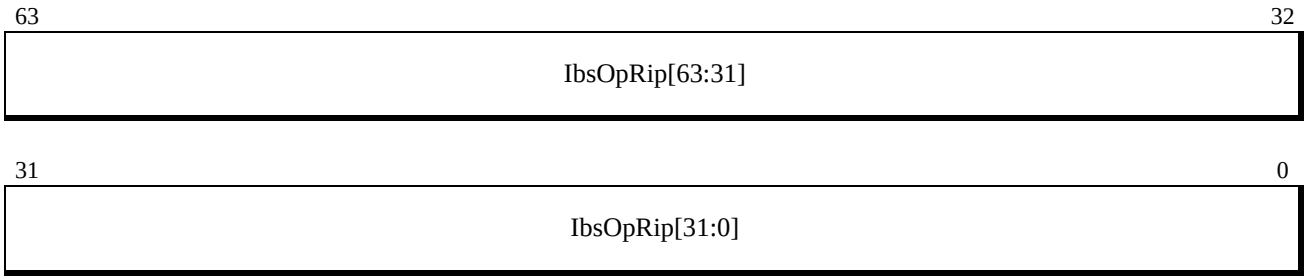
Bit(s)	Field Mnemonic	Descriptive Name	R/W
63:59	—	Reserved, MBZ	
58:32	IbsOpCurCnt[26:0]	IBS Op Current Count, bits 26:0	R/W
31:27	—	Reserved, MBZ	
26:20	IbsOpMaxCnt[26:20]	IBS Op Maximum Count, bits 26:20	R/W
19	IbsOpCntCtl	IBS Op Counter Control	R/W
18	IbsOpVal	IBS Op Sample Valid	R/W
17	IbsOpEn	IBS Op Sampling Enable	R/W
16	—	Reserved, MBZ	
15:0	IbsOpMaxCnt[19:4]	IBS Op Maximum Count, bits 19:4	R/W

Figure 13-14. IBS Execution Control Register (IbsOpCtl)

The fields shown in Figure 13-14 are further described below:

- IbsOpCurCnt[26:0] (IBS Op Current Count)—Bits 58:32, read/write. This field returns the current value of the op counter, and provides the starting value of the counter when software writes this register to clear the IbsOpVal bit and start another sampling interval.
- IbsOpMaxCnt[26:20] (IBS Op Maximum Count[26:20])—Bits 26:20, read/write. This field is used to specify the most significant 7 bits of the IbsOpMaxCnt.
- IbsOpCntCtl (IBS Op Counter Control)—Bit 19, read/write. This bit controls op tagging. When this bit is zero, IBS counts core clock cycles in order to select an op for tagging. When this bit is one, IBS counts dispatched ops in order to select an op for tagging.
- IbsOpVal (IBS Op Sample Valid)—Bit 18, read/write. This bit is set when a tagged op retires and indicates that new instruction execution data is available. The op counter stops counting. An interrupt is generated as specified by the local APIC. The software interrupt handler captures the performance data before clearing the bit to enable the hardware to take another sample.
- IbsOpEn (IBS Op Sample Enable)—Bit read/write. Software sets this bit to enable IBS execution sampling. Clearing this bit disables IBS execution sampling.
- IbsOpMaxCnt[19:4] (IBS Op Maximum Count[19:4]): read/write. This field specifies the maximum count value for bits 19:4 of the op interval counter. When the value in bits 26:4 of the op interval counter equal the value specified by the concatenation of the IbsOpMaxCnt[26:20] field with this field, the next op is tagged for profiling.

IBS Op Linear Address Register (IbsOpRip)



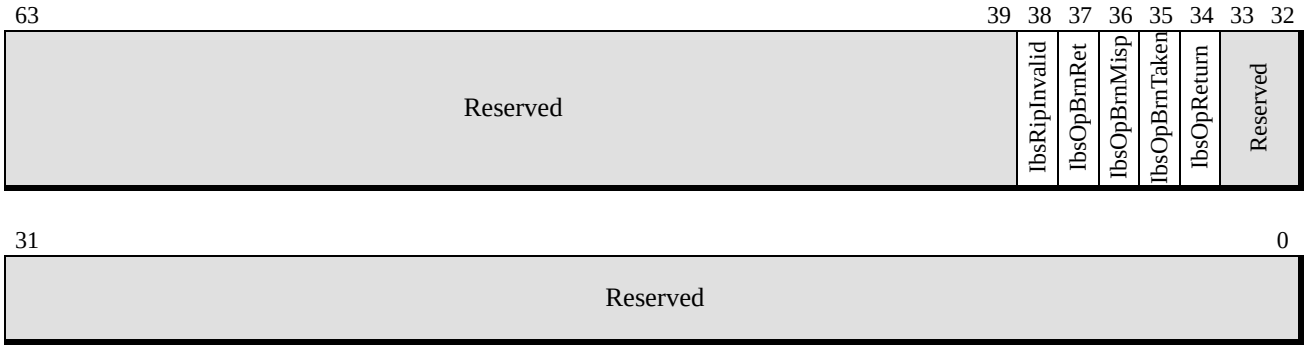
Bit(s)	Field Mnemonic	Descriptive Name	R/W
63:0	IbsOpRip	IBS Op Linear Address	R/W

Figure 13-15. IBS Op Linear Address Register (IbsOpRip)

IbsOpRip[63:0] (IBS Op Linear Address): read/write. Specifies the linear address for the instruction from which the tagged op was issued. The address is valid only if the IbsOpCtl[IbsOpVal] bit is set and the IbsOpData1[IbsRipInvalid] bit is cleared. The address is in canonical form.

IBS Op Data 1 Register (IbsOpData1)

The IBS Op Data 1 Register provides core cycle counts for tagged ops and performance data for tagged ops which perform a branch.



Bit(s)	Field Mnemonic	Descriptive Name	R/W
63:39	—	Reserved	
38	IbsRipInvalid	IbsOpRip Register Invalid	R/W
37	IbsOpBrnRet	IBS Op Branch Retired	R/W
36	IbsOpBrnMisp	IBS Op Branch Mispredicted	R/W
35	IbsOpBrnTaken	IBS Op Branch Taken	R/W
34	IbsOpReturn	IBS Op RET	R/W
33:0	—	Reserved	

Figure 13-16. IBS Op Data 1 Register (IbsOpData1)

The fields shown in Figure 13-16 are further described below:

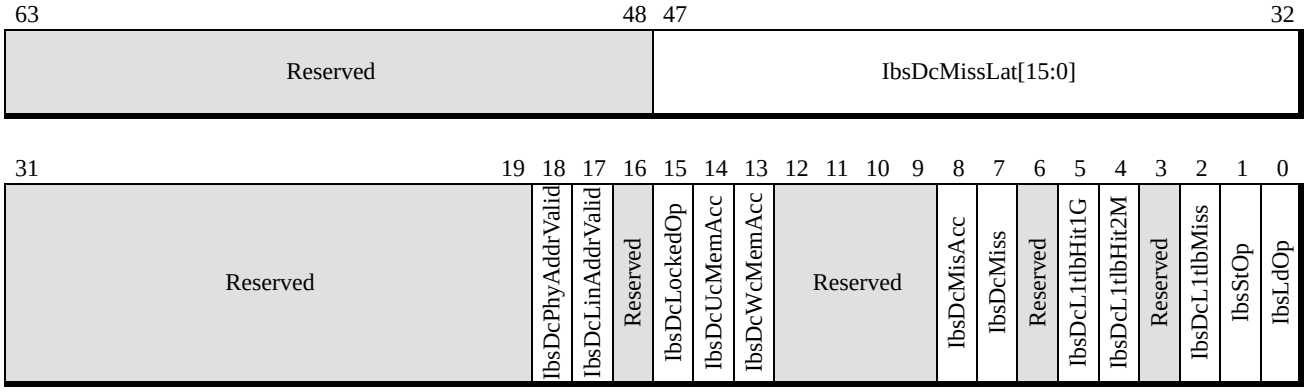
- IbsRipInvalid (IbsOpRip Register Invalid)—Bit 38, read/write. If this bit is set, the contents of the IbsOpRip register are not valid.
- IbsOpBrnRet (IBS Op Branch Retired)—Bit 37, read/write. This bit is set if the tagged op performs a branch that retired.
- IbsOpBrnMisp (IBS Op Branch Mispredicted)—Bit 36, read/write. This bit is set if the tagged op performs a retired mispredicted branch.
- IbsOpBrnTaken (IBS Op Branch Taken)—Bit 35, read/write. This bit is set if the tagged op performs a retired taken branch.
- IbsOpReturn (IBS Op RET)—Bit 34, read/write. This bit is set if the tagged op performs a retired subroutine return (RET).

IBS Op Data 2 Register (IbsOpData2)

The IBS Op Data 2 Register captures northbridge-related performance data. The information captured is implementation-dependent. See the *BIOS and Kernel Developer's Guide (BKDG)* or *Processor Programming Reference Manual (PPR)* applicable to your product for details.

IBS Op Data 3 Register (IbsOpData3)

Data Cache (first-level cache) performance data is captured in IBS Op Data 3 Register. If a load or store operation crosses a 128-bit boundary, the data returned in this register is the data for the access to the data below the 128-bit boundary.



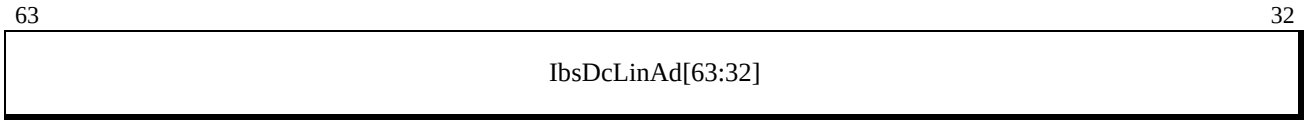
Bit(s)	Field Mnemonic	Descriptive Name	R/W
63:48	—	Reserved	
47:32	IbsDcMissLat[15:0]	IBS Data Cache Miss Latency	R/W
31:19	—	Reserved	
18	IbsDcPhyAddrValid	IBS Data Cache Physical Address Valid	R/W
17	IbsDcLinAddrValid	IBS Data Cache Linear Address Valid	R/W
16	—	Reserved	
15	IbsDcLockedOp	IBS Data Cache Locked Op	R/W
14	IbsDcUcMemAcc	IBS Data Cache UC Memory Access	R/W
13	IbsDcWcMemAcc	IBS Data Cache WC Memory Access	R/W
12:9	—	Reserved	
8	IbsDcMisAcc	IBS Data Cache Misaligned Access Penalty	R/W
7	IbsDcMiss	IBS Data Cache Miss	R/W
6	—	Reserved	
5	IbsDcL1tlbHit1G	IBS Data Cache L1 TLB Hit 1-Gbyte Page	R/W
4	IbsDcL1tlbHit2M	IBS Data Cache L1 TLB Hit 2-Mbyte Page	R/W
3	—	Reserved	
2	IbsDcL1tlbMiss	IBS Data Cache L1 TLB Miss	R/W
1	IbsStOp	IBS Store Operation	R/W
0	IbsLdOp	IBS Load Operation	R/W

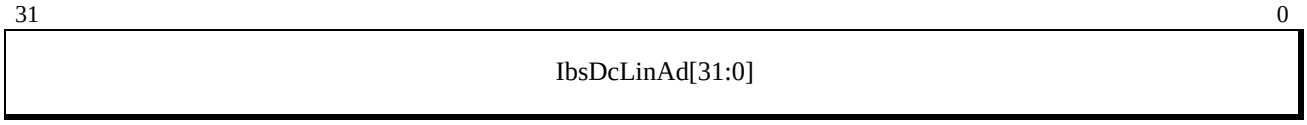
Figure 13-17. IBS Op Data 3 Register (IbsOpData3)

The fields shown in Figure 13-17 are further described below:

- IbsDcMissLat[15:0] (IBS Data Cache Miss Latency)—Bits 47:32, read/write. This field indicates the number of core clock cycles from when a miss is detected in the data cache to when the data is delivered to the core. The value is not valid for data cache store operations.
- IbsDcPhyAddrValid (IBS Data Cache Physical Address Valid)—Bit 18, read/write. This bit is set if the physical address in the IBS DC Physical Address Register is valid for a load or store operation.
- IbsDcLinAddrValid (IBS Data Cache Linear Address Valid)—Bit 17, read/write. This bit is set if the linear address in the IBS DC Linear Address Register is valid for a load or store operation.
- IbsDcLockedOp (IBS Data Cache Locked Op)—Bit 15, read/write. This bit is set if the tagged load or store operation was a locked operation.
- IbsDcUcMemAcc (IBS Data Cache UC Memory Access)—Bit 14, read/write. This bit is set if the tagged load or store operation accessed uncacheable memory.
- IbsDcWcMemAcc (IBS Data Cache WC Memory Access)—Bit 13, read/write. This bit is set if the tagged load or store operation accessed write combining memory.
- IbsDcMisAcc (IBS Data Cache Misaligned Access Penalty)—Bit 8, read/write. This bit is set if a tagged load or store operation incurred a performance penalty due to a misaligned access.
- IbsDcMiss (IBS Data Cache Miss)—Bit 7, read/write. This bit is set if the cache line used by the tagged load or store operation was not present in the data cache.
- IbsDcL1tlbHit1G (IBS Data Cache L1 TLB Hit 1-Gbyte Page)—Bit 5, read/write. This bit is set if the physical address for the tagged load or store operation was present in a 1-Gbyte page table entry in the data cache L1 TLB.
- IbsDcL1tlbHit2M (IBS Data Cache L1 TLB Hit 2-Mbyte Page)—Bit 4, read/write. This bit is set if the physical address for the tagged load or store operation was present in a 2-Mbyte page table entry in the data cache L1 TLB.
- IbsDcL1tlbMiss (IBS Data Cache L1 TLB Miss)—Bit 2, read/write. This bit is set if the physical address for the tagged load or store operation was not present in the data cache L1 TLB.
- IbsStOp (IBS Store Op)—Bit 1, read/write. This bit is set if the tagged op was a store.
- IbsLdOp (IBS Load Op)—Bit 0, read/write. This bit is set if the tagged op was a load.

IBS Data Cache Linear Address Register (IbsDcLinAd)



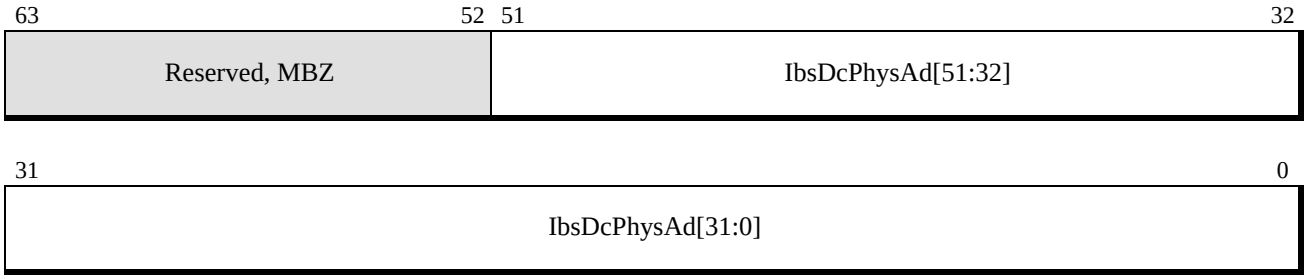


Bit(s)	Field Mnemonic	Descriptive Name	R/W
63:0	IbsDcLinAd	IBS Data Cache Linear Address	R/W

Figure 13-18. IBS Data Cache Linear Address Register (IbsDcLinAd)

IbsDcLinAd[63:0] (IBS Data Cache Linear Address): read/write. Specifies the linear address of the tagged op's memory operand. The address is valid only if IbsOpData3[IbsDcLinAdVal] is set. The address is in canonical form.

IBS Data Cache Physical Address Register (IbsDcPhysAd)



Bit(s)	Field Mnemonic	Descriptive Name	R/W
63:52	—	Reserved, MBZ	
51:0	IbsDcPhysAd	IBS Data Cache Physical Address	R/W

Figure 13-19. IBS Data Cache Physical Address Register (IbsDcPhysAd)

IbsDcPhysAd (IBS Data Cache Physical Address): read/write. Specifies the physical address of the tagged op's memory operand. The address is valid only if IbsOpData3[IbsDcPhyAdVal] is set.

IBS Branch Target Address Register (IbsBrTarget)

Bit(s)	Field Mnemonic	Descriptive Name	R/W
63:0	IbsBrTarget	IBS branch target linear address	R/W

Figure 13-20. IBS Branch Target Address Register (IbsBrTarget)

IbsBrTarget (IBS Branch Target): read/write. Specifies the 64-bit linear address for the branch target. The address is in canonical form. The branch target address is valid if it is non-zero. For a conditional branch not taken, the value supplied in this register is the fall-through address.

13.4 Lightweight Profiling

Lightweight Profiling (LWP) is an AMD64 extension that allows user mode processes to gather performance data about themselves with very low overhead. LWP is supported in both long mode and legacy mode. Modules such as managed runtime environments and dynamic optimizers can use LWP to monitor the running program with high accuracy and high resolution. They can quickly discover performance problems and opportunities and immediately act on this information.

LWP allows a program to gather performance data and examine it either by polling or by taking an occasional interrupt. It introduces minimal additional state to the CPU and the process. LWP differs from the existing performance counters and from Instruction Based Sampling (IBS) because it collects large quantities of data before taking an interrupt. This substantially reduces the overhead of using performance feedback. An application can avoid the need to enable and process interrupts by polling the LWP data.

A program can control LWP data collection entirely in user mode. It can start, stop, and reconfigure profiling without calling the kernel.

LWP runs within the context of a thread, so it can be used by multiple processes in a system at the same time without interference. This also means that if one thread is using LWP and another is not, the latter thread incurs no profiling overhead.

LWP can be programmed to run in one of two modes: *synchronized mode* or *continuous mode*. In synchronized mode the recording of events stops when the buffer set up to hold event records becomes full. In continuous mode, the storing of events wraps in the buffer overwriting older records.

13.4.1 Overview

When enabled, LWP hardware monitors one or more events during the execution of user-mode code and periodically inserts event records into a ring buffer in the address space of the running process. If performance timestamping is supported and enabled, each event record captured is timestamped using

the value read from the performance timestamp counter (PTSC). Timestamping is enabled by setting the Flags.PTSC bit of the Lightweight Profiling Control Block (LWPCB). When the ring buffer is filled beyond a user-specified threshold, the hardware can cause an interrupt which the operating system (OS) uses to signal a process to empty the ring buffer. With proper OS support, the interrupt can even be delivered to a separate process or thread.

LWP only counts instructions that retire in user mode (CPL = 3). Instructions that change to CPL 3 from some other level are not counted, since the instruction address is not an address in user mode space. LWP does not count hardware events while the processor is in system management mode (SMM) and while entering or leaving SMM.

Once LWP is enabled, each user-mode thread uses the LLWPCB and SLWPCB instructions to control LWP operation. These instructions refer to a data structure in application memory called the Lightweight Profiling Control Block, or LWPCB, to specify the profiling parameters and to interact with the LWP hardware. The LWPCB in turn points to a buffer in memory in which LWP stores event records.

Each thread in a multi-threaded process must configure LWP separately. A thread has its own ring buffer and counters which are context switched with the rest of the thread state. However, a single monitor thread could collect and process LWP data from multiple other threads.

LWP may be set up to run in one of two modes:

- Synchronized Mode

  LWP runs in synchronized mode when it is started with LWPCB.Flags.CONT = 0. In this mode, LWP will not advance the ring buffer pointer when the event ring buffer is full. It simply increments LWPCB.MissedEvents to count the number of missed event records. In synchronized mode, a thread can remove event records from the ring buffer by advancing the ring buffer tail pointer without stopping LWP in the executing thread. If the buffer had been full, event records will again be written and the ring buffer pointer will be advanced.

- Continuous Mode

  LWP runs in continuous mode when it is started with LWPCB.Flags.CONT = 1. In this mode, LWP will store an event record even when the event ring buffer is full, wrapping around in the ring buffer and overwriting the oldest event record. In continuous mode, LWPCB.MissedEvents counts the number of times that such wrapping has occurred. The only reliable way to read events from the ring buffer when LWP is in continuous mode is to stop LWP in the running thread before accessing the LWPCB and the ring buffer contents. Support for continuous mode is indicated by CPUID Fn8000_001C_EAX[LwpCont].

During profiling, the LWP hardware monitors and reports on one or more types of events. Following are the steps in this process:

1. **Count—**Each time an instruction is retired, LWP decrements its internal event counters for all of the events associated with the instruction. An instruction can cause zero, one, or multiple events. For instance, an indirect jump through a pointer in memory counts as an instruction retired, a branch retired, and may also cause up to two DCache misses (or more, if there is a TLB miss) and up to two ICache misses.
   - Some events may have filters or conditions on them that regulate counting. For instance, the application may configure LWP so that only cache miss events with latency greater than a specified minimum are eligible to be counted.
2. **Gather—**When an event counter becomes negative, the event should be reported. LWP gathers an event record and, if enabled, samples the value in the PTSC to be included in the record as the TimeStamp value. The event's counter may continue to count below zero until the record is written to the event ring buffer.

   For most events, such as instructions retired, LWP gathers an event record describing the instruction that caused the counter to become negative. However, it is valid for LWP to gather event record data for the *next* instruction that causes the event, or to take other measures to capture a record. Some of these options are described with the individual events.
   - An implementation can choose to gather event information on one or many events at any one time. If multiple event counters become negative, an advanced LWP implementation might gather one event record per event and write them sequentially. A basic LWP implementation may choose one of the eligible events. Other events continue counting but wait until the first event record is written. LWP picks the next eligible instructions for the waiting events. This situation should be extremely uncommon if software chooses large event interval values.
   - LWP may discard an event occurrence. For instance, if the LWPCB or the event ring buffer needs to be paged in from disk, LWP might choose not to preserve the pending event data. If an event is discarded, LWP gathers an event record for the next instruction to cause the event.
   - Similarly, if LWP needs to replay an instruction to gather a complete event record, the replay may abort instead of retiring. The event counter continues counting below zero and LWP gathers an event record for the next instruction to cause the event.
3. **Store—**When a complete event record is gathered, LWP stores it into the event ring buffer in the process' address space and advances the ring buffer head pointer.
   - LWP checks to see if the ring buffer is full, i.e., if advancing the ring buffer head pointer would make it equal to the tail pointer. If the buffer is full, LWP increments the 64-bit counter LWPCB.MissedEvents. If LWP is running in synchronized mode, it does not advance the head pointer. If LWP is running in continuous mode, it always advances the head pointer and LWPCB.MissedEvents counts the number of times that the buffer wrapped.
   - If more than one event record reaches the Store stage simultaneously, only one need be stored. Though LWP might store all such event records, it may delay storing some event records or it may discard the information and proceed to choose the next eligible instruction for the discarded event type(s). This behavior is implementation dependent.
   - The store need not complete synchronously with the instruction retiring. In other words, if LWP buffers the event record contents, the Store stage (and subsequent stages) may complete

some number of cycles after the tagged instruction retires. The data about the event and the instruction are precise, but the Report and Reset steps (below) may complete later.

4. **Report—**If LWP threshold interrupts are enabled and the space used in the event ring buffer exceeds a user-defined threshold, LWP initiates an interrupt. The OS can use this to signal the process to empty the ring buffer. Note that the interrupt may occur significantly later than the event that caused the threshold to be reached.

5. **Reset—**For each event that was stored, the counter is reset to its programmed interval. If requested by the application, LWP applies randomization to the low order bits of the interval. Counting for that event continues. Reset happens if the ring buffer head pointer was advanced or if the missed event counter was incremented. If the event counter went below -1, indicating that additional events occurred between the selected event and the time it was reported, that overrun value reduces the reset value so as to preserve the statistical distribution of events.

   For all events except the LWPVAL instruction, the hardware may impose a minimum on the reset value of an event counter. This prevents the system from spending too much time storing samples rather than making forward progress on the application. Any minimum imposed by the hardware can be detected by examining the EventInterval*n* fields in the LWPCB after enabling LWP.

An application should periodically remove event records from the ring buffer and advance the tail pointer. (If the application does not process the event records quickly enough or often enough, the LWP hardware will detect that the ring buffer is full and will miss events.) There are two ways to process the gathered events: interrupts or polling.

The application can wait until a threshold interrupt occurs to process the event records in the ring buffer. This requires OS or driver support. (As a consequence, interrupts can only be enabled if a kernel mode routine allows it; see “LWP_CFG—LWP Configuration MSR” on page 439) One usage model is to associate the LWP interrupt with a semaphore or mutex. When the interrupt occurs, the OS or driver signals the associated object. A thread waiting on the object wakes up and empties the ring buffer. Other models are possible, of course.

Alternatively, the application can have a thread that periodically polls the ring buffer. The polling thread need not be part of the process that is using LWP. It can be in a separate process that shares the memory containing the LWP control block and ring buffer.

Access to the ring buffer uses a lockless protocol between the LWP hardware and the application. The hardware owns the head pointer and the area in the ring buffer from the head pointer up to (but not including) the tail pointer. The application must not modify the head pointer nor rely on any data in the area of the ring buffer owned by the hardware. If the application has a stale value for the head pointer, it may miss an existing event record but it will never read invalid data. When the application is done emptying the ring buffer, it should refresh its copy of the head pointer to see if the LWP hardware has added any new event records.

Similarly, the application owns the tail pointer and the area in the ring buffer from the tail pointer up to (but not including) the head pointer. The hardware will never modify the tail pointer or overwrite the data in that region of the ring buffer. If the hardware has a stale value for the tail pointer, it may

consider that the ring buffer is full or at its threshold, but it will never overwrite valid data. Instead, it refreshes its copy of the tail pointer and rechecks to see if the full or threshold condition still applies.

When LWP is in continuous mode, this lockless protocol does not work, since the LWP hardware may overwrite the event records in the ring buffer when it advances the head pointer past the tail pointer. Because of this, the application must stop LWP before removing event records from the ring buffer. This prevents the hardware from wrapping through the ring buffer asynchronously from the application's attempt to remove data from it.

To use continuous mode properly, the application should set LWPCB.MissedEvents to 0 and set the head and tail pointers to the start of the ring buffer before starting LWP. To empty the ring buffer, the application should stop LWP. If LWPCB.MissedEvents is 0, the buffer did not wrap and there are event records starting at the tail pointer and continuing up to (but not including) the head pointer. If MissedEvents is not 0, the buffer wrapped and there are event records starting with the oldest one pointed to by the head pointer and continuing (possibly wrapping) all the way around to the newest one just before the head pointer.

13.4.2 Events and Event Records

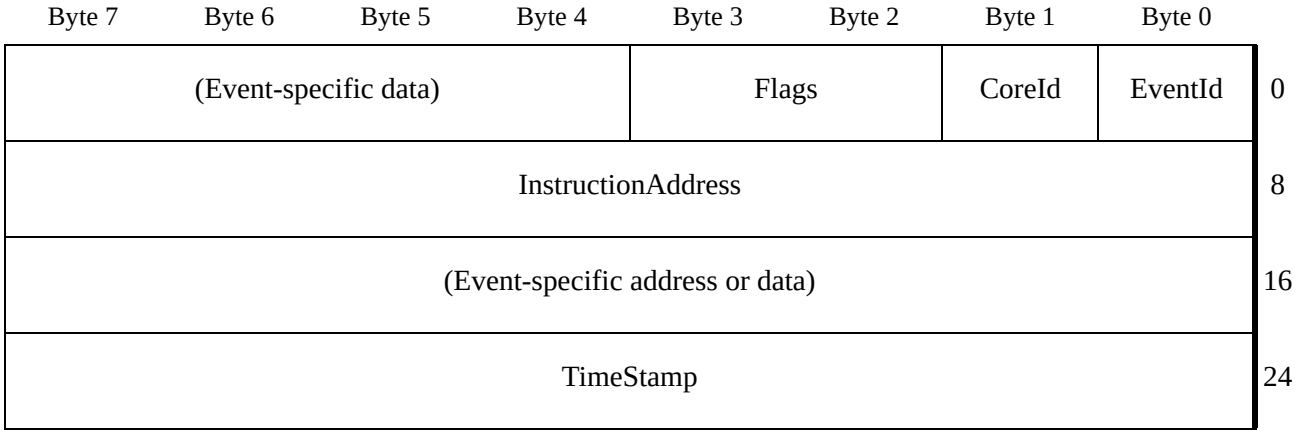
When a monitored event overflows its event counter, LWP puts an event record into the LWP event ring buffer. If event timestamping is supported and enabled, each event record will include a TimeStamp value. This value is a copy of the contents of Performance Timestamp Counter (PTSC) zero-extended if necessary to 64 bits.

The PTSC is a free-running counter that increments at a constant rate of 100MHz and is synchronized across all cores on a node to within +/-1. This counter starts when the processor is initialized and cannot be reset or modified. It is at least 40 bits wide. Privileged code can read the PTSC value via the RDMSR instruction. The size of the counter is indicated by the 2-bit field CPUID Fn8000_0008_ECX[PerfTscSize]. A value of 00b means that the PTSC is 40 bits wide; 01b means 48 bits, 10b means 56 bits, and 11b indicates a full 64 bits.

The PTSC can be correlated to the architectural TSC that runs at the P0 frequency. An application can read the TSC and PTSC, wait a 1000 clock periods or so, then read them again. The ratio of the differences is the scaling factor for the counters.

The event record size is fixed but may vary based on implementation. The event record size for a given processor is discovered by executing CPUID Fn8000_001C and extracting the value of the LwpEventSize field. (See "Detecting LWP Capabilities" on page 436). Current implementations fix the record size at 32 bytes and this size is used in the record format specifications below.

Reserved fields and fields that are not defined for a particular event are set to zero when LWP writes an event record.



Bytes	Field	Description
0	EventId	Event identifier specifying the event record type. Valid identifiers are 1 to 255. 0 is an invalid identifier.
1	CoreId	CPU core identifier value from COREID field of LWP_CFG (see “LWP_CFG—LWP Configuration MSR” on page 439). For multicore systems, this typically identifies the core on which LWP is running. This allows software to aggregate event records from multiple threads into a single data structure without losing CPU information. It also allows software to detect when a thread has migrated from one core to another.
3–2	Flags	Event-specific flags.
7–4		Event-specific data.
15–8	InstructionAddress	The Effective Address of the instruction that triggered this event record. This is the value before adding in the CS base address. If the base is non-zero, software must track it. (Modern operating systems use a CS base of zero, and CS is unused in long mode.)
23–16		Event-specific address or other data.
31–24	TimeStamp	Performance Time Stamp Counter value if LWP was started with LWPCB.Flags.PTSC = 1, zero otherwise.

Figure 13-21. Generic Event Record

Table 13-6 below lists the event identifiers for the events defined in version 1 of LWP. They are described in detail in the following sections.

Table 13-6. EventId Values

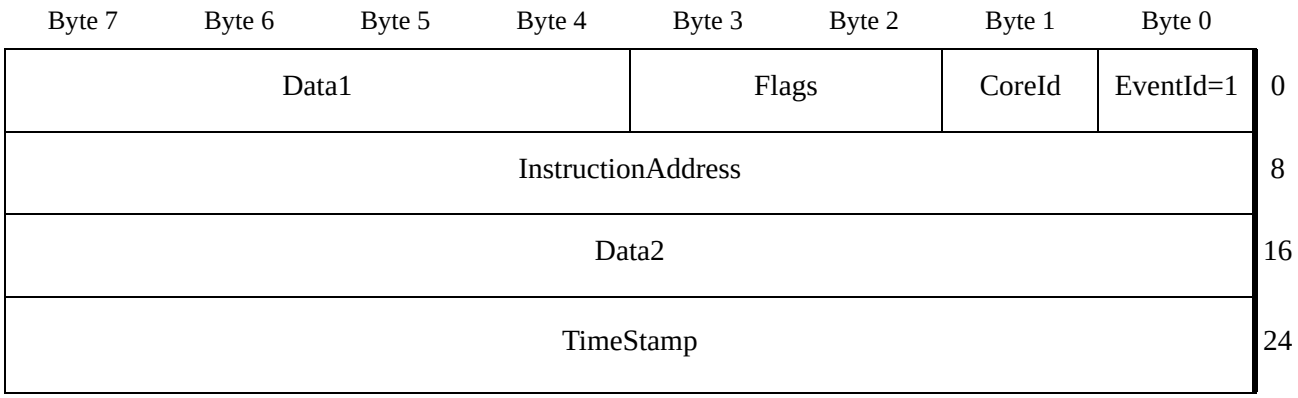
EventId	Description
0	Reserved – invalid event
1	Programmed value sample
2	Instructions retired
3	Branches retired
4	DCache misses

Table 13-6. EventId Values (continued)

EventId	Description
5	CPU clocks not halted
6	CPU reference clocks not halted
255	Programmed event

13.4.2.1 Programmed Value Sample

LWP decrements the event counter each time the program executes the LWPVAL instruction (see “LWPVAL—Insert Value Sample in LWP Ring Buffer” on page 443). When the counter becomes negative, it stores an event record with an EventId of 1. The data in the event record come from the operands to the instruction as detailed in the instruction description.



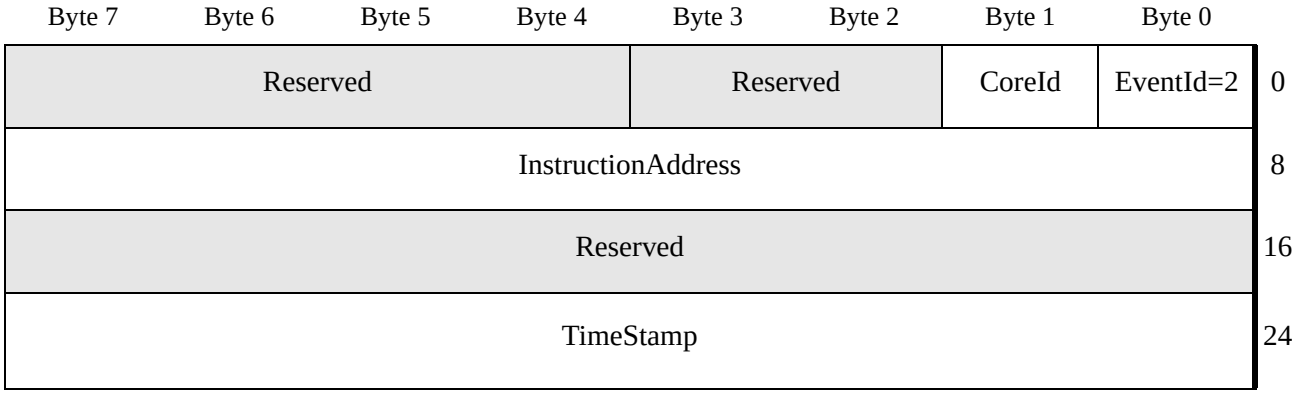
Bytes	Field	Description
0	EventId	Event identifier = 1
1	CoreId	CPU core identifier from LWP_CFG
3–2	Flags	Immediate value (bottom 16 bits)
7–4	Data1	Reg/mem value
15–8	InstructionAddress	Instruction address of LWPVAL instruction
23–16	Data2	Reg value (zero extended if running in legacy mode)
31–24	TimeStamp	Performance Time Stamp Counter value if LWP was started with LWPCB.Flags.PTSC = 1, zero otherwise.

Figure 13-22. Programmed Value Sample Event Record

13.4.2.2 Instructions Retired

LWP decrements the event counter each time an instruction retires. When the counter becomes negative, it stores a generic event record with an EventId of 2.

Instructions are counted if they execute entirely in user mode (CPL = 3). Instructions that change to CPL 3 from some other level are not counted, since the instruction address is not an address in user mode space. All user mode instructions are counted, including LWPVAL and LWPINS.



Bytes	Bits	Field	Description
0	7:0	EventId	Event identifier = 2
1	7:0	CoreId	CPU identifier from LWP_CFG
7–2			Reserved
15–8		InstructionAddress	Instruction address
23–16			Reserved
31–24		TimeStamp	Performance Time Stamp Counter value if LWP was started with LWPCB.Flags.PTSC = 1, zero otherwise.

Figure 13-23. Instructions Retired Event Record

13.4.2.3 Branches Retired

LWP decrements the event counter each time a transfer of control retires, regardless of whether or not it is taken. When the counter becomes negative, it stores an event record with an EventId of 3.

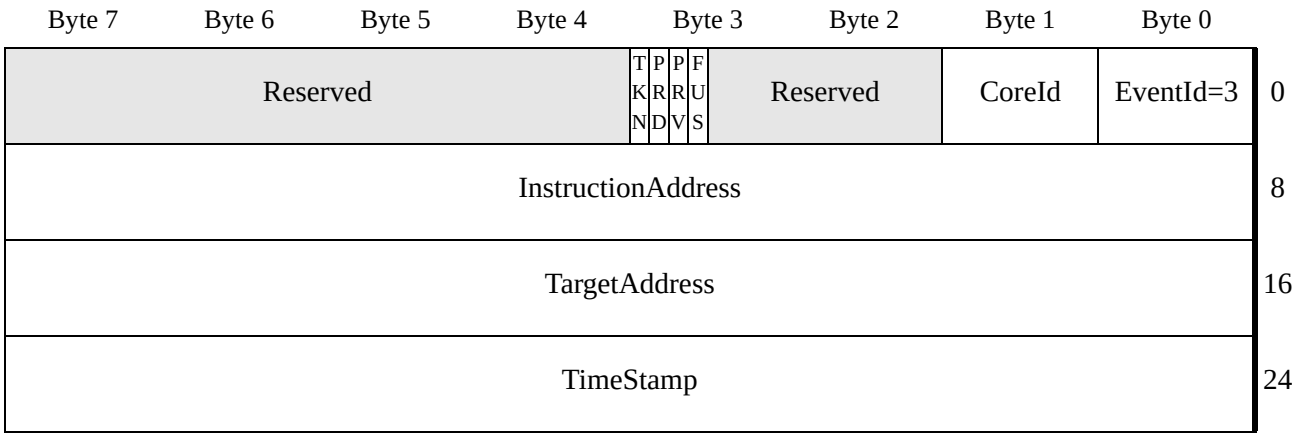
Control transfer instructions that are counted are:

- JMP (near), Jcc, JCXZ, JEXCZ, and JRCXZ
- LOOP, LOOPE, and LOOPNE
- CALL (near) and RET (near)

LWP does not count JMP (far), CALL (far), RET (far), traps, or interrupts (whether synchronous or asynchronous), nor does it count operations that switch to or from ring 3, SMM, or SVM, such as SYSCALL, SYSENTER, SYSEXIT, SYSRET, VMMCALL, INT, or INTO.

Some implementations of the AMD64 architecture perform an optimization called “fusing” when a compare operation (or other operation that sets the condition codes) is followed immediately by a conditional branch. The processor fuses these into a single operation internally before they are executed. While this is invisible to the programmer, the address of the actual branch is not available for LWP to report when the (fused) instruction retires. In this case, LWP sets the FUS bit in the event record and reports the address of the operation that set the condition codes. If FUS is set, software can find the address of the actual branch by decoding the instruction at the reported InstructionAddress and

adding its length to that address. (Note that fused instructions do count as 2 instructions for the Instructions Retired event, since there were 2 x86 instructions originally.)



Bytes	Bits	Field	Description
0	7:0	EventId	Event identifier = 3
1	7:0	CoreId	CPU core identifier from LWP_CFG
3–2	11:0		Reserved
3	4	FUS	1—Fused operation. InstructionAddress points to a compare operation (or other operation that sets the condition codes) immediately preceding the branch. 0—InstructionAddress points to the branch instruction.
3	5	PRV	1—PRD bit is valid 0—Prediction information is not available Some implementations of LWP may be unable to capture branch prediction information on some or all branches.
3	6	PRD	1—Branch was predicted correctly 0—Mispredicted If PRV = 0, the value of PRD is unpredictable and should be ignored. For unconditional branches, PRD=1 if PRV=1.
3	7	TKN	1—Branch was taken 0—Branch not taken Always 1 for unconditional branches.
7–4			Reserved
15–8		InstructionAddress	Instruction address
23–16		TargetAddress	Address of instruction executed after branch. This is the target if the branch was taken and the fall-through address if the branch was a not-taken conditional branch. TargetAddress is the Effective Address value before adding in the CS base address.
31–24		TimeStamp	Performance Time Stamp Counter value if LWP was started with LWPCB.Flags.PTSC = 1, zero otherwise.

Figure 13-24. Branch Retired Event Record

13.4.2.4 DCache Misses

LWP decrements the event counter each time a load from memory causes a DCache miss whose latency exceeds the LwpCacheLatency threshold and/or whose data come from a level of the cache or memory hierarchy that is selected for counting. When the counter becomes negative, LWP stores an event record with an EventId of 4.

A misaligned access that causes two misses on a single load decrements the event counter by 1 and, if it reports an event, the data are for the lowest address that missed. LWP only counts loads directly caused by the instruction. It does not count cache misses that are indirectly due to TLB walks, LDT or GDT references, TLB misses, etc. Cache misses caused by LWP itself accessing the LWPCB or the event ring buffer are not counted.

Measuring Latency

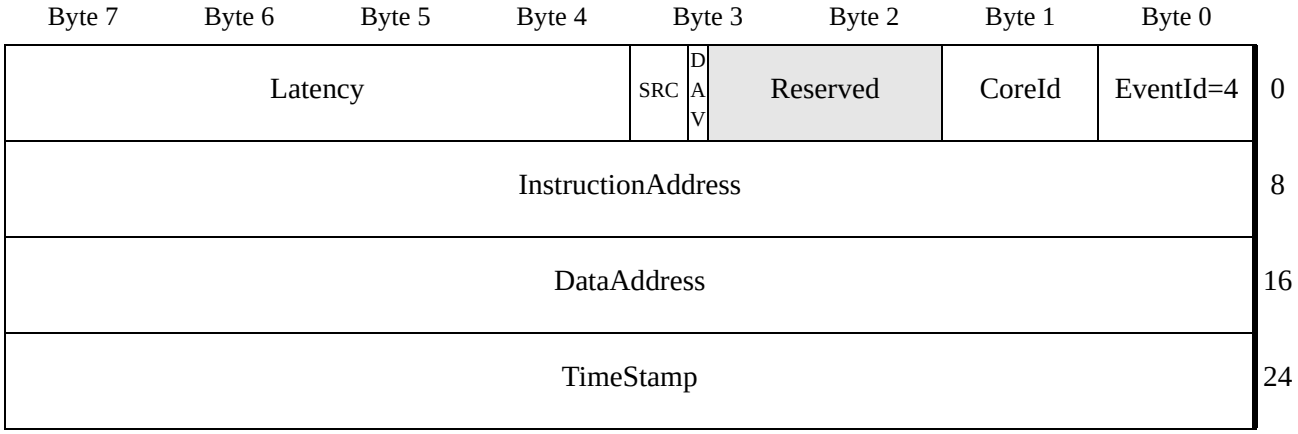
The x86 architecture allows multiple loads to be outstanding simultaneously. An implementation of LWP might not have a full latency counter for every load that is waiting for a cache miss to be resolved. Therefore, an implementation may apply any of the following simplifications. Software using LWP should be prepared for this.

- The implementation may round the latency to a multiple of 2^*j*. This is a small power of 2, and the value of *j* must be 1 to 4. For example, in the rest of this section, assume that *j* = 4, so 2^*j* = 16. The low 4 bits of latency reported in the event record will be 0. The actual latency counter is incremented by 16 every 16 cycles of waiting. The value of *j* is returned as LwpLatencyRnd (see “Detecting LWP Capabilities” on page 436).
- The implementation may do an approximation when starting to count latency. If counting is in increments of 16, the 16 cycles need not start when the load begins to wait. The implementation may bump the latency value from 0 to 16 any time during the first 16 cycles of waiting.
- The implementation may cap total latency to 2^*n*-16 (where *n* >= 10). The latency counter is thus a saturating counter that stops counting when it reaches its maximum value. For example, if *n* = 10, the latency value will count from 0 to 1008 in steps of 16 and then stop at 1008. (If *n* = 10, each counter is only 6 bits wide.) The value of *n* is returned as LwpLatencyMax (see “Detecting LWP Capabilities” on page 436).

Note that the latency threshold used to filter events is a multiple of 16. This value is used in the comparison that decides whether a cache miss event is eligible to be counted.

Reporting the DCache Miss Data Address

The event record for a DCache miss reports the linear address of the data (after adding in the segment base address, if any). The way an implementation records the linear address affects the exact event that is reported and the amount of time it takes to report a cache miss event. The implementation may report the event immediately, report the next eligible event once the counter becomes negative, or replay the instruction.

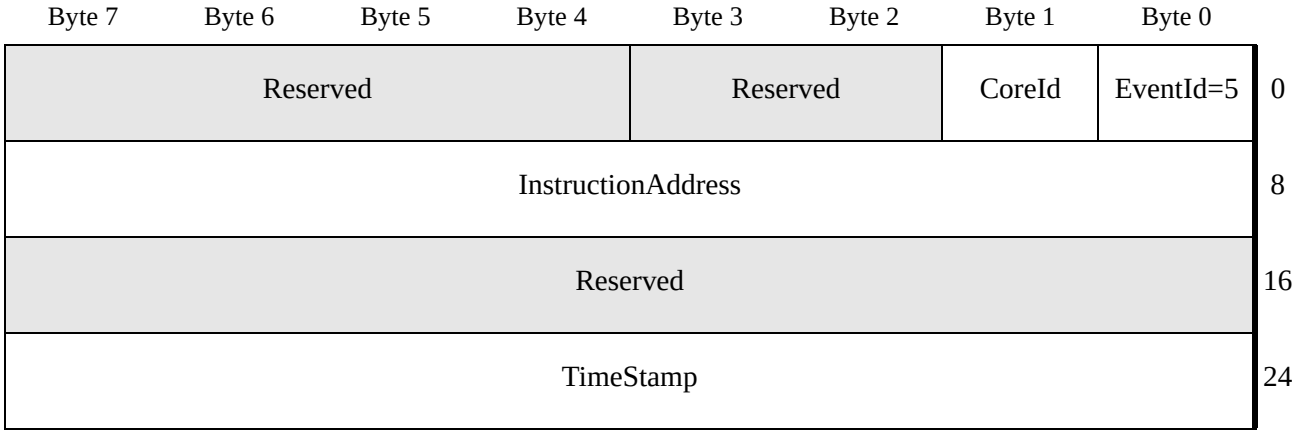


Bytes	Bits	Field	Description
0	7:0	EventId	Event identifier = 4
1	7:0	CoreId	CPU identifier from LWP_CFG
2–3	11:0		Reserved
3	4	DAV	1—DataAddress is valid 0—Address is unavailable
3	5:7	SRC	Data source for the requested data 0 No valid status 1 Local L3 cache 2 Remote CPU or L3 cache 3 DRAM 4 Reserved (for Remote cache) 5 Reserved 6 Reserved 7 Other (MMIO/Config/PCI/APIC)
7–4		Latency	Total latency of cache miss (in cycles)
15–8		InstructionAddress	Instruction address
23–16		DataAddress	Address of memory reference (if flag bit 28 = 1)
31–24		TimeStamp	Performance Time Stamp Counter value if LWP was started with LWPCB.Flags.PTSC = 1, zero otherwise.

Figure 13-25. DCache Miss Event Record

13.4.2.5 CPU Clocks not Halted

LWP decrements the event counter each clock cycle that the CPU is not in a halted state (due to STPCLK or a HLT instruction). When the counter becomes negative, it stores a generic event record with an EventId of 5. This counter varies in real-time frequency as the core clock frequency changes.



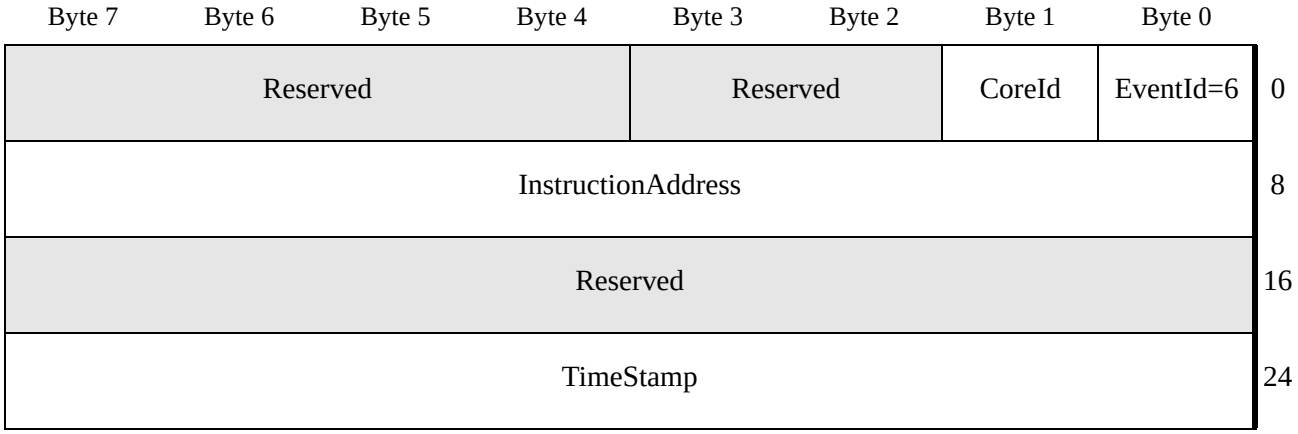
Bytes	Bits	Field	Description
0	7:0	EventId	Event identifier = 5
1	7:0	CoreId	CPU identifier from LWP_CFG
7–2			Reserved
15–8		InstructionAddress	Instruction address
23–16			Reserved
31–24		TimeStamp	Performance Time Stamp Counter value if LWP was started with LWPCB.Flags.PTSC = 1, zero otherwise.

Figure 13-26. CPU Clocks not Halted Event Record

13.4.2.6 CPU Reference Clocks not Halted

LWP decrements the event counter each reference clock cycle that the CPU is not in a halted state (due to STPCLK or a HLT instruction). When the counter becomes negative, it stores a generic event record with an EventId of 6.

The reference clock runs at a constant frequency that is independent of the core frequency and of the performance state. The reference clock frequency is processor dependent. The processor may implement this event by subtracting the ratio of (reference clock frequency / core clock frequency) each core clock cycle.

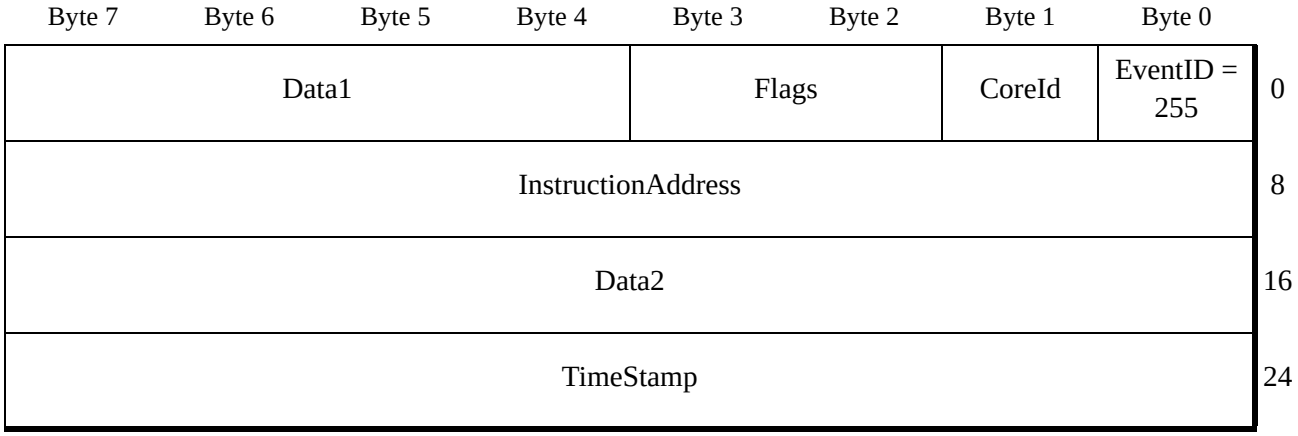


Bytes	Bits	Field	Description
0	7:0	EventId	Event identifier = 6
1	7:0	CoreId	CPU identifier from LWP_CFG
2–7			Reserved
15–8		InstructionAddress	Instruction address
23–16			Reserved
31–24		TimeStamp	Performance Time Stamp Counter value if LWP was started with LWPCB.Flags.PTSC = 1, zero otherwise.

Figure 13-27. CPU Reference Clocks not Halted Event Record

13.4.2.7 Programmed Event

When a program executes the LWPINS instruction (see “LWPINS—Insert User Event Record in LWP Ring Buffer” on page 444), the processor stores an event record with an event identifier of 255. The data in the event record come from the operands to the instruction as detailed in the instruction description.



Bytes	Field	Description
0	EventId	Event identifier = 255
1	CoreId	CPU identifier from LWP_CFG
3–2	Flags	Imm16 value
7–4	Data1	Reg/mem value
15–8	InstructionAddress	Instruction address of LWPINS instruction
23–16	Data2	Reg value (zero extended if running in legacy mode)
31–24	TimeStamp	Performance Time Stamp Counter value if LWP was started with LWPCB.Flags.PTSC = 1, zero otherwise.

Figure 13-28. Programmed Event Record

13.4.2.8 Other Events

The overall design of LWP allows easy extension to the list of events that it can monitor. The following are possibilities for events that may be added in future versions of LWP:

- DTLB misses
- FPU operations
- ICache misses
- ITLB misses

13.4.3 Detecting LWP

An application uses the CPUID instruction to identify whether Lightweight Profiling is present and which of its capabilities are available for use. An operating system uses CPUID to determine whether LWP is supported on the hardware and to determine which features of LWP are supported and can be made available to applications.

13.4.3.1 Detecting LWP Presence

LWP is supported on a processor if CPUID Fn8000_0001_ECX[LWP] (bit 15) is set. This bit is identical to the value of CPUID Fn0000_000D_EDX_x0[bit 30], which is bit 62 of the XFeatureSupportedMask and indicates XSAVE support for LWP. A system can check either of those bits to determine if LWP is supported. Since LWP requires XSAVE, software can assume that this bit being set implies that CPUID Fn0000_0001_ECX[XSAVE] (bit 26) is also set.

13.4.3.2 Detecting LWP XSAVE Area

The size of the LWP extended state save area used by XSAVE/XRSTOR is 128 bytes (080h). This value is returned by CPUID Fn0000_000D_ EAX_x3E (ECX=62).

The offset of the LWP save area from the beginning of the XSAVE/XRSTOR area is 832 bytes (340h). This value is returned by CPUID Fn0000_000D_ EBX_x3E (ECX=62).

The size of the LWP save area is included in the XFeatureSupportedSizeMax value returned by CPUID Fn0000_000D_ECX_x0 (ECX=0).

If LWP is enabled in the XFEATURE_ENABLED_MASK, the size of the LWP save area is included in the XFeatureEnabledSizeMax value returned by CPUID Fn0000_000D_EBX_x0 (ECX=0).

13.4.3.3 Detecting LWP Capabilities

The values returned by CPUID Fn8000_001C indicate the capabilities of LWP. See Table 13-7, “Lightweight Profiling CPUID Values” for a listing of the returned values.

Bit 0 of EAX is a copy of bit 62 from XFEATURE_ENABLED_MASK and indicates whether LWP is available for use by applications. If it is 1, the processor supports LWP and the operating system has enabled LWP for applications.

Bits 31:1 returned in EAX are taken from the LWP_CFG MSR and reflect the LWP features that are available for use. These are a subset of the bits returned in EDX, which reflect the full capabilities of LWP on current processor. The operating system can make a subset of LWP available if it cannot handle all supported features. For instance, if the OS cannot handle an LWP threshold interrupt, it can disable the feature. User-mode software must assume that the bits in EAX describe the features it can use. Operating systems should use the bits from EDX to determine the supported capabilities of LWP and make all or some of those features available.

Under SVM, if a VMM allows the migration of guests among processors that all support LWP, it must arrange for CPUID to report the logical AND of the supported feature bits over all processors in the migration pool. Other CPUID values must also be reported as the “least common denominator” among the processors.

Table 13-7. Lightweight Profiling CPUID Values

Reg	Bits	Field	Description
EAX	0	LwpAvail	1—LWP is available to application programs. The hardware and the operating system support LWP. 0—LWP is not available. This bit is a copy of bit 62 of the XFEATURE_ENABLED_MASK register (XCR0).
	1	LwpVAL	LWPVAL instruction (EventId = 1) is available.
	2	LwpIRE	Instructions retired event (EventId = 2) is available.
	3	LwpBRE	Branch retired event (EventId = 3) is available.
	4	LwpDME	DCache miss event (EventId = 4) is available.
	5	LwpCNH	CPU clocks not halted event (EventId = 5) is available.
	6	LwpRNH	CPU reference clocks not halted event (EventId = 6) is available.
	28:7		Reserved
	29	LwpCont	Sampling in continuous mode is available.
	30	LwpPTSC	Performance Time Stamp Counter in event records is available.
	31	LwpInt	Interrupt on threshold overflow is available.
EBX	7:0	LwpCbSize	Size in quadwords of the LWPCB. This value is at least (LwpEventOffset / 8) + LwpMaxEvents but an implementation may require a larger control block.
	15:8	LwpEventSize	Size in bytes of an event record in the LWP event ring buffer. (32 for LWP Version 1.)
	23:16	LwpMaxEvents	Maximum supported EventId value (not including EventId 255 used by the LWPINS instruction). Not all events between 1 and LwpMaxEvents are necessarily supported.
	31:24	LwpEventOffset	Offset from the start of the LWPCB to the EventInterval1 field. Software uses this value to locate the area of the LWPCB that describes events to be sampled. This permits expansion of the initial fixed region of the LWPCB. LwpEventOffset is always a multiple of 8.

Table 13-7. Lightweight Profiling CPUID Values

Reg	Bits	Field	Description
ECX	4:0	LwpLatencyMax	Number of bits in cache latency counters (10 to 31). 0 if DCache miss event is not supported (EDX[LwpDME] = 0).
	5	LwpDataAddress	1—Cache miss event records report the data address of the reference. 0—Data address is not reported. 0 if DCache miss event is not supported (EDX[LwpDME] = 0).
	8:6	LwpLatencyRnd	The amount by which cache latency is rounded. The bottom LwpLatencyRnd bits of latency information will be zero. The actual number of bits implemented for the counter is (LwpLatencyMax – LwpLatencyRnd). Must be 0 to 4. 0 if DCache miss event is not supported (EDX[LwpDME] = 0).
	15:9	LwpVersion	Version of LWP implementation. (1 for LWP Version 1.)
	23:16	LwpMinBufferSize	Minimum size of the LWP event ring buffer, in units of 32 event records. At least 32*LwpMinBufferSize records must be allocated for the LWP event ring buffer, and hence the size of the ring buffer must be at least 32 * LwpMinBufferSize * LwpEventSize bytes. If 0, there is no minimum.
	27:24		Reserved
	28	LwpBranchPrediction	1—Branches Retired events can be filtered based on whether the branch was predicted properly. The values of NMB and NPB in the LWPCB enable filtering based on prediction. 0—NMB and NPB fields of the LWPCB are ignored. 0 if Branches Retired event is not supported (EDX[LwpBRE] = 0).
	29	LwpIpFiltering	1—IP filtering is supported. 0—IP filtering is not supported. The IPI, IPF, BaseIP, and LimitIP fields of the LWPCB are ignored.
	30	LwpCacheLevels	1—Cache-related events can be filtered by the cache level that returned the data. The value of CLF in the LWPCB enables cache level filtering. 0—CLF is ignored. An implementation must support filtering either by latency or by cache level. It may support both. 0 if DCache miss event is not supported (EDX[LwpDME] = 0).
	31	LwpCacheLatency	1—Cache-related events can be filtered by latency. The value of MinLatency in the LWPCB controls filtering. 0—MinLatency is ignored. An implementation must support filtering either by latency or by cache level. It may support both. 0 if DCache miss event is not supported (EDX[LwpDME] = 0).
EDX	0	LwpAvail	LWP is supported. If 0, the remainder of the data returned by CPUID should be ignored. This bit is a copy of CPUID Fn8000_0001_ECX[LWP] (bit 15).
	1	LwpVAL	LWPVAL instruction (EventId = 1) is supported.

Table 13-7. Lightweight Profiling CPUID Values

Reg	Bits	Field	Description
	2	LwpIRE	Instructions retired event (EventId = 2) is supported.
	3	LwpBRE	Branch retired event (EventId = 3) is supported.
	4	LwpDME	DCache miss event (EventId = 4) is supported.
	5	LwpCNH	CPU clocks not halted event (EventId = 5) is supported.
	6	LwpRNH	CPU reference clocks not halted event (EventId = 6) is supported.
	28:7		Reserved
	29	LwpCont	Sampling in continuous mode is supported.
	30	LwpPTSC	Performance Time Stamp Counter in event records is supported.
	31	LwpInt	Interrupt on threshold overflow is supported.

For more information on using the CPUID instruction, refer to Section 3.3, “Processor Feature Identification,” on page 71.

13.4.4 LWP Registers

The XFEATURE_ENABLED_MASK register (extended control register XCR0) and the LWP model-specific registers describe and control the LWP hardware. The MSRs are available if CPUID Fn8000_0001_ECX[LWP] (bit 15) is set. LWP can only be used if the system has made support for LWP state management available in XFEATURE_ENABLED_MASK.

13.4.4.1 XFEATURE_ENABLED_MASK Support

LWP requires that the processor support the XSAVE/XRSTOR instructions to manage LWP state, along with the XSETBV/XGETBV instructions that manage the enabled state mask. An operating system uses XSETBV to set bit 62 of XFEATURE_ENABLED_MASK to indicate that it supports management of LWP state and allows applications to use LWP. When the system makes LWP available by setting bit 62 of XFEATURE_ENABLED_MASK, LWP is initially disabled (LWP_CBADDR is zero).

See “Guidelines for Operating Systems” on page 462 for details on how to implement LWP support in an operating system.

13.4.4.2 LWP_CFG—LWP Configuration MSR

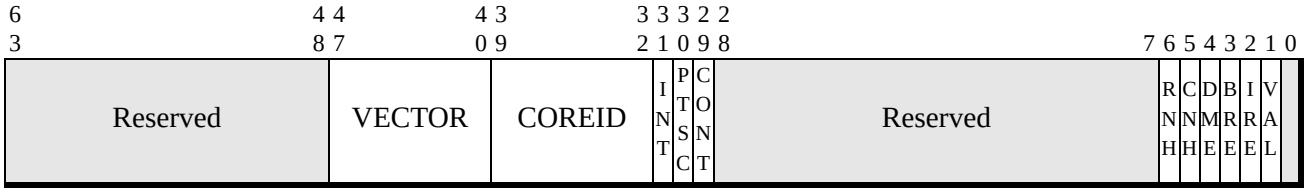
LWP_CFG (MSR C000_0105h) controls which features of LWP are available on the processor. The operating system loads LWP_CFG at start-up time (or at the time an LWP driver is loaded) to indicate its level of support for LWP. Only bits for supported features (those that are set in CPUID Fn8000_001C_EDX) can be turned on in LWP_CFG. Attempting to set other bits causes a #GP fault.

User code can examine LWP_CFG bits 31:1 by reading CPUID Fn8000_001C_EAX.

Bits 39:32 of LWP_CFG contains the COREID value that LWP will store into the CoreId field of every event record written by this core. The operating system should initialize this value to be the local APIC number, obtained from CPUID Fn0000_0001_EBX[LocalApicId] (bits 31:24). COREID is present so that when LWP is used in a virtualized environment, it has access to the core number without needing to enter the hypervisor. On systems that support x2APIC, local APIC numbers may be more than 8 bits wide. The operating system may then assign LWP COREID values that are small and identify the core within a cluster. If the system has more than 256 cores, there will be unavoidable duplication of COREID values.

Bits 47:40 of LWP_CFG specify the vector number that LWP will use when it signals a ring buffer threshold interrupt.

The reset value of LWP_CFG is 0.



Bits	Field	Description
0		Reserved
1	VAL	Allow the LWPVAL instruction.
2	IRE	Allow LWP to count instructions retired.
3	BRE	Allow LWP to count branches retired.
4	DME	Allow LWP to count DCache misses.
5	CNH	Allow LWP to count CPU clocks not halted.
6	RNH	Allow LWP to count CPU reference clocks not halted.
28:7		Reserved
29	CONT	Enable continuous mode. If 0, LWP will always use synchronized mode.
30	PTSC	Enable storing Performance Time Stamp Counter (PTSC) in the TimeStamp field of event records, if PTSC is available.
31	INT	Allow LWP to generate an interrupt when threshold is exceeded.
39:32	COREID	Value to store in CoreId field when writing an event record.
47:40	VECTOR	Interrupt vector number to use for LWP Threshold interrupts. Must be provided if INT=1.
63:48		Reserved

Figure 13-29. LWP_CFG—Lightweight Profiling Features MSR

13.4.4.3 LWP_CBADDR—LWPCB Address MSR

LWP_CBADDR (MSR C000_0106h) provides access to the internal copy of the LWPCB linear address.

RDMSR from this register returns the current LWPCB address without performing any of the operations described for the SLWPCB instruction.

WRMSR to this register with a non-zero value generates a #GP fault; use LLWPCB or XRSTOR to load an LWPCB address.

Writing a zero to LWP_CBADDR immediately disables LWP, discarding any internal state. For instance, an operating system can write a zero to stop LWP when it terminates a thread.

Note that LWP_CBADDR contains the linear address of the control block. All references to the LWPCB that are made by microcode during the normal operation of LWP ignore the DS segment register.

The reset value of LWP_CBADDR is 0. This means that when the system sets bit 62 of XFEATURE_ENABLED_MASK to make LWP available, it is initially disabled.

13.4.5 LWP Instructions

This section describes the instructions included in the AMD64 architecture to support LWP. These instructions raise #UD if LWP is not supported or if bit 62 of XFEATURE_ENABLED_MASK is 0 indicating that LWP is not available.

The LLWPCB instruction enables or disables Lightweight Profiling and controls the events being profiled. The SLWPCB instruction queries the current state of Lightweight Profiling.

LWP provides two instructions for inserting user data into the event ring buffer. The LWPINS instruction unconditionally stores an event record into the ring buffer, while the LWPVAL instruction uses an LWP event counter to sample program values at defined intervals.

The instructions LLWPCB, SLWPCB, LWPINS, and LWPVAL are also described in the chapter "General-Purpose Instruction Reference" of Volume 3. Refer to reference pages for the individual instruction for information on instruction encoding, flags affected, and exception behavior.

13.4.5.1 LLWPCB—Load LWPCB Address

Parses the Lightweight Profiling Control Block at the address contained in the specified register. If the LWPCB is valid, writes the address into the LWP_CBADDR MSR and enables Lightweight Profiling.

The LWPCB must be in memory that is readable and writable in user mode. For better performance, it should be aligned on a 64-byte boundary in memory and placed so that it does not cross a page boundary, though neither of these suggestions is required.

Action

1. If LWP is not available or if the machine is not in protected mode, LLWPCB immediately causes a #UD exception.
2. If LWP is already enabled, the processor flushes the LWP state to memory in the old LWPCB. See “SLWPCB—Store LWPCB Address” on page 443 for details on saving the active LWP state.

If the flush causes a #PF exception, LWP remains enabled with the old LWPCB still active. Note that the flush is done before LWP attempts to access the new LWPCB.

3. If the specified LWPCB address is 0, LWP is disabled and the execution of LLWPCB is complete.
4. The LWPCB address is non-zero. LLWPCB validates it as follows:
   - If any part of the LWPCB or the ring buffer is beyond the data segment limit, LLWPCB causes a #GP exception.
   - If the ring buffer size is below the implementation's minimum ring buffer size, LLWPCB causes a #GP exception.
   - While doing these checks, LWP reads and writes the LWPCB, which may cause a #PF exception.

   If any of these exceptions occurs, LLWPCB aborts and LWP is left disabled. Usually, the operating system will handle a #PF exception by making the memory available and returning to retry the LLWPCB instruction. The #GP exceptions indicate application programming errors.
5. LWP converts the LWPCB address and the ring buffer address to linear address form by adding the DS base address and stores the addresses internally.
6. LWP examines the LWPCB.Flags field to determine which events should be enabled and whether threshold interrupts should be taken. It clears the bits for any features that are not available and stores the result back to LWPCB.Flags to inform the application of the actual LWP state.
7. For each event being enabled, LWP examines the EventInterval*n* value and, if necessary, sets it to an implementation-defined minimum. (The minimum event interval for LWPVAL is zero.) It loads its internal counter for the event from the value in EventCounter*n*. A zero or negative value in EventCounter*n* means that the next event of that type will cause an event record to be stored. To count every j^{th} event, a program should set EventInterval*n* to *j-1* and EventCounter*n* to some starting value (where *j-1* is a good initial count). If the counter value is larger than the interval, the first event record will be stored after a larger number of events than subsequent records.
8. LWP is started. The execution of LLWPCB is complete.

Notes

If none of the bits in the LWPCB.Flags specifies an available event, LLWPCB still enables LWP to allow the use of the LWPINS instruction. However, no other event records will be stored.

A program can temporarily disable LWP by executing SLWPCB to obtain the current LWPCB address, saving that value, and then executing LLWPCB with a register containing 0. It can later re-enable LWP by executing LLWPCB with a register containing the saved address.

When LWP is enabled, it is typically an error to execute LLWPCB with the address of the active LWPCB. When the hardware flushes the existing LWP state into the LWPCB, it may overwrite fields that the application may have set to new LWP parameter values. The flushed values will then be loaded as LWP is restarted. To reuse an LWPCB, an application should stop LWP by passing a zero to LLWPCB, then prepare the LWPCB with new parameters and execute LLWPCB again to restart LWP.

Internally, LWP keeps the linear address of the LWPCB and the ring buffer. If the application changes the value of DS, LWP will continue to collect samples even if the new DS value would no longer allows it to access the LWPCB or the ring buffer. However, a #GP fault will occur if the application uses XRSTOR to restore LWP state saved by XSAVE. Programs should avoid using XSAVE/XRSTOR on LWP state if DS has changed. This only applies when the CPL ≠ 0; kernel mode operation of XRSTOR is unaffected by changes to DS. See “XSAVE/XRSTOR” on page 455 for details.

Operating system and hypervisor code that runs when the CPL ≠ 3 should use XSAVE and XRSTOR to control LWP rather than using LLWPCB (see below). Use WRMSR to write 0 to LWP_CBADDR to immediately stop LWP without saving its current state (see “LWP_CBADDR—LWPCB Address MSR” on page 440).

It is possible to execute LLWPCB when the CPL ≠ 3 or when SMM is active, but the system software must ensure that the LWPCB and the entire ring buffer are properly mapped into writable memory in order to avoid a #PF or #GP fault. Furthermore, if LWP is enabled when a kernel executes LLWPCB, both the old and new control blocks and ring buffers must be accessible. Using LLWPCB in these situations is not recommended.

13.4.5.2 SLWPCB—Store LWPCB Address

Flushes LWP state to memory and returns the current effective address of the LWPCB in the specified register.

If LWP is not currently enabled, SLWPCB sets the specified register to zero.

The flush operation stores the internal event counters for active events and the current ring buffer head pointer into the LWPCB. If there is an unwritten event record pending, it is written to the event ring buffer.

If LWP_CBADDR is not zero, the value returned is an effective address that is calculated by subtracting the current DS.Base address from the linear address kept in LWP_CBADDR. Note that if DS has changed between the time LLWPCB was executed and the time SLWPCB is executed, this might result in an address that is not currently accessible by the application.

SLWPCB generates an invalid opcode exception (#UD) if the machine is not in protected mode or if LWP is not available.

It is possible to execute SLWPCB when the CPL ≠ 3 or when SMM is active, but if the LWPCB pointer is not zero, the system software must ensure that the LWPCB and the entire ring buffer are properly mapped into writable memory in order to avoid a #PF fault. Using SLWPCB in these situations is not recommended.

13.4.5.3 LWPVAL—Insert Value Sample in LWP Ring Buffer

Decrements the event counter associated with the Programmed Value Sample event (see “Programmed Value Sample” on page 428). If the resulting counter value is negative, inserts an event record into the

LWP event ring buffer in memory and advances the ring buffer pointer. If the counter is not negative and the ModRM operand specifies a memory location, that location is not accessed.

The event record has an EventId of 1. The value in the register specified by vvvv (first operand) is stored in the Data2 field at bytes 23–16 (zero extended if the operand size is 32). The value in a register or memory location (second operand) is stored in the Data1 field at bytes 7–4. The immediate value (third operand) is truncated to 16 bits and stored in the Flags field at bytes 3–2. See Figure 13-22 on page 428.

If the ring buffer is not full or if LWP is running in continuous mode, the head pointer is advanced and the event counter is reset to the interval for the event (subject to randomization). If the ring buffer threshold is exceeded and threshold interrupts are enabled, an interrupt is signaled. If LWP is in continuous mode and the new head pointer equals the tail pointer, the MissedEvents counter is incremented to indicate that the buffer wrapped.

If the ring buffer is full and LWP is running in synchronized mode, the event record overwrites the last record in the buffer, the MissedEvents counter in the LWPCB is incremented, and the head pointer is not advanced.

LWPVAL generates an invalid opcode exception (#UD) if the machine is not in protected mode or if LWP is not available.

LWPVAL does nothing if LWP is not enabled or if the Programmed Value Sample event is not enabled in LWPCB.Flags. This allows LWPVAL instructions to be harmlessly ignored if profiling is turned off.

It is possible to execute LWPVAL when the CPL ≠ 3 or when SMM is active, but the system software must ensure that the memory operand (if present), the LWPCB, and the entire ring buffer are properly mapped into writable memory in order to avoid a #PF or #GP fault. Using LWPVAL in these situations is not recommended.

LWPVAL can be used by a program to perform value profiling. This is the technique of sampling the value of some program variable at a predetermined frequency. For example, a managed runtime might use LWPVAL to sample the value of the divisor for a frequently executed divide instruction in order to determine whether to generate specialized code for a common division. It might sample the target location of an indirect branch or call to see if one destination is more frequent than others. Since LWPVAL does not modify any registers or condition codes, it can be inserted harmlessly between any instructions.

Note

When LWPVAL completes (whether or not it stored an event record in the event ring buffer), it counts as an instruction retired. If the Instructions Retired event is active, this might cause that counter to become negative and immediately store an event record. If LWPVAL also stored an event record, the buffer will contain two records with the same instruction address (but different EventId values).

13.4.5.4 LWPINS—Insert User Event Record in LWP Ring Buffer

Inserts a record into the LWP event ring buffer in memory and advances the ring buffer pointer.

The record has an EventId of 255. The value in the register specified by vvvv (first operand) is stored in the Data2 field at bytes 23–16 (zero extended if the operand size is 32). The value in a register or memory location (second operand) is stored in the Data1 field at bytes 7–4. The immediate value (third operand) is truncated to 16 bits and stored in the Flags field at bytes 3–2. See Figure 13-28 on page 435.

If the ring buffer is not full or if LWP is running in continuous mode, the head pointer is advanced and the CF flag is cleared. If the ring buffer threshold is exceeded and threshold interrupts are enabled, an interrupt is signaled. If LWP is in continuous mode and the new head pointer equals the tail pointer, the MissedEvents counter is incremented to indicate that the buffer wrapped.

If the ring buffer is full and LWP is running in synchronized mode, the event record overwrites the last record in the buffer, the MissedEvents counter in the LWPCB is incremented, the head pointer is not advanced, and the CF flag is set.

LWPINS generates an invalid opcode exception (#UD) if the machine is not in protected mode or if LWP is not available.

LWPINS simply clears CF if LWP is not enabled. This allows LWPINS instructions to be harmlessly ignored if profiling is turned off.

It is possible to execute LWPINS when the CPL $\neq 3$ or when SMM is active, but the system software must ensure that the memory operand (if present), the LWPCB, and the entire ring buffer are properly mapped into writable memory in order to avoid a #PF or #GP fault. Using LWPINS in these situations is not recommended.

LWPINS can be used by a program to mark significant events in the ring buffer as they occur. For instance, a program might capture information on changes in the process' address space such as library loads and unloads, or changes in the execution environment such as a change in the state of a user-mode thread of control.

Note that when the LWPINS instruction finishes writing a event record in the event ring buffer, it counts as an instruction retired. If the Instructions Retired event is active, this might cause that counter to become negative and immediately store another event record with the same instruction address (but different EventId values).

13.4.6 LWP Control Block

An application uses the LWP Control Block (LWPCB) to specify the details of Lightweight Profiling operation. It is an interactive region of memory in which some fields are controlled and modified by the LWP hardware and others are controlled and modified by the software that processes the LWP event records.

Most of the fields in the LWPCB are constant for the duration of a LWP session (the time between enabling LWP and disabling it). This means that they are loaded into the LWP hardware when it is enabled, and may be periodically reloaded from the same location as needed. The contents of the

constant fields must not be changed during a LWP run or results will be unpredictable. Changing the LWPCB memory to read-only or unmapped will cause an exception the next time LWP attempts to access it. To change values in the LWPCB, disable LWP, change the LWPCB (or create a new one), and re-enable LWP.

A few fields are modified by the LWP hardware to communicate progress to the software that is emptying the event ring buffer. Software may read them but should never modify them during an LWP session. Other fields are for software to modify to indicate that progress has been made in emptying the ring buffer. Software writes these fields and the LWP hardware reads them as needed.

For efficiency, some of the LWPCB fields may be shadowed internally in the LWP hardware unit when profiling is enabled. LWP refreshes these fields from (or flushes them to) memory as needed to allow software to make progress. For more information, refer to “LWPCB Access” on page 461.

The BufferTailOffset field is at offset 64 in the LWPCB in order to place it in a separate cache line on most implementations, assuming that the LWPCB itself is aligned properly. This allows the software thread that is emptying the ring buffer to retain write ownership of that cache line without colliding with the changes made by LWP when writing BufferHeadOffset. In addition, most implementations will use a value of 128 as the offset to the EventInterval1 field, since that places the event information in a separate cache line.

All fields in the LWPCB (as shown in Figure 13-30) that are marked as “Reserved” (or “Rsvd”) should be zero.

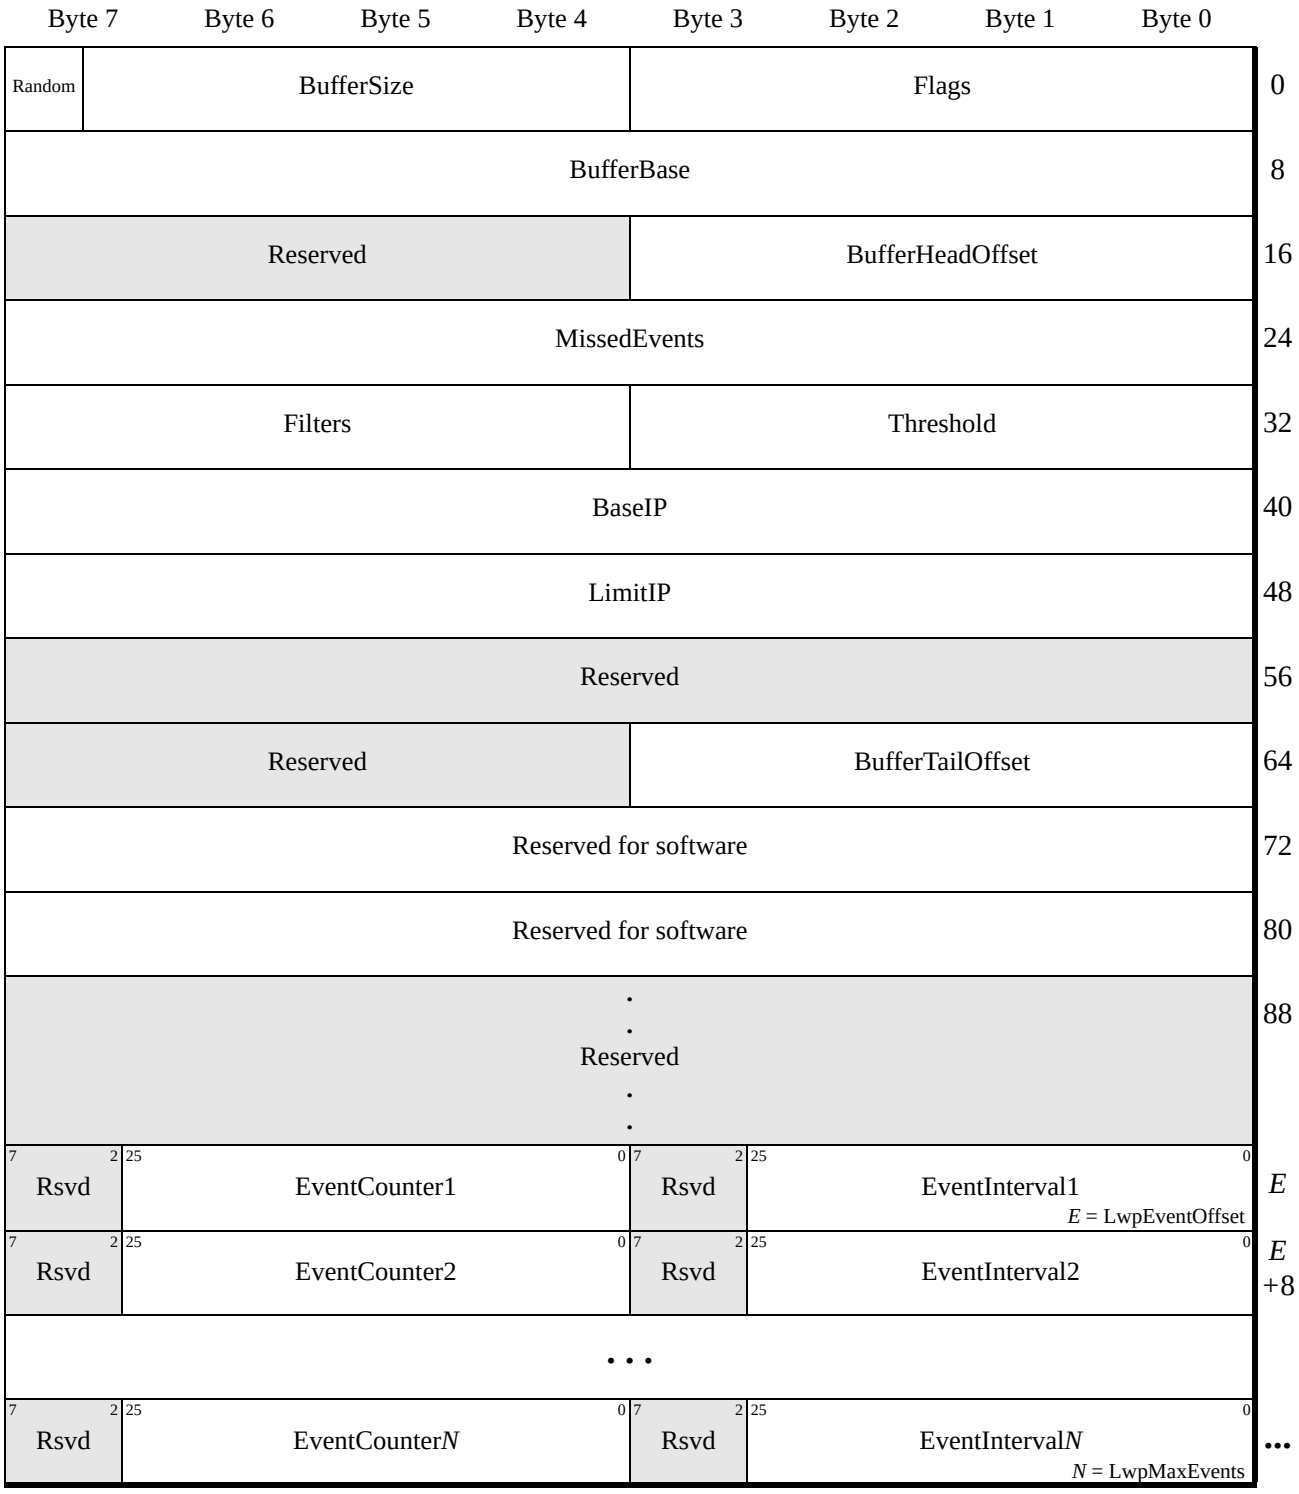


Figure 13-30. LWPCB—Lightweight Profiling Control Block

The R/W column in Table 13-8 below indicates how a field is used while LWP is enabled:

- LWP—hardware modifies the field; software may read it, but must not change it
- Init—hardware reads and modifies the field while executing LLWPCB; the field must then remain unchanged as long as the LWPCB is in use
- SW—software may modify the field; hardware may read it, but does not change it
- No—field must remain unchanged as long as the LWPCB is in use

Table 13-8. LWPCB—Lightweight Profiling Control Block Fields

Bytes	Bits	Field	Description	R/W
3–0		Flags	Flags indicating which events should be or are being counted (see Figure 13-31, “LWPCB Flags”) and whether threshold interrupts should be enabled. Before executing LLWPCB, the application sets Flags to a bit mask of the events (and interrupt) that should be enabled. LLWPCB does a logical “and” of this mask with the available feature bits in LWP_CFG and rewrites Flags with the mask of features actually enabled.	Init
7–4	27:0	BufferSize	Total size of the event ring buffer (in bytes). Must be a multiple of the event record size LwpEventSize (the value used internally will be rounded down if not). BufferSize must be at least (32 * LwpMinBufferSize * LwpEventSize).	No
7	7:4	Random	Number of bits of randomness to use in counters. Each time a counter is loaded from an interval to start counting down to the next event to record, the bottom Random bits are set to a random value. This avoids fixed patterns in events.	No
15–8		BufferBase	The Effective Address of the event ring buffer. Should be aligned on a 64-byte boundary for reasonable performance. Software is encouraged to align the ring buffer to a page boundary for best performance. If the default address size is less than 64 bits, the upper bits of BufferBase must be zero. LLWPCB converts BufferBase to a linear address and stores it internally. LWPCB.BufferBase is not modified.	No
19–16		BufferHeadOffset	Unsigned offset from BufferBase specifying where the LWP hardware will store the next event record. When BufferHeadOffset == BufferTailOffset, the ring buffer is empty. BufferHeadOffset must always be less than BufferSize; LWP will use a value of 0 if BufferHeadOffset is too large. Also, it must always be a multiple of LwpEventSize; LWP will round it down if not.	LWP
23–20			Reserved	
31–24		MissedEvents	The 64-bit count of the number of events that were missed. A missed event occurs when LWP stores an event record, attempts to advance BufferHeadOffset, and discovers that it would be equal to BufferTailOffset. In this case, LWP leaves BufferHeadOffset unchanged and instead increments the MissedEvents counter. Thus, when the ring buffer is full, the last event record is overwritten.	LWP

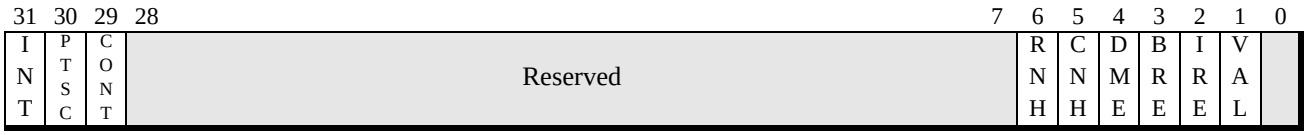
Table 13-8. LWPCB—Lightweight Profiling Control Block Fields (continued)

Bytes	Bits	Field	Description	R/W
35–32		Threshold	Threshold for signaling an interrupt to indicate that the ring buffer is filling up. If threshold interrupts are enabled in Flags, then when LWP advances BufferHeadOffset, it computes the space used as ((BufferHeadOffset – BufferTailOffset) % BufferSize). If the space used equals or exceeds Threshold, LWP causes an interrupt. If Threshold is greater than BufferSize, no interrupt will ever be taken. If Threshold is zero, an interrupt will be taken every time an event record is stored in the ring buffer. Threshold is an unsigned integer multiple of LwpEventSize (the value used internally will be rounded down if not). Ignored if threshold interrupts are not available in LWP_CFG or if they are not enabled in Flags	No
39–36		Filters	Filters to qualify which events are eligible to be counted. This field includes bits to filter branch events by type and prediction status, and bits and values to filter cache events by type and latency. See Figure 13-32, “LWPCB Filters” for details.	
47–40		BaseIP	Low limit of the IP filtering range. An instruction must start at a location greater than or equal to BaseIP to be in range. Ignored if IPF is zero or if the CPUID LwpIpFiltering bit is 0 to indicate that IP filtering is not supported.	No
55–48		LimitIP	High limit of the IP filtering range. An instruction must start at a location less than or equal to LimitIP to be in range. Ignored if IPF is zero or if the CPUID LwpIpFiltering bit is 0 to indicate that IP filtering is not supported.	No
63–56			Reserved	
67–64		BufferTailOffset	Unsigned offset from BufferBase to the oldest event record in the ring buffer. BufferTailOffset is maintained by software and must always be less than BufferSize and a multiple of LwpEventSize. If software stores a value of BufferTailOffset into the LWPCB that violates these rules, the LWP hardware might not detect ring buffer overflow or threshold conditions properly.	SW
71–68			Reserved	
72–87			Reserved for software use. These bytes are never read or written by the LWP hardware	SW
(*E*-1) – 88			Reserved area between the fixed portion of the LWPCB and the event specifiers. Should be zero. The EventInterval1 field is at offset *E* = LwpEventOffset.	

Table 13-8. LWPCB—Lightweight Profiling Control Block Fields (continued)

Bytes	Bits	Field	Description	R/W
(*E*+3)–*E*	25:0	EventInterval1	Reset value for counting events of type EventId = 1 (Programmed Value Sample). A value of *n* specifies that after *n+1* (modified by Random) LWPVAL instructions, LWP will store an event record in the ring buffer. EventInterval1 is a signed value. If it is negative, LLWPCB will use zero and will store zero into EventInterval1 in the LWPCB. The Programmed Value Sample event is the only one which allows an interval to be below the implementation minimum interval value.	Init
E+3	7:2		Reserved	
(*E*+7)–(*E*+4)	25:0	EventCounter1	Starting (LLWPCB) or current (SLWPCB) value of counter. This is a signed number. LLWPCB treats a negative value as zero.	LWP
E+7	7:2		Reserved	
(*E*+11)–(*E+8*)	25:0	EventInterval2	Reset value for counting events of type EventId = 2 (Instructions Retired). A value of *n* specifies that after *n+1* (modified by Random) instructions are retired, LWP will store an event record in the ring buffer. EventInterval2 is a signed value. If it is negative or is below the implementation minimum, LLWPCB will use the minimum and will store that value into EventInterval2 in the LWPCB.	Init
E+11	7:2		Reserved	
(*E*+15)–(*E*+12)	57:32	EventCounter2	Starting (LLWPCB) or current (SLWPCB) value of counter. This is a signed number. LLWPCB treats a negative value as zero.	LWP
E+15	7:2		Reserved	
		Event3…	Repeat event configuration similar to EventInterval2 and EventCounter2 for EventId values from 3 to LwpMaxEvents.	

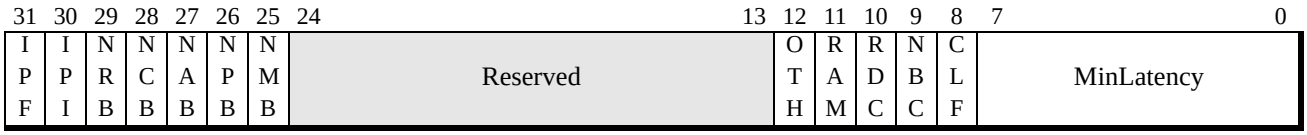
The LLWPCB instruction reads the Flags word from the LWPCB to determine which events to profile and whether threshold interrupts should be enabled. LLWPCB writes the Flags word after turning off bits corresponding to features which are not currently available.



Bit	Field	Input to LLWPCB	Value after LLWPCB
0		Reserved	
1	VAL	Enable LWPVAL instruction	LWPVAL instruction enabled
2	IRE	Enable Instructions Retired event	Instructions Retired event enabled
3	BRE	Enable Branches Retired event	Branches Retired event enabled
4	DME	Enable DCache miss event	DCache Miss event enabled
5	CNH	Enable CPU clocks not halted event	CPU Clocks Not Halted event enabled
6	RNH	Enable CPU reference clocks not halted event	CPU Reference Clocks Not Halted event enabled
28:7		Reserved	
29	CONT	1—Use continuous mode. If the ring buffer overflows, LWP continues to store events and advance BufferHead. Software must stop LWP in order to empty the ring buffer. 0—Use synchronized mode.	LWP operates in continuous mode if input bit is set and continuous mode is available. Otherwise, LWP operates in synchronous mode.
30	PTSC	1—Store the Performance Time Stamp Counter (PTSC) in the TimeStamp field of each event record, if PTSC is available. 0—Store 0 in the TimeStamp field.	Performance Time Stamp Counter value will be stored if input bit is set and PTSC feature is available. Otherwise 0 is stored.
31	INT	Enable threshold interrupts.	Threshold interrupts are enabled.

Figure 13-31. LWPCB Flags

Event counting can be filtered by a number of conditions which are specified in the Filters word of the LLWPCB. The IP filtering applies to all events. Cache level filtering applies to all events that interact with the caches. Branch filtering applies to the Branches Retired event.



Bits	Field	Description
7:0	MinLatency	Minimum latency for a cache-related event
8	CLF	Cache level filtering
9	NBC	Northbridge cache events
10	RDC	Remote data cache events
11	RAM	DRAM cache events
12	OTH	Other cache events
24:13		Reserved
25	NMB	No mispredicted branches
26	NPB	No predicted branches
27	NAB	No absolute branches
28	NCB	No conditional branches
29	NRB	No unconditional relative branches
30	IPI	IP filtering invert
31	IPF	IP filtering

Figure 13-32. LWPCB Filters

The following table provides detailed descriptions of the fields in the Filters word.

Table 13-9. LWPCB Filters Fields

Bits	Field	Description
7:0	MinLatency	Minimum latency for a cache-related event to be eligible for LWP counting. Applies to all cache-related events being monitored. MinLatency is multiplied by 16 to get the actual latency in cycles, providing less resolution but a larger range for filtering. An implementation may have a maximum for the latency value. If MinLatency*16 exceeds this maximum value, the maximum is used instead. A value of 0 disables filtering by latency. Ignored if no cache latency event is enabled or if the CPUID LwpCacheLatency bit is 0 to indicate that the implementation does not filter by latency (use the CLF bits to get a similar effect). At least one of these mechanisms is supported if any cache miss events are supported.
8	CLF	Cache level filtering. 1—Enables filtering cache-related events by the cache level or memory level that returned the data. It enables the next 4 bits. Cache-related events are only eligible for counting if the bit describing the memory level is on. 0—Disables cache level filtering. The next 4 bits are ignored, and any cache or memory level is eligible. Ignored if no cache latency event is enabled or if the CPUID LwpCacheLevels bit is 0 to indicate that the implementation does not filter by cache level (use the MinLatency field to get a similar effect). At least one of these mechanisms is supported if any cache miss events are supported.
9	NBC	Northbridge cache events. 1—Count cache-related events that are satisfied from data held in a cache that resides on the northbridge. 0—Ignore northbridge cache events Ignored if CLF is 0.
10	RDC	Remote data cache events. 1—Count cache-related events that are satisfied from data held in a remote data cache. 0—Ignore remote cache events. Ignored if CLF is 0.
11	RAM	DRAM cache events. 1—Count cache-related events that are satisfied from DRAM. 0—Ignore DRAM cache events. Ignored if CLF is 0.
12	OTH	Other cache events. 1—Count cache-related events that are satisfied from other sources, such as MMIO, Config space, PCI space, or APIC. 0—Ignore such cache events Ignored if CLF is 0.
24:13		Reserved

Table 13-9. LWPCB Filters Fields (continued)

Bits	Field	Description
25	NMB	No mispredicted branches. 1—Mispredicted branches will not be counted. 0—Mispredicted branches will be counted if not suppressed by other filter conditions. Caution: If NMB and NPB are both set, no branches will be counted. Ignored if the Branches Retired event is not enabled or if the CPUID LwpBranchPrediction bit is 0 to indicate that the implementation does not filter by prediction.
26	NPB	No predicted branches. 1—Correctly predicted branches will not be counted. Note that since direct branches are always predicted correctly, this is a superset of the NDB filter. 0—Correctly predicted branches will be counted if not suppressed by other filter conditions. Caution: If NMB and NPB are both set, no branches will be counted. Ignored if the Branches Retired event is not enabled or if the CPUID LwpBranchPrediction bit is 0 to indicate that the implementation does not filter by prediction.
27	NAB	No absolute branches. 1—Absolute branches will not be counted. This only applies to jumps through a register or memory (JMP opcode FF /4) and calls through a register or memory (CALL opcode FF /2). Relative branches (both conditional and unconditional) are counted normally if not disabled via the NRB or NCB bits. 0—Absolute branches will be counted if not suppressed by other filter conditions. Caution: If NRB, NCB, and NAB are all set, no branches will be counted. Ignored if the Branches Retired event is not enabled.
28	NCB	No conditional branches. 1—Conditional branches will not be counted. This only applies to conditional jumps (Jcc) and loops (LOOPcc). Unconditional relative branches, indirect jumps through a register or memory, and returns are counted normally if not disabled via the NRB or NAB bits. 0—Conditional branches will be counted if not suppressed by other filter conditions. Caution: If NRB, NCB, and NAB are all set, no branches will be counted. Ignored if the Branches Retired event is not enabled.

Table 13-9. LWPCB Filters Fields (continued)

Bits	Field	Description
29	NRB	No unconditional relative branches. 1—Unconditional relative branches will not be counted. This applies to unconditional jumps (JMP), calls (CALL), and returns (RET). Conditional branches and indirect jumps or calls through a register or memory are counted normally if not disabled via the NCB or NAB bits. 0—Direct branches will be counted if not suppressed by other filter conditions. Caution: If NRB, NCB, and NAB are all set, no branches will be counted. Ignored if the Branches Retired event is not enabled.
30	IPI	IP filtering invert. 1—IP filtering inverted. Only instructions outside the range from BaseIP to LimitIP are eligible for LWP counting. 0—IP filtering normal. Only instructions inside the range from BaseIP to LimitIP are eligible for LWP counting. Ignored if IPF is zero or if the CPUID LwpIpFiltering bit is 0 to indicate that IP filtering is not supported.
31	IPF	IP filtering. 1—IP filtering enabled. The values of the BaseIP and LimitIP fields specify a range of instruction addresses that are eligible for LWP event counting and reporting. The range is inclusive if IPI is 0 and exclusive if IPI is 1. 0—IP filtering disabled; instructions at every address are eligible for LWP counting. Ignored if the CPUID LwpIpFiltering bit is 0 to indicate that IP filtering is not supported.

13.4.7 XSAVE/XRSTOR

LWP requires that the processor support the XSAVE/XRSTOR instructions for managing extended processor state components.

13.4.7.1 Configuration

The processor uses bit 62 of XFEATURE_ENABLED_MASK (register XCR0) to indicate whether LWP state can be saved and restored, and thus whether LWP is available to applications. The LWP XSAVE area length and offset from the beginning of the XSAVE area are available from the CPUID instruction (see “Detecting LWP XSAVE Area” on page 436). In Version 1 of LWP, the LWP XSAVE area is 128 (080h) bytes long and the offset is 832 (340h) bytes.

13.4.7.2 XSAVE Area

Figure 13-33 below shows the layout of the XSAVE area for LWP. It is large enough to allow for future expansion of the number of event counters. Details of the fields are in Table 13-10.

All fields in the XSAVE area that are marked as “Reserved” (or “Rsvd”) must be zero.

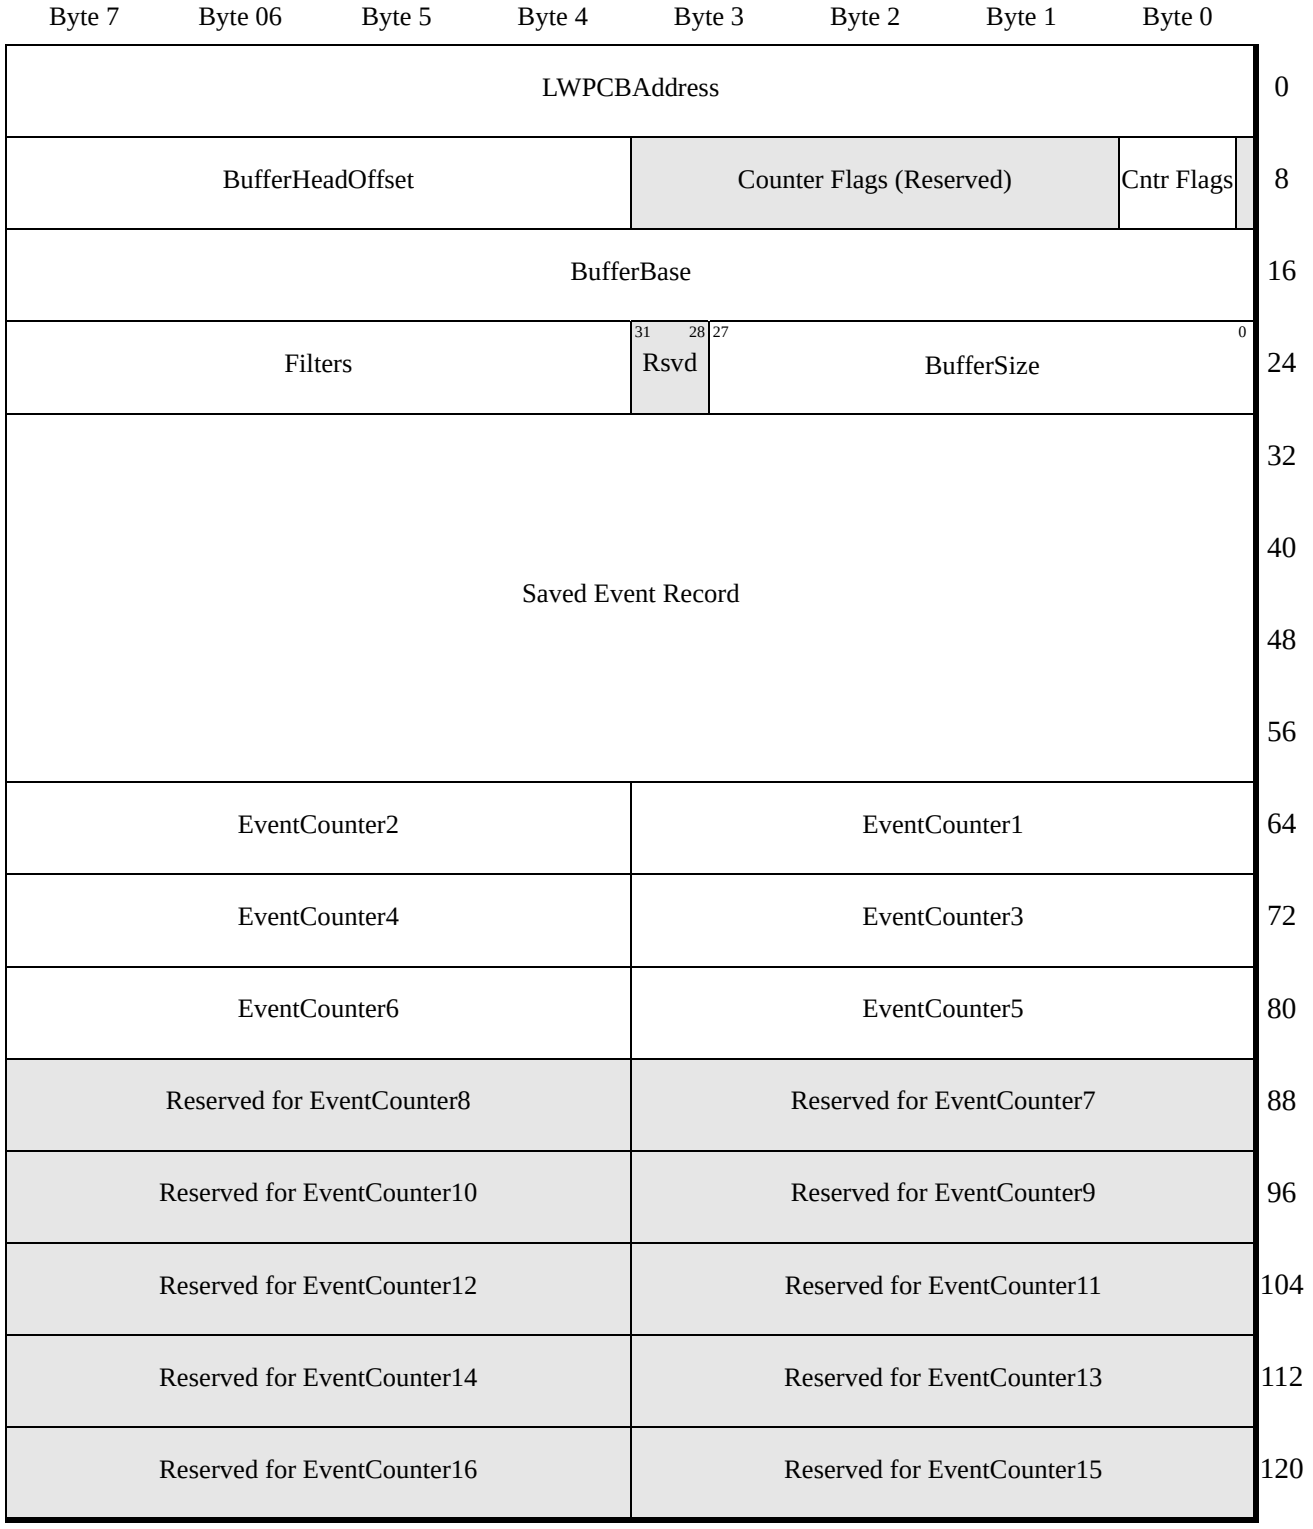


Figure 13-33. XSAVE Area for LWP

Table 13-10. XSAVE Area for LWP Fields

Bytes	Bits	Field	Description
7–0		LWPCBAddress	Address of LWPCB. 0 if LWP is disabled, in which case the rest of the save area is ignored. This is a linear address.
9–8	0	—	Reserved
9–8	1	CntrFlags.Counter1	1—Event with EventId 1 is active. XRSTOR will make the event active and restore its counter from EventCounter1. 0—Event 1 is not active. XRSTOR will make the event inactive.
9–8	6:2	CntrFlags.Counter*n*	Bit flags defined as above for EventCounter2–6.
9–8	15:7	—	Reserved for counter flags
11–10	15:0	—	Reserved for counter flags
15–12		BufferHeadOffset	BufferHeadOffset value
23–16		BufferBase	Address of the event ring buffer. This is a linear address.
27–24	27:0	BufferSize	Size of the event ring buffer
27–24	31:28	—	Reserved
31–28		Filters	Profiling filters (same as the Filters field in the LWPCB)
63–32		SavedEventRecord	If an event record is pending, the data to write. May be sparse. Zero in the EventId field means no record pending.
67–64		EventCounter1	Counter for event 1 (valid if CntrFlags.Counter1 bit is set)
87–68		EventCounter*n*	Counters for events 2–6 (valid if the respective Counter*n* bit is set)
127–88		—	Reserved for future event counters

13.4.7.3 XSAVE operation

If LWP is not currently enabled (i.e., if LWP_CBADDR = 0), no state needs to be stored. XSAVE sets bit 62 in XSAVE.HEADER.XSTATE_BV to 0 so that an attempt to restore state from this save area will use the processor supplied values. See “Processor supplied values” on page 459.

If LWP is enabled, XSAVE stores the various internal LWP values into the XSAVE area with no checking or conversion and sets bit 62 in XSAVE.HEADER.XSTATE_BV to 1.

13.4.7.4 XRSTOR operation

If bit 62 in XFEATURE_ENABLED_MASK (XCR0) is 0 or if bit 62 of EDX:EAX (EDX[30]) is 0, XRSTOR does not alter the LWP state.

If the above bits are 1 but bit 62 in XSAVE.HEADER.XSTATE_BV is 0, XRSTOR writes the LWP state using the processor supplied values, disabling LWP. See “Processor supplied values” on page 459.

If all of the above bits are 1, XRSTOR loads LWP state from the XSAVE area as follows:

1. The internal pointers and sizes are loaded.

- If BufferSize is below the implementation minimum, LWP is disabled and XRSTOR of LWP state terminates.
- If BufferSize is not a multiple of the event record size, it is rounded down.
- If BufferHeadOffset is greater than (BufferSize - LwpEventSize), a value of 0 is used instead.
- If BufferHeadOffset is not a multiple of the event record size, it is rounded down.

2. For each bit that is set in the Flags field that corresponds to an available event (as currently set in the LWP_CFG MSR), the corresponding event is enabled and the event counter is loaded from the EventCounter*n* field. All other events are disabled.
3. If the EventId field in the SavedEventRecord is non-zero, there was a pending event when XSAVE was executed. XRSTOR loads the event record into hardware. LWP will store it into the event ring buffer as soon as possible once the CPL is 3.

   Software should not alter the SavedEventRecord field. An implementation may ignore a saved event record if it was not constructed by XSAVE. Storing an event into SavedEventRecord and then executing XRSTOR is not a reliable way of injecting an event into the ring buffer.

Note that if LWP is already enabled when executing XRSTOR, the old LWP state is overwritten without being saved.

No interrupt is generated by XRSTOR if the restored value of BufferHeadOffset results in a buffer that is filled beyond the threshold. The interrupt will occur the next time an event record is stored.

XRSTOR may not restore all of the state necessary for LWP to operate. The LWP hardware will read additional state from the LWPCB when it stores then next event record.

If the CPL = 0, XRSTOR simply reloads the LWPCB address and the ring buffer address from the XSAVE area. Kernel software is trusted not to alter the area in such a way as to allow access to memory that the application could not otherwise read or write. The linear addresses in the XSAVE area were validated when the application executed LLWPCB.

If the CPL ≠ 0, XRSTOR first validates the LWPCB and ring buffer pointers. This prevents an application from altering the XSAVE area in order to gain access to memory that it could not otherwise read or write (based on the current values in the DS segment register). Note that if a program's DS value changes after doing a successful LLWPCB, it might be incapable of doing an XSAVE and then an XRSTOR of LWP state. The XRSTOR will fail if the new DS value no longer allows access to the linear addresses corresponding to the LWPCB or the ring buffer. Programs should avoid this behavior.

If XRSTOR is executed when the CPL ≠ 0, the system performs additional checks on the LWPCB and ring buffer addresses according to the pseudo-code below. A "Store-type Segment_check" fails if the limit check fails (address is beyond the segment limit) or if the segment is read-only.

```
bool Check(uint64 addr, uint32 size) { // Utility function
      if (!64bit_Mode)
            addr = truncate32(addr - DS.BASE)
      uint64 top = addr + size - 1;
      if (! Store-type Segment_check on DS:[addr] || // Check lower bound
          ! Store-type Segment_check on DS:[top])    // and upper bound
```

```
            return false;
      return true;
}

if (! Check(XSAVE.LWPCBAddress, sizeof(LWPCB)) ||
    ! Check(XSAVE.BufferAddress, XSAVE.BufferSize))
      Disable LWP
```

If any of the address checks fails, LWP is disabled. No fault is generated. A program that executes XRSTOR when the CPL ≠ 0 and DS has changed can use SLWPCB to check whether LWP is running.

As with all features that use XSAVE and XRSTOR, if bit 62 of XFEATURE_ENABLED_MASK (XCR0) is 0 but bit 62 of XSAVE.HEADER.XSTATE_BV is 1, XRSTOR will cause a #GP(0) exception.

13.4.7.5 Processor supplied values

If XRSTOR is executed when bit 62 of XFEATURE_ENABLED_MASK (XCR0) and EDX:EAX are both 1, but the corresponding bit in XSAVE.HEADER.XSTATE_BV is 0, it indicates that there is no LWP state to restore. In this case, LWP_CBADDR is set to 0 and LWP is disabled. Other processor internal state for LWP is set to 0 as necessary to avoid security issues.

13.4.8 Implementation Notes

The following subsections describe other LWP considerations.

13.4.8.1 Multiple Simultaneous Events

Multiple events are possible when an instruction retires. For instance, an indirect jump through a pointer in memory can trigger the instructions retired, branches retired, and DCache miss events simultaneously. LWP counts all events that apply to the instruction, but might not store event records for all events whose event counters became negative. It is implementation dependent as to how many event records are stored when multiple event counters simultaneously become negative. If not all events cause event records to be stored, the choice of which event(s) to report is implementation dependent and may vary from run to run on the same processor.

13.4.8.2 Processor State for Context Switch, SVM, and SMM

Implementations of LWP have internal state to hold information such as the current values of the counters for the various events, a pointer into the event ring buffer, and a copy of the tail pointer for quick detection of threshold and overflow states.

There are times when the system must preserve the volatile LWP state. When the operating system context switches from one user thread to another, the old user state must be saved with the thread's context and the new state must be loaded. When a hypervisor decides to switch from one guest OS to another, the same must be done for the guest systems' states. Finally, state must be stored and reloaded when the system enters and exits SMM, since the SMM code may decide to shut off power to the core.

Hardware does not maintain the LWP state in the active LWPCB. This is because the counters change with every event (not just every reported event), so keeping them in memory would generate a large amount of unnecessary memory traffic. Also, the LWPCB is in user memory and may be paged out to disk at any time, so the memory may not be available when needed.

Saving State at Thread Context Switches

LWP requires that an operating system use the XSAVE and XRSTOR instructions to save and restore LWP state across context switches.

XRSTOR restores the LWP volatile state when restoring other system state. Some additional LWP state will be restored from the LWPCB when operations in ring 3 require that information.

LWP does not support the “lazy” state save and restore that is possible for floating point and SSE state. It does not interact with the CR0[TS] bit. Operating systems that support LWP must always do an XSAVE to preserve the old thread’s LWP context and an XRSTOR to set up the new LWP context. The OS can continue to do a lazy switch of the FP and SSE state by ensuring that the corresponding bits in EDX:EAX are clear when it executes the XSAVE and XRSTOR to handle the LWP context.

Saving State at SVM Worldswitch to a Different Guest

Hypervisors that allow guests to use LWP must save and restore LWP state when the guest OS changes. In addition to the usual information in the VMCB, the hypervisor must use XSAVE/XRSTOR to maintain the volatile LWP state and must also save and restore LWP_CFG. When switching between a guest that uses LWP and one that does not, the hypervisor changes the value of XFEATURE_ENABLED_MASK (XCR0), which ensures that LWP is only enabled in the appropriate guest(s).

A hypervisor need not modify the LWP state if the guest OS is not changed.

Enabling SVM Live Migration

Some hypervisors support live migration of a guest virtual machine. Live migration is when a hypervisor preserves the entire state of the guest running on one physical machine, copies that state to another physical machine, and then resumes execution of the guest on the new hardware.

To allow live migration among machines which may have different internal implementations of LWP, the hypervisor must present the common subset of features among all the hosts in the pool of machines that can be used. Furthermore, since the hypervisor may XSAVE LWP state on one machine and XRSTOR it on another machine, the contents of the XSAVE area must be consistent across all implementations.

This means that an implementation of LWP keeps all event counters internally, not in the LWPCB. If implementations were permitted to differ in this detail, a counter might not get properly restored after migrating the guest machine.

Saving State at SMM Entry and Exit

SMM entry and exit must save and restore LWP state when the processor is going to change power state. SMM must use XSAVE/XRSTOR and must also save and restore LWP_CFG. Since LWP is ring 3 only and is inactive in System Management Mode, its state should not need to be saved and restored otherwise.

Notes on Restoring LWP State

The LWPCB may not be in memory at all times. Therefore, the LWP hardware does not attempt to access it while still in the OS kernel/VMM/SMM, since that access might fault. Some LWP state is restored once the processor is in ring 3 and can take a #PF exception without crashing. This usually happens the next time LWP needs to store an event record into the ring buffer.

13.4.8.3 LWPCB Access

Several LWPCB fields are written asynchronously by the LWP hardware and by the user software. This section discusses techniques for reducing the associated memory traffic. This is interesting to software because it influences what state is kept internally in LWP, and it explains the protocol between the hardware filling the event ring buffer and the software emptying it.

The hardware keeps an internal copy of the event ring buffer head pointer. It need not flush the head pointer to the LWPCB every time it stores an event record. The flush can be done periodically or it can be deferred until a threshold or buffer full condition happens or until the application executes LLWPCB or SLWPCB. Exceeding the buffer threshold always forces the head pointer to memory so that the interrupt handler emptying the ring buffer sees the threshold condition.

The hardware may keep an internal copy of the event ring buffer tail pointer. It need not read the software-maintained tail pointer unless it detects a threshold or buffer full condition. At that point, it rereads the tail pointer to see if software has emptied some records from the ring buffer. If so, it recomputes the condition and acts accordingly. This implies that software polling the ring buffer should begin processing event records when it detects a threshold condition itself. To avoid a race condition with software, the hardware rereads the tail pointer every time it stores an event record while the threshold condition appears to be true. (An implementation can relax this to “every n^{th} time” for some small value of n.) It also rereads it whenever the ring buffer appears to be full.

The interval values used to reset the counters can be cached in the hardware when the LLWPCB instruction is executed, or they can be read from the LWPCB each time the counter overflows.

The ring buffer base and size are cached in the hardware.

The MissedEvents value is a counter for an exceptional condition and is kept in memory.

The cached LWP state is refreshed from the LWPCB when LWP is enabled either explicitly via LLWPCB or implicitly when needed in ring 3 after LWP state is restored via XRSTOR.

Caching implies that software cannot reliably change sampling intervals or other cached state by modifying the LWPCB. The change might not be noticed by the LWP hardware. On the other hand, changing state in the LWPCB while LWP is running may change the operation at an unpredictable

moment in the future if LWP context is saved and restored due to context switching. Software must stop and restart LWP to ensure that any changes reliably take effect.

13.4.8.4 Security

The operating system must ensure that information does not leak from one process to another or from the kernel to a user process. Hence, if it supports LWP at all, the operating system must ensure that the state of the LWP hardware is set appropriately when a context switch occurs and when a new process or thread is created. LWP state for a new thread can be initialized by executing XRSTOR with bit 62 of XSAVE.HEADER.XSTATE_BV set to 0 and the corresponding bit in EDX:EAX set to 1.

13.4.8.5 Interrupts

The LWP threshold interrupt vector number is specified in the LWP_CFG MSR. The operating system must assign a vector for LWP threshold interrupts and fill in the corresponding entry in the interrupt-descriptor table. Note that the LWP interrupt is not shared with the performance counter interrupt, since the system allows concurrent and independent use of those two mechanisms.

13.4.8.6 Memory Access During LWP Operation

When LWP needs to save an event record in the event ring buffer, it accesses the user memory containing the ring buffer and sometimes the memory containing the LWPCB. This causes a Page Fault (#PF) exception if those pages are not in memory.

A particular implementation of LWP has several ways to deal with page faults when storing an event record. These may include saving the event record in the XSAVE area and retrying the store later, reexecuting the instruction, or discarding the event and reporting the next event of the appropriate type.

Note that this reinforces the notion that LWP is a sampling mechanism. Programs cannot rely on it to precisely capture every n^{th} instance of an event. It captures *approximately* every n^{th} instance.

13.4.8.7 Guidelines for Operating Systems

To support LWP, an operating system should follow the following guidelines. Most of these operations should be done on each core of a multi-core system.

System initialization

1. Use CPUID Fn0000_0000 to ensure that the system is running on an “Authentic AMD” processor, and then check CPUID Fn8000_0001_ECX[LWP] to ensure that the processor supports LWP.

   Alternatively, check CPUID Fn0000_000D_EDX_x0[30] to ensure that the system supports the LWP XSAVE area, indicating that the processor supports LWP.

2. Enable XSAVE operations by setting CR4[OSXSAVE].
3. Enable LWP by executing XSETBV to set bit 62 of XCR0.

4. Assign a unique interrupt vector number for LWP threshold interrupts and load the corresponding entry in the interrupt-descriptor table with the address of the interrupt handler. This handler should use some system-specific method to forward any threshold interrupts to the application.
5. Make LWP available by setting LWP_CFG. To enable all supported LWP features, set LWP_CFG[31:0] to the value returned by CPUID Fn8000_001C_EDX. Set LWP_CFG[COREID] to the APIC core number (or some other value unique to the core) and LWP_CFG[VECTOR] to the assigned interrupt vector number.

Thread support

- For each thread, allocate an XSAVE area that is at least as big as the XFeatureEnabledSizeMax value returned by CPUID Fn0000_000D_EBX_x0 (ECX=0). This is good practice for any system that supports XSAVE.
- When creating a new process or thread, execute XRSTOR with bit 62 of EDX:EAX set to 1 and bit 62 of XSAVE.HEADER.XSTATE_BV set to 0. This ensures that LWP is turned off for any new thread. Alternatively, use WRMSR to write 0 into LWP_CBADDR before starting the thread.
- When saving a running thread's context, execute XSAVE with bit 62 of EDX:EAX set to 1 to save the thread's LWP state. It takes almost no time or resources if the thread is not using LWP.
- When restoring a thread's context, execute XRSTOR with bit 62 of EDX:EAX set to 1. This restores the LWP state for the thread or disables LWP if the thread is not using it.
- When a thread exits or aborts, use WRMSR to store 0 into LWP_CBADDR. This ensures that LWP is turned off.

13.4.8.8 Summary of LWP State

LWP adds the following visible state to the AMD64 architecture:

- CPUID Fn8000_0001_ECX[LWP] (bit 15) to indicate LWP support.
- CPUID Fn8000_001C to indicate LWP features.
- Two new MSRs: LWP_CFG, LWP_CBADDR,.
- Four new instructions: LLWPCB, SLWPCB, LWPINS, and LWPVAL.
- Bit 62 in XCR0 (XFEATURE_ENABLED_MASK)
- A new XSAVE area for LWP state.
- New fields for LWP state in the SVM and SMM context, whether in the VMCB and SMM save area or elsewhere.

See Section 3.3, "Processor Feature Identification," on page 71 for information on using the CPUID instruction to obtain information about processor capabilites.

14 Processor Initialization and Long Mode Activation

This chapter describes the hardware actions taken following a processor reset and the steps that must be taken to initialize processor resources and activate long mode. In some cases the actions required are implementation-specific with references made to the appropriate implementation-specific documentation.

14.1 Processor Initialization

System logic can initialize the processor in either of two ways. One method, called RESET, is usually initiated by the assertion of an external signal (typically designated RESET#). The other method, called INIT, is typically initiated by another processor by means of an INIT interprocessor interrupt (IPI). See “Interprocessor Interrupts (IPI)” on page 615 for more information.

Both initialization techniques place the processor in real mode and initialize processor resources to a known, consistent state from which software can begin execution. The processor begins execution when the RESET# pin is deasserted or the INIT state is exited.

The RESET method places the processor in a known state and prepares it to begin execution in real mode. The INIT method is similar except it does not modify the state of certain registers. See Section 14.1.3 on page 466 for a comparison of these initialization methods.

System logic ensures that the processor transitions through the RESET state whenever power is reapplied after a planned or unplanned interruption. A RESET can also be performed when power is stable. An INIT can be performed at any time after the processor is powered up.

14.1.1 Built-In Self Test (BIST)

An optional built-in self-test can be performed after the processor is reset. The mechanism for triggering the BIST is implementation-specific, and can be found in the hardware documentation for the implementation. The number of processor cycles BIST can consume before completing is also implementation-specific but typically consumes several million cycles.

BIST can be used by system implementations to assist in verifying system integrity, thereby improving system reliability, availability, and serviceability. The internal BIST hardware generally tests all internal array structures for errors. These structures can include (but are not limited to):

- All internal caches, including the tag arrays as well as the data arrays.
- All TLBs.
- Internal ROMs, such as the microcode ROM and floating-point constant ROM.
- Branch-prediction structures.

EAX is loaded with zero if BIST completes without detecting errors. If any hardware faults are detected during BIST, a non-zero value is loaded into EAX.

14.1.2 Clock Multiplier Selection

The internal processor clock runs at some multiple of the system clock. The processor-to-system clock multiple does not have to be fixed by a processor implementation but instead can be programmable through hardware or software, or some combination of the two. For information on selecting the processor-clock multiplier, see the *BIOS and Kernel Developer's Guide (BKDG)* or *Processor Programming Reference Manual* applicable to your product.

14.1.3 Processor Initialization State

Table 14-1 shows the initial processor state following either RESET or INIT. Except as indicated, processor resources generally are set to the same value after either RESET or INIT.

Table 14-1. Initial Processor State

Processor Resource	Value After RESET	Value After INIT
CR0	0000_0000_6000_0010h	CD and NW are unchanged Bit 4 (reserved) = 1 All others = 0
CR2, CR3, CR4	0	
CR8	0	Not modified
RFLAGS	0000_0000_0000_0002h	
EFER	0	
RIP	0000_0000_0000_FFF0h	
CS	Selector = F000h Base = 0000_0000_FFFF_0000h Limit = FFFFh Attributes = See Table 14-2 on page 468	
DS, ES, FS, GS, SS	Selector = 0000h Base = 0 Limit = FFFFh Attributes = See Table 14-2 on page 468	
GDTR, IDTR	Base = 0 Limit = FFFFh	
LDTR, TR	Selector = 0000h Base = 0 Limit = FFFFh Attributes = See Table 14-2 on page 468	
RAX	0 (non-zero if BIST is run and fails)	0

Table 14-1. Initial Processor State (continued)

Processor Resource	Value After RESET	Value After INIT

	LDTR	S = 0 Type = 0010	LDT
	TR	S = 0 Type = 0011	Busy 16-Bit TSS

14.1.4 Multiple Processor Initialization

Following reset in multiprocessor configurations, the processors use a multiple-processor initialization protocol to negotiate which processor becomes the *bootstrap* processor. This bootstrap processor then executes the system initialization code while the remaining processors wait for software initialization to complete. For further information, see the documentation for particular implementations of the architecture.

14.1.5 Fetching the First Instruction

After a RESET or INIT, the processor is operating in 16-bit real mode. Normally within real mode, the code-segment base-address is formed by shifting the CS-selector value left four bits. The base address is then added to the value in EIP to form the physical address into memory. As a result, the processor can only address the first 1 Mbyte of memory when in real mode.

However, immediately following RESET or INIT, the CS-selector register is loaded with F000h, but the CS base-address is *not* formed by left-shifting the selector. Instead, the CS base-address is initialized to FFFF_0000h. EIP is initialized to FFF0h. Therefore, the first instruction fetched from memory is located at physical-address FFFF_FFF0h (FFFF_0000h + 0000_FFF0h).

The CS base-address remains at this initial value until the CS-selector register is loaded by software. This can occur as a result of executing a far jump instruction or call instruction, for example. When CS is loaded by software, the new base-address value is established as defined for real mode (by left shifting the selector value four bits).

14.2 Hardware Configuration

14.2.1 Processor Implementation Information

Software can read processor-identification information from the EDX register immediately following RESET or INIT. This information can be used to initialize software to perform processor-specific functions. The information stored in EDX is defined as follows:

- *Stepping ID (bits 3:0)*—This field identifies the processor-revision level.
- *Extended Model (bits 19:16) and Model (bits 7:4)*—These fields combine to differentiate processor models within a instruction family. For example, two processors may share the same microarchitecture but differ in their feature set. Such processors are considered different models within the same instruction family. This is a split field, comprising an extended-model portion in bits 19:16 with a legacy portion in bits 7:4
- *Extended Family (bits 27:20) and Family (bits 11:8)*—These fields combine to differentiate processors by their microarchitecture.

The CPUID instruction can be used to obtain the same information. This is done by executing CPUID with either function 1 or function 8000_0001h. Additional information about the processor and the features supported can be gathered using CPUID with other feature codes. See Section 3.3, “Processor Feature Identification,” on page 71 for additional information.

14.2.2 Enabling Internal Caches

Following a RESET (but not an INIT), all instruction and data caches are disabled, and their contents are invalidated (the MOESI state is set to the invalid state). Software can enable these caches by clearing the cache-disable bit (CR0.CD) to zero (RESET sets this bit to 1). Software can further refine caching based on individual pages and memory regions. Refer to “Cache Control Mechanisms” on page 202 for more information on cache control.

Memory-Type Range Registers (MTRRs). Following a RESET (but not an INIT), the MTRRdefType register is cleared to 0, which disables the MTRR mechanism. The variable-range and fixed-range MTRR registers are not initialized and are therefore in an undefined state. Before enabling the MTRR mechanism, the initialization software (usually platform firmware) must load these registers with a known value to prevent unexpected results. Clearing these registers, for example, sets memory to the uncacheable (UC) type.

14.2.3 Initializing Media and x87 Processor State

Some resources used by x87 floating-point instructions and media instructions must be initialized by software before being used. Initialization software can use the CPUID instruction to determine whether the processor supports these instructions, and then initialize their resources as appropriate.

x87 Floating-Point State Initialization. Table 14-3 on page 470 shows the differences between the initial x87 floating-point state following a RESET and the state established by the FINIT/FNINIT instruction. An INIT does not modify the x87 floating-point state. The initialization software can

execute an FINIT or FNINIT instruction to prepare the x87 floating-point unit for use by application software. The FINIT and FNINIT instructions have no effect on the 64-bit media state.

Table 14-3. x87 Floating-Point State Initialization

x87 Floating-Point Resource	RESET	FINIT/FNINIT Instructions
FPR0–FPR7	0	Not modified
Control Word	0040h • Round to nearest • Single precision • Unmask all exceptions	037Fh • Round to nearest • Extended precision • Mask all exceptions
Status Word	0000h	
Tag Word	5555h (FPR*n* contain zero)	FFFFh (FPR*n* are empty)
Instruction CS	0000h	
Instruction Offset	0	
x87 Instruction Opcode	0	
Data-Operand DS	0000h	
Data-Operand Offset	0	

Initialization software should also load the MP, EM, and NE bits in the CR0 register as appropriate for the operating system. The recommended settings are:

- *MP=1*—Setting MP to 1 causes a device-not-available exception (#NM) to occur when the FWAIT/WAIT instruction is executed and the task-switched bit (CR0.TS) is set to 1. This supports operating systems that perform lazy context-switching of x87 floating-point state.
- *EM=0*—Clearing EM to 0 allows the x87 floating-point unit to execute instructions rather than causing a #NM exception (CR0.EM=1). System software sets EM to 1 only when software emulation of x87 instructions is desired.
- *NE=1*—Setting NE to 1 causes x87 floating-point exceptions to be handled by the floating-point exception-pending exception (#MF) handler. Clearing this bit causes the processor to externally indicate the exception occurred, and an external device can then cause an external interrupt to occur in response.

Refer to “CR0 Register” on page 42 for additional information on these control bits.

64-Bit Media State Initialization. There are no special requirements placed on software to initialize the processor state used by 64-bit media instructions. This state is initialized completely by the processor following a RESET. System software should leave CR0.EM cleared to 0 to allow execution of the 64-bit media instructions. If CR0.EM is set to 1, attempted execution of the 64-bit media instructions causes an invalid-opcode exception (#UD).

The 64-bit media state is not modified by an INIT.

SSE State Initialization. Platform firmware or system software must also prepare the processor to allow execution of SSE instructions. The required preparations include:

- Leaving CR0.EM cleared to 0 to allow execution of the SSE instructions. If CR0.EM is set to 1, attempted execution of the SSE instructions except FXSAVE/FXRSTOR causes an invalid-opcode exception (#UD). An attempt to execute either of these instructions when CR0.EM is set results in a #NM exception.
- Enabling the SSE instructions by setting CR4.OSFXSR to 1. Software cannot execute the SSE instructions unless this bit is set. Setting this bit also indicates that system software uses the FXSAVE and FXRSTOR instructions to save and restore, respectively, the SSE state. These instructions also save and restore the 64-bit media state and x87 floating-point state.
- Indicating that system software uses the SIMD floating-point exception (#XF) for handling SSE floating-point exceptions. This is done by setting CR4.OSXMMEXCPT to 1.
- Setting (optionally) the MXCSR mask bits to mask or unmask SSE floating-point exceptions as desired. Because this register can be read and written by application software, it is not absolutely necessary for system software to initialize it.

Refer to “CR4 Register” on page 47 for additional information on these CR4 control bits.

14.2.4 Model-Specific Initialization

Implementations of the AMD64 architecture can contain model-specific features and registers that are not initialized by the processor and therefore require system-software initialization. System software must use the CPUID instruction to determine which features are supported. Model-specific features are generally configured using model-specific registers (MSRs), which can be read and written using the RDMSR and WRMSR instructions, respectively.

Some of the model-specific features are pervasive across many processor implementations of the AMD64 architecture and are therefore described within this volume. These include:

- System-call extensions, which must be enabled in the EFER register before using the SYSCALL and SYSRET instructions. See “System-Call Extension (SCE) Bit” on page 57 for information on enabling these instructions.
- Memory-typing MSRs. See “Memory-Type Range Registers (MTRRs)” on page 469 for information on initializing and using these registers.
- The machine-check mechanism. See “Initializing the Machine-Check Mechanism” on page 311 for information on enabling and using this capability.
- Extensions to the debug mechanism. See “Software-Debug Resources” on page 386 for information on initializing and using these extensions.
- The performance-monitoring resources. See “Performance Monitoring Counters” on page 400 for information on initializing and using these resources.

Initialization of other model-specific features used by the page-translation mechanism and long mode are described throughout the remainder of this section.

Some model-specific features are not pervasive across processor implementations and are therefore not described in this volume. For more information on these features and their initialization requirements, see the *BIOS and Kernel Developer's Guide (BKDG)* or *Processor Programming Reference Manual* applicable to your product.

14.3 Initializing Real Mode

A basic real-mode (real-address-mode) operating environment must be initialized so that system software can initialize the protected-mode operating environment. This real-mode environment must include:

- A real-mode IDT for vectoring interrupts and exceptions to the appropriate handlers while in real mode. The IDT base-address value in the IDTR initialized by the processor can be used, or system software can relocate the IDT by loading a new base-address into the IDTR.
- The real-mode interrupt and exception handlers. These must be loaded before enabling external interrupts.

  Because the processor can always accept a non-maskable interrupt (NMI), it is possible an NMI can occur before initializing the IDT or the NMI handler. System hardware must provide a mechanism for disabling NMIs to allow time for the IDT and NMI handler to be properly initialized. Alternatively, the IDT and NMI handler can be stored in non-volatile memory that is referenced by the initial values loaded into the IDTR.

  Maskable interrupts can be enabled by setting EFLAGS.IF after the real-mode IDT and interrupt handlers are initialized.
- A valid stack pointer (SS:SP) to be used by the interrupt mechanism should interrupts or exceptions occur. The values of SS:SP initialized by the processor can be used.
- One or more data-segment selectors for storing the protected-mode data structures that are created in real mode.

Once the real-mode environment is established, software can begin initializing the protected-mode environment.

14.4 Initializing Protected Mode

Protected mode must be entered before activating long mode. A minimal protected-mode environment must be established to allow long-mode initialization to take place. This environment must include the following:

- A protected-mode IDT for vectoring interrupts and exceptions to the appropriate handlers while in protected mode.
- The protected-mode interrupt and exception handlers referenced by the IDT. Gate descriptors for each handler must be loaded in the IDT.
- A GDT which contains:

- A code descriptor for the code segment that is executed in protected mode.
- A read/write data segment that can be used as a protected-mode stack. This stack can be used by the interrupt mechanism if interrupts or exceptions occur.

Software can optionally load the GDT with one or more data segment descriptors, a TSS descriptor, and an LDT descriptor for use by long-mode initialization software.

After the protected-mode data structures are initialized, system software must load the IDTR and GDTR with pointers to those data structures. Once these registers are initialized, protected mode can be enabled by setting CR0.PE to 1.

If legacy paging is used during the long-mode initialization process, the page-translation tables must be initialized before enabling paging. At a minimum, one page directory and one page table are required to support page translation. The CR3 register must be loaded with the starting physical address of the highest-level table supported in the page-translation hierarchy. After these structures are initialized and protected mode is enabled, paging can be enabled by setting CR0.PG to 1.

14.5 Initializing Long Mode

From protected mode, system software can initialize the data structures required by long mode and store them anywhere in the first 4 Gbytes of physical memory. These data structures can be relocated above 4 Gbytes once long mode is activated. The data structures required by long mode include the following:

- An IDT with 64-bit interrupt-gate descriptors. Long-mode interrupts are always taken in 64-bit mode, and the 64-bit gate descriptors are used to transfer control to interrupt handlers running in 64-bit mode. See “Long-Mode Interrupt Control Transfers” on page 272 for more information.
- The 64-bit mode interrupt and exception handlers to be used in 64-bit mode. Gate descriptors for each handler must be loaded in the 64-bit IDT.
- A GDT containing segment descriptors for software running in 64-bit mode and compatibility mode, including:
  - Any LDT descriptors required by the operating system or application software.
  - A TSS descriptor for the single 64-bit TSS required by long mode.
  - Code descriptors for the code segments that are executed in long mode. The code-segment descriptors are used to specify whether the processor is operating in 64-bit mode or compatibility mode. See “Code-Segment Descriptors” on page 97, “Long (L) Attribute Bit” on page 98, and “CS Register” on page 79 for more information.
  - Data-segment descriptors for software running in compatibility mode. The DS, ES, and SS segments are ignored in 64-bit mode. See “Data-Segment Descriptors” on page 98 for more information.
  - FS and GS data-segment descriptors for 64-bit mode, if required by the operating system. If these segments are used in 64-bit mode, system software can also initialize the full 64-bit base

addresses using the WRMSR instruction. See “FS and GS Registers in 64-Bit Mode” on page 80 for more information.

The existing protected-mode GDT can be used to hold the long-mode descriptors described above.

- A single 64-bit TSS for holding the privilege-level 0, 1, and 2 stack pointers, the interrupt-stack-table pointers, and the I/O-redirection-bitmap base address (if required). This is the only TSS required, because hardware task-switching is not supported in long mode. See “64-Bit Task State Segment” on page 371 for more information.
- The 4-level page-translation tables required by long mode. Long mode also requires the use of physical-address extensions (PAE) to support physical-address sizes greater than 32 bits. See “Long-Mode Page Translation” on page 141 for more information.

If paging is enabled during the initialization process, it *must* be disabled before enabling long mode. After the long-mode data structures are initialized, and paging is disabled, software can enable and activate long mode.

14.6 Enabling and Activating Long Mode

Long mode is *enabled* by setting the long-mode enable control bit (EFER.LME) to 1. However, long mode is not *activated* until software also enables paging. When software enables paging while long mode is enabled, the processor activates long mode, which the processor indicates by setting the long-mode-active status bit (EFER.LMA) to 1. The processor behaves as a 32-bit x86 processor in all respects until long mode is activated, even if long mode is enabled. None of the new 64-bit data sizes, addressing, or system aspects available in long mode can be used until EFER.LMA=1.

Table 14-4 shows the control-bit settings for enabling and activating the various operating modes of the AMD64 architecture. The default address and data sizes are shown for each mode. For the methods of overriding these default address and data sizes, see “Instruction Prefixes” in Volume 1.

Table 14-4. Processor Operating Modes

Mode		Encoding			Default Address Size (bits)[2]	Default Data Size (bits)[2]
		EFER.LMA[1]	CS.L	CS.D		
Long Mode	64-Bit Mode	1	1	0	64	32
	Compatibility Mode		0	1	32	32
				0	16	16
Legacy Mode		0	x	1	32	32
				0	16	16

Note:
1. *EFER.LMA is set by the processor when software sets EFER.LME and CR0.PG according to the sequence described in "Activating Long Mode" on page 475.*
2. *See "Instruction Prefixes" in Volume 1 for overrides to default sizes.*

Long mode uses two code-segment-descriptor bits, CS.L and CS.D, to control the operating submodes. If long mode is active, CS.L = 1, and CS.D = 0, the processor is running in 64-bit mode, as shown in Table 14-4 on page 475. With this encoding (CS.L=1, CS.D=0), default operand size is 32 bits and default address size is 64 bits. Using instruction prefixes, the default operand size can be overridden to 64 bits or 16 bits, and the default address size can be overridden to 32 bits.

The final encoding of CS.L and CS.D in long mode (CS.L=1, CS.D=1) is reserved for future use.

When long mode is active and CS.L is cleared to 0, the processor is in compatibility mode, as shown in Table 14-4 on page 475. In compatibility mode, CS.D controls default operand and address sizes exactly as it does in the legacy x86 architecture. Setting CS.D to 1 specifies default operand and address sizes as 32 bits. Clearing CS.D to 0 specifies default operand and address sizes as 16 bits.

14.6.1 Activating Long Mode

Switching the processor to long mode requires several steps. In general, the sequence involves disabling paging (CR0.PG=0), enabling physical-address extensions (CR4.PAE=1), loading CR3, enabling long mode (EFER.LME=1), and finally enabling paging (CR0.PG=1).

Specifically, software must follow this sequence to activate long mode:

1. If starting from page-enabled protected mode, disable paging by clearing CR0.PG to 0. This requires that the MOV CR0 instruction used to disable paging be located in an identity-mapped page (virtual address equals physical address).
2. In any order:

- Enable physical-address extensions by setting CR4.PAE to 1. Long mode requires the use of physical-address extensions (PAE) in order to support physical-address sizes greater than 32 bits. Physical-address extensions must be enabled before enabling paging.
- Load CR3 with the physical base-address of the level-4 page-map-table (PML4). See “Long-Mode Page Translation” on page 141 for details on creating the 4-level page translation tables required by long mode.
- Enable long mode by setting EFER.LME to 1.

3. Enable paging by setting CR0.PG to 1. This causes the processor to set the EFER.LMA bit to 1. The instruction following the MOV CR0 that enables paging must be a branch, and both the MOV CR0 and the following branch instruction must be located in an identity-mapped page.

14.6.2 Consistency Checks

The processor performs long-mode consistency checks whenever software attempts to modify any of the control bits directly involved in activating long mode (EFER.LME, CR0.PG, and CR4.PAE). A general-protection exception (#GP) occurs when a consistency check fails. Long-mode consistency checks ensure that the processor does not enter an undefined mode or state that results in unpredictable behavior.

Long-mode consistency checks cause a general-protection exception (#GP) to occur if:

- An attempt is made to enable or disable long mode while paging is enabled.
- Long mode is enabled, and an attempt is made to enable paging before enabling physical-address extensions (PAE).
- Long mode is enabled, and an attempt is made to enable paging while CS.L=1.
- Long mode is active and an attempt is made to disable physical-address extensions (PAE).

Table 14-5 summarizes the long-mode consistency checks made during control-bit transitions.

Table 14-5. Long-Mode Consistency Checks

Control Bit	Transition	Check
EFER.LME	0 Ⓡ 1	If (CR0.PG=1) then #GP(0)
	1 Ⓡ 0	If (CR0.PG=1) then #GP(0)
CR0.PG	0 Ⓡ 1	If ((EFER.LME=1) & (CR4.PAE=0) then #GP(0) If ((EFER.LME=1) & (CS.L=1)) then #GP(0)
CR4.PAE	1 Ⓡ 0	If (EFER.LMA=1) then #GP(0)

14.6.3 Updating System Descriptor Table References

Immediately after activating long mode, the system-descriptor-table registers (GDTR, LDTR, IDTR, TR) continue to reference legacy descriptor tables. The tables referenced by these descriptors all reside in the lower 4 Gbytes of virtual-address space. After activating long mode, 64-bit operating-system software should use the LGDT, LLDT, LIDT, and LTR instructions to load the system descriptor-table

registers with references to the 64-bit versions of the descriptor tables. See “Descriptor Tables” on page 82 for details on descriptor tables in long mode.

Long mode requires 64-bit interrupt-gate descriptors to be stored in the interrupt-descriptor table (IDT). Software must not allow exceptions or interrupts to occur between the time long mode is activated and the subsequent update of the interrupt-descriptor-table register (IDTR) that establishes a reference to the 64-bit IDT. This is because the IDTR continues to reference a 32-bit IDT immediately after long mode is activated. If an interrupt or exception occurred before updating the IDTR, a legacy 32-bit interrupt gate would be referenced and interpreted as a 64-bit interrupt gate, with unpredictable results.

External interrupts can be disabled using the CLI instruction. Non-maskable interrupts (NMI) and system-management interrupts (SMI) must be disabled using external hardware. See “Long-Mode Interrupt Control Transfers” on page 272 for more information on long mode interrupts.

14.6.4 Relocating Page-Translation Tables

The long-mode page-translation tables must be located in the first 4 Gbytes of physical-address space before activating long mode. This is necessary because the MOV CR3 instruction used to initialize the page-map level-4 base address must be executed in legacy mode before activating long mode. Because the MOV CR3 is executed in legacy mode, only the low 32 bits of the register are written, which limits the location of the page-map level-4 translation table to the low 4 Gbytes of memory. Software can relocate the page tables anywhere in physical memory, and re-initialize the CR3 register, after long mode is activated.

14.7 Leaving Long Mode

To return from long mode to legacy protected mode with paging enabled, software must deactivate and disable long mode using the following sequence:

1. Switch to compatibility mode and place the processor at the highest privilege level (CPL=0).
2. Deactivate long mode by clearing CR0.PG to 0. This causes the processor to clear the LMA bit to 0. The MOV CR0 instruction used to disable paging must be located in an identity-mapped page. Once paging is disabled, the processor behaves as a standard 32-bit x86 processor.
3. Load CR3 with the physical base-address of the legacy page tables.
4. Disable long mode by clearing EFER.LME to 0.
5. Enable legacy page-translation by setting CR0.PG to 1. The instruction following the MOV CR0 that enables paging must be a branch, and both the MOV CR0 and the following branch instruction must be located in an identity-mapped page.

14.8 Long-Mode Initialization Example

Following is sample code that outlines the steps required to place the processor in long mode.

```

   <insert 64-bit code here>
```

15 Secure Virtual Machine

The AMD Virtualization™ (AMD-V™) architecture is designed to support enterprise-class server virtualization software technology and facilitate virtualization development and deployment on any type of system, through the Secure Virtual Machine (SVM) extension. An SVM-enabled virtual machine architecture provides hardware resources that allow a single physical machine to run multiple operating systems efficiently, while maintaining secure, hardware-enforced isolation.

15.1 The Virtual Machine Monitor

A *virtual machine monitor* (VMM), also known as a *hypervisor*, consists of software that controls the execution of multiple *guest* operating systems on a single physical machine. The VMM provides each guest the appearance of full control over a complete computer system (memory, CPU, and all peripheral devices). The use of the term *host* refers to the execution context of the VMM. *World switch* refers to the operation of switching between the host and guest. A guest may have one or more virtual CPUs (vCPUs) managed by the guest OS, just as on a non-virtualized system, and a VMM may run any mix of vCPUs from the same or different guests on different logical processors simultaneously with no hardware-imposed constraints.

Fundamentally, VMMs work by *intercepting* and emulating in a safe manner sensitive operations in the guest (such as changing the page tables, which could give a guest access to memory it is not allowed to access, or accessing peripheral devices that are shared among multiple guests). The AMD SVM architecture provides hardware assists to improve performance and facilitate implementation of virtualization.

15.2 SVM Hardware Overview

SVM processor support provides a set of hardware extensions designed to enable economical and efficient implementation of virtual machine systems. Generally speaking, hardware support falls into two complementary categories: *virtualization* support and *security* support.

15.2.1 Virtualization Support

The AMD virtual machine architecture is designed to provide:

- A guest/host tagged TLB to reduce virtualization overhead
- External (DMA) access protection for memory
- Assists for interrupt handling, virtual interrupt support, and enhanced pause filter
- The ability to intercept selected instructions or events in the guest
- Mechanisms for fast world switch between VMM and guest

15.2.2 Guest Mode

This new processor mode is entered through the VMRUN instruction. When in guest mode, the behavior of some x86 instructions changes to facilitate virtualization.

The CPUID function numbers 4000_0000h–4000_00FFh have been reserved for software use. Hypervisors can use these function numbers to provide an interface to pass information from the hypervisor to the guest. This is similar to extracting information about a physical CPU by using CPUID. Hypervisors use the CPUID Fn 400000[FF:00] bit to denote a virtual platform.

Feature bit CPUID Fn0000_0001_ECX[31] has been reserved for use by hypervisors to indicate the presence of a hypervisor. Hypervisors set this bit to 1 and physical CPU's set this bit to zero. This bit can be probed by the guest software to detect whether they are running inside a virtual machine.

15.2.3 External Access Protection

Guests may be granted direct access to selected I/O devices. Hardware support is designed to prevent devices owned by one guest from accessing memory owned by another guest (or the VMM).

15.2.4 Interrupt Support

To facilitate efficient virtualization of interrupts, the following support is provided under control of VMCB flags:

Intercepting physical interrupt delivery. The VMM can request that physical interrupts cause a running guest to exit, allowing the VMM to process the interrupt.

Virtual interrupts. The VMM can inject virtual interrupts into the guest. Under control of the VMM, a virtual copy of the EFLAGS.IF interrupt mask bit, and a virtual copy of the APIC's task priority register are used transparently by the guest instead of the physical resources.

Sharing a physical APIC. SVM allows multiple guests to share a physical APIC with isolation of each guest's manipulation of APIC state from the other guests' views of their own APIC state, so that no guest can interfere with delivery of interrupts to another guest.

Direct interrupt delivery. On models that support it, the Advanced Virtual Interrupt Controller (AVIC) extension virtualizes the APIC's interrupt delivery functions. This provides for delivery of device or inter-processor interrupts directly to a target vCPU or vCPUs, which avoids the overhead of having the VMM to determine interrupt routing and speeds up interrupt delivery. (see section 15.29).

15.2.5 Restartable Instructions

SVM is designed to safely restart, with the exception of task switches, any intercepted instruction (either atomic or idempotent) after the intercept.

15.2.6 Security Support

To further support secure initialization and execution, SVM provides additional system support through a variety of extensions.

Attestation. The SKINIT instruction and associated system support (the Trusted Platform Module, or TPM) allow for verifiable startup of trusted software (such as a hypervisor, or a native operating system), based on secure hash comparison. (section 15.27).

Encrypted memory. On models that support it, the Secure Encrypted Virtualization (SEV) and SEV Encrypted State (SEV-ES) extensions guard against inspection of guest memory and (for SEV-ES) guest register state by malicious hypervisor code, memory bus tracing or memory device removal through encryption of guest memory and register contents (section 15.34 and section 15.35).

Secure Nested Paging. On models that support it, the SEV-SNP extension provides additional protection for guest memory against malicious manipulation of address translation mechanisms by hypervisor code. (section 15.36).

15.3 SVM Processor and Platform Extensions

SVM hardware extensions can be grouped into the following categories:

- State switch—VMRUN, VMSAVE, VMLOAD instructions, global interrupt flag (GIF), and instructions to manipulate the latter (STGI, CLGI). (section 15.5, section 15.5.2, section 15.17)
- Intercepts—allow the VMM to intercept sensitive operations in the guest. (section 15.7 through section 15.14)
- Interrupt and APIC assists—physical interrupt intercepts, virtual interrupt support, APIC.TPR virtualization. (section 15.17 and section 15.21)
- SMM intercepts and assists (section 15.22)
- External (DMA) access protection (section 15.24)
- Nested paging support for two levels of address translation. (section 15.25)
- Security—SKINIT instruction. (section 15.27)

15.4 Enabling SVM

The VMRUN, VMLOAD, VMSAVE, CLGI, VMMCALL, and INVLPGA instructions can be used when the EFER.SVME is set to 1; otherwise, these instructions generate a #UD exception. The SKINIT and STGI instructions can be used when either the EFER.SVME bit is set to 1 or the feature flag CPUID Fn8000_0001_ECX[SKINIT] is set to 1; otherwise, these instructions generate a #UD exception.

Before enabling SVM, software should detect whether SVM can be enabled using the following algorithm:

```
if (CPUID Fn8000_0001_ECX[SVM] == 0)
  return SVM_NOT_AVAIL;

if (VM_CR.SVMDIS == 0)
  return SVM_ALLOWED;

if (CPUID Fn8000_000A_EDX[SVML]==0)
  return SVM_DISABLED_AT_BIOS_NOT_UNLOCKABLE
  // the user must change a platform firmware setting to enable SVM
else return SVM_DISABLED_WITH_KEY;
  // SVMLock may be unlockable; consult platform firmware or TPM to obtain the
key.
```

For more information on using the CPUID instruction to obtain processor capability information, see Section 3.3, “Processor Feature Identification,” on page 71.

15.5 VMRUN Instruction

The VMRUN instruction is the cornerstone of SVM. VMRUN takes, as a single argument, the physical address of a 4KB-aligned page, the *virtual machine control block* (VMCB), which describes a virtual machine (guest) to be executed. The VMCB contains:

- a list of instructions or events in the guest (e.g., write to CR3) to intercept,
- various control bits that specify the execution environment of the guest or that indicate special actions to be taken before running guest code, and
- guest processor state (such as control registers, etc.).

Note that VMRUN is not supported inside the SMM handler and the behavior is undefined.

15.5.1 Basic Operation

The VMRUN instruction has an implicit addressing mode of [rAX]. Software must load RAX (EAX in 32-bit mode) with the physical address of the VMCB, a 4-Kbyte-aligned page that describes a virtual machine to be executed. The portion of RAX used in forming the address is determined by the current effective address size.

The VMCB is accessed by physical address and should be mapped as writeback (WB) memory.

VMRUN is available only at CPL 0. A #GP(0) exception is raised if the CPL is greater than 0. Furthermore, the processor must be in protected mode and EFER.SVME must be set to 1, otherwise, a #UD exception is raised.

The VMRUN instruction saves some host processor state information in the host state-save area in main memory at the physical address specified in the VM_HSAVE_PA MSR; it then loads corresponding guest state from the VMCB state-save area. VMRUN also reads additional control bits from the VMCB that allow the VMM to flush the guest TLB, inject virtual interrupts into the guest, etc.

The VMRUN instruction then checks the guest state just loaded. If an illegal state has been loaded, the processor exits back to the host (section 15.6).

Otherwise, the processor now runs the guest code until an intercept event occurs, at which point the processor suspends guest execution and resumes host execution at the instruction following the VMRUN. This is called a #VMEXIT and is described in detail in (section 15.6).

VMRUN saves or restores a minimal amount of state information to allow the VMM to resume execution after a guest has exited. This allows the VMM to handle simple intercept conditions quickly. If additional guest state information must be saved or restored (e.g., to handle more complex intercepts or to switch to a different guest), the VMM must use the VMLOAD and VMSAVE instructions to handle the additional guest state (section 15.5.2).

Saving Host State. To ensure that the host can resume operation after #VMEXIT, VMRUN saves at least the following host state information:

- CS.SEL, NEXT_RIP—The CS selector and rIP of the instruction following the VMRUN. On #VMEXIT the host resumes running at this address.
- RFLAGS, RAX—Host processor mode and the register used by VMRUN to address the VMCB.
- SS.SEL, RSP—Stack pointer for host.
- CR0, CR3, CR4, EFER—Paging/operating mode for host.
- IDTR, GDTR—The pseudo-descriptors. VMRUN does not save or restore the host LDTR.
- ES.SEL and DS.SEL.

Processor implementations may store only part or none of host state in the memory area pointed to by VM_HSAVE_PA MSR and may store some or all host state in hidden on-chip memory. Different implementations may choose to save the hidden parts of the host's segment registers as well as the selectors. For these reasons, software must not rely on the format or contents of the host state save area, nor attempt to change host state by modifying the contents of the host save area.

Loading Guest State. After saving host state, VMRUN loads the following guest state from the VMCB:

- CS, rIP—Guest begins execution at this address. The hidden state of the CS segment register is also loaded from the VMCB.
- RFLAGS, RAX.
- SS, RSP—Includes the hidden state of the SS segment register.
- CR0, CR2, CR3, CR4, EFER—Guest paging mode. Writing paging-related control registers with VMRUN does *not* flush the TLB since address spaces are switched. (section 15.16.)
- INTERRUPT_SHADOW—This flag indicates whether the guest is currently in an interrupt lockout shadow; (section 15.21.5).
- IDTR, GDTR.
- ES and DS—Includes the hidden state of the segment registers.

- DR6 and DR7—The guest's breakpoint state.
- V_TPR—The guest's virtual TPR.
- V_IRQ—The flag indicating whether a virtual interrupt is pending in the guest.
- CPL—If the guest is in real mode, the CPL is forced to 0; if the guest is in v86 mode, the CPL is forced to 3. Otherwise, the CPL saved in the VMCB is used.

The processor checks the loaded guest state for consistency. If a consistency check fails while loading guest state, the processor performs a #VMEXIT. For additional information, see "Canonicalization and Consistency Checks" on page 489.

If the guest is in PAE paging mode according to the registers just loaded and nested paging is not enabled, the processor will also read the four PDPEs pointed to by the newly loaded CR3 value; setting any reserved bits in the PDPEs also causes a #VMEXIT.

It is possible for the VMRUN instruction to load a guest rIP that is outside the limit of the guest code segment or that is non-canonical (if running in long mode). If this occurs, a #GP fault is delivered inside the guest; the rIP falling outside the limit of the guest code segment is not considered illegal guest state.

After all guest state is loaded, and intercepts and other control bits are set up, the processor reenables interrupts by setting GIF to 1. It is assumed that VMM software cleared GIF some time before executing the VMRUN instruction, to ensure an atomic state switch.

Some processor models allow the VMM to designate certain guest VMCB fields as "clean," meaning that they haven't been modified relative to the current state of hardware. This allows the hardware to optimize execution of VMRUN. See section 15.15 for details on which fields may be affected by this. The descriptions below assume all fields are loaded.

Control Bits. Besides loading guest state, the VMRUN instruction reads various control fields from the VMCB; most of these fields are not written back to the VMCB on #VMEXIT, since they cannot change during guest execution:

- TSC_OFFSET—an offset to add when the guest reads the TSC (time stamp counter). Guest writes to the TSC can be intercepted and emulated by changing the offset (without writing the physical TSC). This offset is cleared when the guest exits back to the host.
- V_INTR_PRIO, V_INTR_VECTOR, V_IGN_TPR—fields used to describe a virtual interrupt for the guest (see "Injecting Virtual (INTR) Interrupts" on page 518).
- V_INTR_MASKING—controls whether masking of interrupts (in EFLAGS.IF and TPR) is to be virtualized (section 15.21).
- The address space ID (ASID) to use while running the guest.
- A field to control flushing of the TLB during a VMRUN (see Section 15.16).
- The intercept vectors describing the active intercepts for the guest. On exit from the guest, the internal intercept registers are cleared so no host operations will be intercepted.

The maximum ASID value supported by a processor is implementation specific. The value returned in EBX after executing CPUID Fn8000_000A is the number of ASIDs supported by the processor.

See Section 3.3, “Processor Feature Identification,” on page 71 for more information on using the CPUID instruction.

Segment State in the VMCB. The segment registers are stored in the VMCB in a format similar to that for SMM: both base and limit are fully expanded; segment attributes are stored as 12-bit values formed by the concatenation of bits 55:52 and 47:40 from the original 64-bit (in-memory) segment descriptors; the descriptor “P” bit is used to signal NULL segments (P=0) where permissible and/or relevant. The loading of segment attributes from the VMCB (which may have been overwritten by software) may result in attribute bit values that are otherwise not allowed. However, only some of the attribute bits are actually observed by hardware, depending on the segment register in question:

- CS—D, L, P, and R.
- SS—B, P, E, W, and Code/Data
- DS, ES, FS, GS —D, P, DPL, E, W, and Code/Data.
- LDTR—P, S, and Type (LDT)
- TR—P, S, and Type (32- or 16-bit TSS)

NOTE: For the Stack Segment attributes, P is observed in legacy and compatibility mode. In 64-bit mode, P is ignored because all stack segments are treated as present.

The VMM should follow these rules when storing segment attributes into the VMCB:

- For NULL segments, set all attribute bits to zero; otherwise, write the concatenation of bits 55:52 and 47:40 from the original 64-bit (in-memory) segment descriptors.
- The processor reads the current privilege level from the CPL field in the VMCB. The CS.DPL will match the CPL field.
- When in virtual x86 or real mode, the processor ignores the CPL field in the VMCB and forces the values of 3 and 0, respectively.

When examining segment attributes after a #VMEXIT:

- Test the Present (P) bit to check whether a segment is NULL; note that CS and TR never contain NULL segments and so their P bit is ignored;
- Retrieve the CPL from the CPL field in the VMCB, not from any segment DPL.

Canonicalization and Consistency Checks. The VMRUN instruction performs consistency checks on guest state and #VMEXIT performs the appropriate subset of these consistency checks on host state. Illegal guest state combinations cause a #VMEXIT with error code VMEXIT_INVALID. The following conditions are considered illegal state combinations (note that some checks may be subject to VMCB Clean field settings, see below):

- EFER.SVME is zero.
- CR0.CD is zero and CR0.NW is set.

- CR0[63:32] are not zero.
- Any MBZ bit of CR3 is set.
- Any MBZ bit of CR4 is set.
- DR6[63:32] are not zero.
- DR7[63:32] are not zero.
- Any MBZ bit of EFER is set.
- EFER.LMA or EFER.LME is non-zero and this processor does not support long mode.
- EFER.LME and CR0.PG are both set and CR4.PAE is zero.
- EFER.LME and CR0.PG are both non-zero and CR0.PE is zero.
- EFER.LME, CR0.PG, CR4.PAE, CS.L, and CS.D are all non-zero.
- The VMRUN intercept bit is clear.
- The MSR or IOIO intercept tables extend to a physical address that is greater than or equal to the maximum supported physical address.
- Illegal event injection (section 15.20).
- ASID is equal to zero.
- Any reserved bit is set in S_CET
- CR4.CET=1 when CR0.WP=0
- CR4.CET=1 and U_CET.SS=1 when EFLAGS.VM=1
- any reserved bit set in U_CET (SEV_ES only):

  - VMRUN results in VMEXIT(INVALID)

  - VMEXIT forces reserved bits to 0

VMRUN can load a guest value of CR0 with PE = 0 but PG = 1, a combination that is otherwise illegal (see Section 15.19).

In addition to consistency checks, VMRUN and #VMEXIT canonicalize (i.e., sign-extend to bit 63):

- All base addresses in the segment registers that have been loaded.
- SSP
- ISST_ADDR
- PL0_SSP, PL1_SSP, PL2_SSP, PL3_SSP

VMCB Clean field behavior: On processor models that support designation of clean fields, the final merged hardware state is used for consistency checks. This may include state from fields marked as clean, if the processor chooses to ignore the indication.

VMRUN and TF/RF Bits in EFLAGS. When considering interactions of VMRUN with the TF and RF bits in EFLAGS, one must distinguish between the behavior of host as opposed to that of the guest.

From the host point of view, VMRUN acts like a single instruction, even though an arbitrary number of guest instructions may execute before a #VMEXIT effectively completes the VMRUN. As a single host instruction, VMRUN interacts with EFLAGS.RF and EFLAGS.TF like ordinary instructions. EFLAGS.RF suppresses any potential instruction breakpoint match on the VMRUN, and EFLAGS.TF causes a #DB trap after the VMRUN completes on the host side (i.e., after the #VMEXIT from the guest). As with any normal instruction, completion of the VMRUN instruction clears the host EFLAGS.RF bit.

The value of EFLAGS.RF from the VMCB affects the first guest instruction. When VMRUN loads a guest value of 1 for EFLAGS.RF, that value takes effect and suppresses any potential (guest) instruction breakpoint on the first guest instruction. When VMRUN loads a guest value of 1 in EFLAGS.TF, that value does *not* cause a trace trap between the VMRUN and the first guest instruction, but rather *after* completion of the first guest instruction.

Host values of EFLAGS have no effect on the guest and guest values of EFLAGS have no effect on the host.

See also section 15.7.1 regarding the value of EFLAGS.RF saved on #VMEXIT.

15.5.2 VMSAVE and VMLOAD Instructions

These instructions transfer additional guest register context, including hidden context that is not otherwise accessible, between the processor and a guest's VMCB for a more complete context switch than VMRUN and #VMEXIT perform. The system physical address of the VMCB is specified in rAX. When these operations are needed, VMLOAD would be executed as desired prior to executing a VMRUN, and VMSAVE at any desired point after a #VMEXIT.

The VMSAVE and VMLOAD instructions take the physical address of a VMCB in rAX. These instructions complement the state save/restore abilities of VMRUN instruction and #VMEXIT. They provide access to hidden processor state that software cannot otherwise access, as well as additional privileged state.

These instructions handle the following register state:

- FS, GS, TR, LDTR (including all hidden state)
- KernelGsBase
- STAR, LSTAR, CSTAR, SFMASK
- SYSENTER_CS, SYSENTER_ESP, SYSENTER_EIP

Like VMRUN, these instructions are only available at CPL0 (otherwise causing a #GP(0) exception) and are only valid in protected mode with SVM enabled via EFER.SVME (otherwise causing a #UD exception).

15.6 #VMEXIT

When an intercept triggers, the processor performs a #VMEXIT (i.e., an exit from the guest to the host context).

On #VMEXIT, the processor:

- Disables interrupts by clearing the GIF, so that after the #VMEXIT, VMM software can complete the state switch atomically.
- Writes back to the VMCB the current guest state—the same subset of processor state as is loaded by the VMRUN instruction, including the V_IRQ, V_TPR, and the INTERRUPT_SHADOW bits.
- Saves the reason for exiting the guest in the VMCB's EXITCODE field; additional information may be saved in the EXITINFO1 or EXITINFO2 fields, depending on the intercept. Note that the contents of the EXITINFO1 and EXITINFO2 fields are undefined for intercepts where their use is not indicated.
- Clears all intercepts.
- Resets the current ASID register to zero (host ASID).
- Clears the V_IRQ and V_INTR_MASKING bits inside the processor.
- Clears the TSC_OFFSET inside the processor.
- Reloads the host state previously saved by the VMRUN instruction. The processor reloads the host's CS, SS, DS, and ES segment registers and, if required, re-reads the descriptors from the host's segment descriptor tables, depending on the implementation. The segment descriptor tables must be mapped as present and writable by the host's page tables. Software should keep the host's segment descriptor tables consistent with the segment registers when executing VMRUN instructions. Immediately after #VMEXIT, the processor still contains the guest value for LDTR. So for CS, SS, DS, and ES, the VMM must only use segment descriptors from the global descriptor table. (The VMSAVE instruction can be used for a more complete context switch, allowing the VMM to then load LDTR and other registers not saved by #VMEXIT with desired values; see section 15.5.2 for details.) Any exception encountered while reloading the host segments causes a shutdown.
- If the host is in PAE mode, the processor reloads the host's PDPEs from the page table indicated by the host's CR3. If the PDPEs contain illegal state, the processor causes a shutdown.
- Forces CR0.PE = 1, RFLAGS.VM = 0.
- Sets the host CPL to zero.
- Disables all breakpoints in the host DR7 register.
- Checks the reloaded host state for consistency; any error causes the processor to shutdown. If the host's rIP reloaded by #VMEXIT is outside the limit of the host's code segment or non-canonical (in the case of long mode), a #GP fault is delivered inside the host.

15.7 Intercept Operation

Various instructions and events (such as exceptions) in the guest can be intercepted by means of control bits in the VMCB “Layout of VMCB” on page 679. The two primary classes of intercepts supported by SVM are instruction and exception intercepts.

Exception intercepts. Exception intercepts are checked when normal instruction processing must raise an exception before resolving possible double-fault conditions and before attempting delivery of the exception (which includes pushing an exception frame, accessing the IDT, etc.).

For some exceptions, the processor still writes certain exception-specific registers even if the exception is intercepted. (See the descriptions in section 15.12 and following for details.) When an external or virtual interrupt is intercepted, the interrupt is left pending.

When an intercept occurs while the guest is in the process of delivering a non-intercepted interrupt or exception using the IDT, SVM provides additional information on #VMEXIT (See section 15.7.2).

Instruction intercepts. These occur at well-defined points in instruction execution—before the results of the instruction are committed, but ordered in an intercept-specific priority relative to the instruction’s exception checks. Generally, instruction intercepts are checked after simple exceptions (such as #GP—when CPL is incorrect—or #UD) have been checked, but before exceptions related to memory accesses (such as page faults) and exceptions based on specific operand values. There are several exceptions to this guideline, e.g., the RSM instruction. Instruction breakpoints for the current instruction and pending data breakpoint traps from the previous instruction are designed to be checked before instruction intercepts.

15.7.1 State Saved on Exit

When triggered, intercepts write an EXITCODE into the VMCB identifying the cause of the intercept. The EXITINTINFO field signals whether the intercept occurred while the guest was attempting to deliver an interrupt or exception through the IDT; a VMM can use this information to transparently complete the delivery (section 15.20). Some intercepts provide additional information in the EXITINFO1 and EXITINFO2 fields in the VMCB; see the individual intercept descriptions for details.

The guest state saved in the VMCB is the processor state as of the moment the intercept triggers. In the x86 architecture, traps (as opposed to faults) are detected and delivered after the instruction that triggered them has completed execution. Accordingly, a trap intercept takes place after the execution of the instruction that triggered the trap in the first place. The saved guest state thus includes the effects of executing that instruction.

Example: Assume a guest instruction triggers a data breakpoint (#DB) trap which is in turn intercepted. The VMCB records the guest state after execution of that instruction, so that the saved CS:rIP points to the following instruction, and the saved DR7 includes the effects of matching the data breakpoint.

The next sequential instruction pointer (nRIP) is saved in the guest VMCB control area at location C8h on all #VMEXITs that are due to instruction intercepts, as defined in section 15.9, as well as MSR and IOIO intercepts and exceptions caused by the INT3, INTO, and BOUND instructions. For all other intercepts, nRIP is reset to zero.

The nRIP is the RIP that would be pushed on the stack if the current instruction were subject to a trap-style debug exception, if the intercepted instruction were to cause no change in control flow. If the intercepted instruction would have caused a change in control flow, the nRIP points to the next sequential instruction rather than the target instruction.

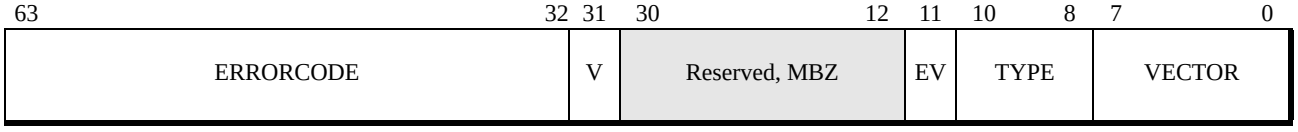
Some exceptions write special registers even when they are intercepted; see the individual descriptions in section 15.12 for details.

Support for the NRIP save on #VMEXIT is indicated by CPUID Fn8000_000A_EDX[NRIPS]. See Section 3.3, “Processor Feature Identification,” on page 71 for more information on using the CPUID instruction.

15.7.2 Intercepts During IDT Interrupt Delivery

It is possible for an intercept to occur while the guest is attempting to deliver an exception or interrupt through the IDT (e.g., #PF because the VMM has paged out the guest’s exception stack). In some cases, such an intercept can result in the loss of information necessary for transparent resumption of the guest. In the case of an external interrupt, for example, the processor will already have performed an interrupt acknowledge cycle with the PIC or APIC to obtain the interrupt type and vector, and the interrupt is thus no longer pending.

To recover from such situations, all intercepts indicate (in the EXITINTINFO field in the VMCB) whether they occurred during exception or interrupt delivery though the IDT. This mechanism allows the VMM to complete the intercepted interrupt delivery, even when it is no longer possible to recreate the event in question.



Bits	Mnemonic	Description
63:32	ERRORCODE	Error Code
31	V	Valid
30:12	—	Reserved, MBZ
11	EV	Error Code Valid
10:8	TYPE	Qualifies the guest exception or interrupt. Table 15-1 shows possible values returned and their corresponding interrupt or exception types. Values not indicated are unused and reserved.
7:0	VECTOR	8-bit IDT vector of the interrupt or exception.

Figure 15-1. EXITINTINFO for All Intercepts

Table 15-1. Guest Exception or Interrupt Types

Value	Type
0	External or virtual interrupt (INTR)
2	NMI
3	Exception (fault or trap)
4	Software interrupt (caused by INT*n* instruction)

Despite the instruction name, the events raised by the INT1 (also known as ICEBP), INT3 and INTO instructions (opcodes F1h, CCh and CEh) are considered exceptions for the purposes of EXITINTINFO, not software interrupts. Only events raised by the INT*n* instruction (opcode CDh) are considered software interrupts.

- Error Code Valid—Bit 11. Set to 1 if the guest exception would have pushed an error code; otherwise cleared to zero.
- Valid—Bit 31. Set to 1 if the intercept occurred while the guest attempted to deliver an exception through the IDT; otherwise cleared to zero.
- Errorcode—Bits 63:32. If EV is set to 1, holds the error code that the guest exception would have pushed; otherwise is undefined.

In the case of multiple exceptions, EXITINTINFO records the aggregate information on all exceptions but the last (intercepted) one.

Example: A guest raises a #GP during delivery of which a #NP is raised (a scenario that, according to x86 rules, resolves to a #DF), and an intercepted #PF occurs during the attempt to deliver the #DF. Upon intercept of the #PF, EXITINTINFO indicates that the guest was in the process of delivering a #DF when the #PF occurred. The information about the intercepted page fault itself is encoded in the EXITCODE, EXITINFO1 and EXITINFO2 fields. If the VMM decides to repair and dismiss the #PF, it can resume guest execution by re-injecting (see section 15.20) the fault recorded in EXITINTINFO. If the VMM decides that the #PF should be reflected back to the guest, it must combine the event in EXITINTINFO with the intercepted exception according to x86 rules. In this case, a #DF plus a #PF would result in a triple fault or shutdown.

15.7.3 EXITINTINFO Pseudo-Code

When delivering exceptions or interrupts in a guest, the processor checks for exception intercepts and updates the value of EXITINTINFO should an intercept occur during exception delivery. The following pseudo-code outlines how the processor delivers an event (exception or interrupt) E.

```
if E is an exception and is intercepted:
    #VMEXIT(E)
E = (result of combining E with any prior events)

if (result was #DF and #DF is intercepted):
    #VMEXIT(#DF)
if (result was shutdown and shutdown is intercepted):
```

```
    #VMEXIT(#shutdown)
EXITINTINFO = E // Record the event the guest is delivering.

Attempt delivery of E through the IDT
Note that this may cause secondary exceptions

Once an exception has been successfully taken in the guest:

EXITINTINFO.V = 0 // Delivery succeeded; no #VMEXIT.
Dispatch to first instruction of handler
```

When an exception triggers an intercept, the EXITCODE, and optionally EXITINFO1 and EXITINFO2, fields always reflect the intercepted exception, while EXITINTINFO, if marked valid, indicates the prior exception the guest was attempting to deliver when the intercept occurred.

15.8 Decode Assists

Decode assists are provided to allow hypervisors to decode guest instructions more efficiently. CPUID Fn8000_000A_EDX[DecodeAssists] = 1 indicates support for this feature. See Section 3.3, "Processor Feature Identification," on page 71 for more information on using the CPUID instruction.

15.8.1 MOV CR*x*/DR*x* Intercepts

The EXITINFO1 field holds a flag indicating whether the instruction was a MOV CRx and the number of the GPR operand. MOV-to-CR instructions always set bit 63 and provide the GPR number, except for CR0 as specified below.

Table 15-2. EXITINFO1 for MOV CR*x*

Bit Offsets	Field Contents
3:0	GPR number
62:4	0
63	Instruction was MOV CR*x*—set to1 if the instruction was a MOV CR*x* instruction; cleared to 0 otherwise.

Table 15-3. EXITINFO1 for MOV DR*x*

Bit Offsets	Field Contents
3:0	GPR number
63:4	0

MOV-to-CR0 Special Case. If the instruction is MOV-to-CR, the GPR number is provided; if the instruction is LMSW or CLTS, no additional information is provided and bit 63 is not set.

MOV-from-CR0 Special Case. If the instruction is MOV-from-CR, the GPR number is provided and bit 63 is set; if the instruction is SMSW, no information is provided and bit 63 is not set.

15.8.2 INT*n* Intercepts

EXITINFO1 records the immediate value of the interrupt number for INT *n* instructions. See Table 15-4.

Table 15-4. EXITINFO1 for INT*n*

Bit Offsets	Field Contents
7:0	Software interrupt number
63:8	0

15.8.3 INVLPG and INVLPGA Intercepts

For an INVLPG intercept, EXITINFO1 provides the linear address after segment base addition and address size masking produce the effective address size. See Table 15-5. For an INVLPGA intercept, the linear address is available directly from the guest rAX register and is not provided in EXITINFO1.

Table 15-5. EXITINFO1 for INVLPG

Bit Offsets	Field Contents
63:0	Linear address

15.8.4 Nested and intercepted #PF

In the case of a Nested Page Fault or intercepted #PF, guest instruction bytes at guest CS:RIP are stored into the 16-byte wide field Guest Instruction Bytes located at offset 0D0h in the VMCB. The format of this field is summarized in Table 15-6 below. Up to 15 bytes are recorded, read from guest CS:RIP. If a faulting condition occurs, such as not-present page or exceeding the CS limit, then the Guest Instruction Bytes field records as many bytes as could be fetched. The number of bytes fetched is put into the first byte of this field. Zero indicates that no bytes were fetched. The default number of bytes is always 15. Fewer bytes are returned only if a fault occurs while fetching.

This field is filled in only during data page faults. Instruction-fetch page faults provide no additional information.

All other intercepts clear bits 0:7 in this field to zero (to indicate an invalid condition); implementations may leave the other bytes untouched.

Table 15-6. Guest Instruction Bytes

Bit Offsets	Field Contents
3:0	Number of bytes fetched
4:7	0
127:8	Instruction bytes

15.9 Instruction Intercepts

Table 15-7 specifies the instructions that check a given intercept and, where relevant, how the intercept is prioritized relative to exceptions.

Table 15-7. Instruction Intercepts

Instruction Intercept	Checked By	Priority
Read/Write of CR0	MOV TO/FROM CR0, LMSW, SMSW, CLTS	Checks non-memory exceptions (CPL, illegal bit combinations, etc.) before the intercept. For LMSW and SMSW, checks SVM intercepts before checking memory exceptions.
Read/Write of CR3 (excluding task switch)	MOV TO/FROM CR3 (not checked by task switch operations)	Checks non-memory exceptions first, then the intercept. If the intercept triggers on a write, the intercept happens *before* the TLB is flushed. If PAE is enabled, the loading of the four PDPEs can cause a #GP; that exception is checked *after* the intercept check, so the VMM handling a CR3 intercept cannot rely on the PDPEs being legal; it must examine them in software if necessary. The reads and writes of CR3 that occur in VMRUN, #VMEXIT or task switches are *not* subject to this intercept check.
Read/Write of other CRs	MOV TO/FROM CR*n*	All normal exception checks take precedence over the SVM intercepts.
Read/Write of Debug Registers, DR*n*	MOV TO/FROM DR*n*. (Not checked by implicit DR6/DR7 writes.)	All normal exception checks take precedence over the SVM intercepts.

Table 15-7. Instruction Intercepts (continued)

Instruction Intercept	Checked By	Priority
Selective CR0 Write Intercept	MOV TO CR0, LMSW	Checks non-memory exceptions (CPL, illegal bit combinations, etc.) before the intercept. For LMSW and SMSW, checks SVM intercepts before checking memory exceptions. The selective write intercept on CR0 triggers only if a bit other than CR0.TS or CR0.MP is being changed by the write. In particular, this means that CLTS does not check this intercept. When both selective and non-selective CR0-write intercepts are active at the same time, the non-selective intercept takes priority. With respect to exceptions, the priority of this intercept is the same as the generic CR0-write intercept. The LMSW instruction treats the selective CR0-write intercept as a non-selective intercept (i.e., it intercepts regardless of the value being written).
Reading or Writing IDTR, GDTR, LDTR, TR	LIDT, SIDT, LGDT, SGDT, LLDT, SLDT, LTR, STR	The SVM intercept is checked after #UD and #GP exception checks, but before any memory access is performed.
RDTSC	RDTSC	Checks all exceptions before the SVM intercept.
RDPMC	RDPMC	Checks all exceptions before the SVM intercept.
PUSHF	PUSHF	Takes priority over any exceptions.
POPF	POPF	Takes priority over any exceptions.
CPUID	CPUID	No exceptions to check.
RSM	RSM	The intercept takes priority over any exceptions.
IRET	IRET	The intercept takes priority over any exceptions.
Software Interrupt	INT*n*	The intercept occurs before any exceptions are checked. The CS:rIP reported on #VMEXIT are those of the intercepted INTn instruction. Though the INT*n* instruction may dispatch through IDT vectors in the range of 0–31, those events cannot be intercepted by means of exception intercepts (see “Exception Intercepts” on page 504).
INVD	INVD	Exceptions (#GP) are checked before the intercept.

Table 15-7. Instruction Intercepts (continued)

Instruction Intercept	Checked By	Priority
PAUSE	PAUSE	No exceptions to check. VMRUN copies the VMCB.PauseFilterCount into an internal counter. Each PAUSE instruction decrements the counter, and the PAUSE intercept only occurs if the counter goes below zero while the PAUSE intercept is enabled. The VMCB.PauseFilterCount field is not written by the processor. Certain events, including SMI, can cause the internal count to be reloaded from the VMCB. VMCB.PauseFilterCount support is indicated by EDX[10] as returned by CPUID extended function 8000_000A. If This feature is not supported or VMCB.PauseFilterCount = 0, then the first PAUSE instruction can be intercepted.
HLT	HLT	Checks all exceptions before checking for this intercept.
INVLPG	INVLPG	Checks all exceptions (#GP) before the intercept.
INVLPGA	INVLPGA	Checks all exceptions (#GP) before the intercept.
VMRUN	VMRUN	Checks exceptions (#GP) before the intercept. *The current implementation requires that the VMRUN intercept always be set in the VMCB.*
VMLOAD	VMLOAD	Checks exceptions (#GP) before the intercept.
VMSAVE	VMSAVE	Checks exceptions (#GP) before the intercept.
VMMCALL	VMMCALL	The intercept takes priority over exceptions. VMMCALL causes #UD in the guest if it is not intercepted.
STGI	STGI	Checks exceptions (#GP) before the intercept.
CLGI	CLGI	Checks exceptions (#GP) before the intercept.
SKINIT	SKINIT	Checks exceptions (#GP) before the intercept.
RDTSCP	RDTSCP	Checks all exceptions before the SVM intercept.
ICEBP	ICEBP(opcode F1h).	Although the ICEBP instruction dispatches through IDT vector 1, that event is not interceptable by means of the #DB exception intercept.
WBINVD	WBINVD, WBNOINVD	Checks exceptions (#GP) before the intercept.
MONITOR	MONITOR, MONITORX	Checks all exceptions before the intercept.

Table 15-7. Instruction Intercepts (continued)

Instruction Intercept	Checked By	Priority
MWAIT	MWAIT, MWAITX	Checks all exceptions before the intercept. There are conditional and unconditional MWAIT intercepts. The conditional MWAIT intercept is checked before the unconditional MWAIT intercept. When both conditional and unconditional MWAIT intercepts are active, the conditional intercept is checked first. A hypervisor that sets both intercepts will receive the conditional MWAIT intercept exit code for a guest MWAIT instruction that would have entered a low-power state, and will receive the unconditional MWAIT intercept exit code for a guest MWAIT instruction that would not have entered the low-power state. These checks also apply to MWAITX.
XSETBV	XSETBV	Checks intercept before exceptions (#GP).
RDPRU	RDPRU	Check all exceptions before the intercept.
INVLPGB	INVLPGB	Intercept takes priority over all exceptions except #GP for CPL<>0.
INVLPGB_ILLEGAL	INVLPGB exception cases	Intercept takes priority over all exceptions except #GP for CPL<>0.
INVPCID	INVPCID	Intercept takes priority over all exceptions except #GP for CPL<>0.
TLBSYNC	TLBSYNC	Checks exceptions (#GP) before the intercept.

15.10 IOIO Intercepts

The VMM can intercept IOIO instructions (IN, OUT, INS, OUTS) on a port-by-port basis by means of the SVM I/O permissions map.

15.10.1 I/O Permissions Map

The I/O Permissions Map (IOPM) occupies 12 Kbytes of contiguous physical memory. The map is structured as a linear array of 64K+3 bits (two 4-Kbyte pages, and the first three bits of a third 4-Kbyte page) and must be aligned on a 4-Kbyte boundary; the physical base address of the IOPM is specified in the IOPM_BASE_PA field in the VMCB and loaded into the processor by the VMRUN instruction. The VMRUN instruction ignores the lower 12 bits of the address specified in the VMCB. If the address of the last byte in the IOPM is greater than or equal to the maximum supported physical address, this is treated as illegal VMCB state and causes a #VMEXIT(VMEXIT_INVALID).

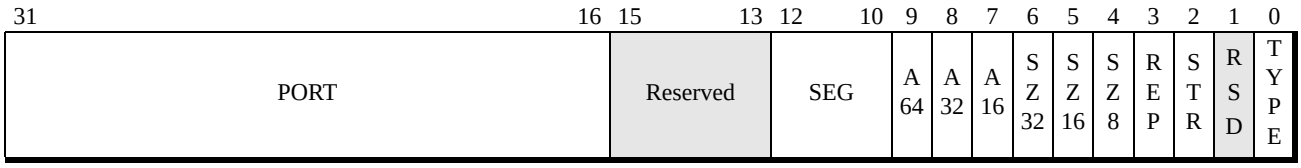
Each bit in the IOPM corresponds to an 8-bit I/O port. Bit 0 in the table corresponds to I/O port 0, bit 1 to I/O port 1 and so on. A bit set to 1 indicates that accesses to the corresponding port should be intercepted. The IOPM is accessed by physical address, and should reside in memory that is mapped as writeback (WB).

15.10.2 IN and OUT Behavior

If the IOIO_PROT intercept bit is set, the IOPM controls port access. For IN/OUT instructions that access more than a single byte, the permission bits for all bytes are checked; if any bit is set to 1, the I/O operation is intercepted.

Exceptions related to virtual x86 mode, IOPL, or the TSS-bitmap are checked *before* the SVM intercept check. All other exceptions are checked *after* the SVM intercept check.

I/O Intercept Information. When an IOIO intercept triggers, the following information (describing the intercepted operation in order to facilitate emulation) is saved in the VMCB's EXITINFO1 field:



Bits	Mnemonic	Description
31:16	PORT	Intercepted I/O port
15-13	—	Reserved
12:10	SEG	Effective segment number
9	A64	64-bit address
8	A32	32-bit address
7	A16	16-bit address
6	SZ32	32-bit operand size
5	SZ16	16-bit operand size
4	SZ8	8-bit operand size
3	REP	Repeated port access
2	STR	String based port access (INS, OUTS)
1	—	Reserved
0	TYPE	Access Type (0 = OUT instruction, 1 = IN instruction)

Figure 15-2. EXITINFO1 for IOIO Intercept

The rIP of the instruction *following* the IN/OUT is saved in EXITINFO2, so that the VMM can easily resume the guest after I/O emulation.

15.10.3 (REP) OUTS and INS

Bits 12:10 of the EXITINFO1 field provide the effective segment number (the default segment is DS). (For segment register encodings, see Table A-32, "16-Bit Register and Memory References" on page 478, in *AMD64 Architecture Programmer's Manual Volume 3: General-Purpose and System Instructions*.)

INS provides the effective segment (always ES, encoded as 0).

On intercepted SMI-on-I/O, bits 12:10 of EXITINFO1 encode the segment. For definitions of the remaining bits of this field, (section 15.13.3).

15.11 MSR Intercepts

The VMM can intercept RDMSR and WRMSR instructions by means of the *SVM MSR permissions map* (MSRPM) on a per-MSR basis.

MSR Permissions Map. The MSR permissions bitmap consists of four separate bit vectors of 16 Kbits (2 Kbytes) each. Each 16 Kbit vector controls guest access to a defined range of 8K MSRs. Each MSR is covered by two bits defining the guest read and write access permissions. The lsb of the two bits controls read access to the MSR and the msb controls write access. A value of 1 indicates that the operation is intercepted. The four separate bit vectors must be packed together and located in two contiguous physical pages of memory. If the MSR_PROT intercept is active, any attempt to read or write an MSR not covered by the MSRPM will automatically cause an intercept.

The following table defines the ranges of MSRs covered by the MSR permissions map. Note that the MSR ranges are not contiguous.

Table 15-8. MSR Ranges Covered by MSRPM

MSRPM Byte Offset	MSR Range
000h–7FFh	0000_0000h–0000_1FFFh
800h–FFFh	C000_0000h–C000_1FFFh
1000h–17FFh	C001_0000h–C001_1FFFh
1800h–1FFFh	Reserved

The MSRPM is accessed by physical address and should reside in memory that is mapped as writeback (WB). The MSRPM must be aligned on a 4KB boundary. The physical base address of the MSRPM is specified in MSRPM_BASE_PA field in the VMCB and is loaded into the processor by the VMRUN instruction. The VMRUN instruction ignores the lower 12 bits of the address specified in the VMCB, and if the address of the last byte in the table is greater than or equal to the maximum supported physical address, this is treated as illegal VMCB state and causes a #VMEXIT(VMEXIT_INVALID).

RDMSR and WRMSR Behavior. If the MSR_PROT bit in the VMCB's intercept vector is clear, RDMSR/WRMSR instructions are not intercepted.

RDMSR and WRMSR instructions check for exceptions and intercepts in the following order:

- Exceptions common to all MSRs (e.g., #GP if not at CPL 0)
- Check SVM intercepts in the MSR permission map, if the MSR_PROT intercept is requested.

- Exceptions specific to a given MSR (including password protection, unimplemented MSRs, reserved bits, etc.)

MSR Intercept Information. On #VMEXIT, the processor indicates in the VMCB's EXITINFO1 whether a RDMSR (EXITINFO1 = 0) or WRMSR (EXITINFO1 = 1) was intercepted.

15.12 Exception Intercepts

When intercepting exceptions that define an error code (normally pushed onto the exception stack), the SVM hardware delivers that error code in the VMCB's EXITINFO1 field; the exception vector number can be derived from the EXITCODE. The CS.SEL and rIP saved in the VMCB on an exception-intercept match those that would otherwise have been pushed onto the exception stack frame, except that when an interrupt-based instruction causes an intercept, the rIP of the instruction is stored in the VMCB, rather than the rIP of the next instruction. The interrupt-based instructions are INT3 (opcode CC), INTO, and BOUND.

Unless otherwise noted below, no special registers are written before an exception is intercepted. For details on guest state saved in the VMCB, see section 15.7.1.

External interrupts and software interrupts (INT*n* instruction) do not check the exception intercepts, even when they use a vector in the range 0 to 31.

Exceptions that occur during the handling of a prior exception are checked for intercepts *before* being combined with the prior exception (e.g., into a double-fault). If the result of combining exceptions is a double-fault or shutdown, the processor checks whether those are intercepted before attempting delivery.

Example: Assume that the VMM intercepts #GP and #DF exceptions, and the guest raises a (non-intercepted) #NP, during the delivery of which it also gets a #GP (e.g., due to an illegal IDT entry)—a situation that, according to x86 semantics, results in a #DF. In this case, #VMEXIT signals an intercepted #GP, *not* an intercepted #DF and fills EXITINTINFO with the #NP fault. On the other hand, if only the #DF intercept were active in this scenario, #VMEXIT would signal an intercepted #DF.

The following subsections detail the individual intercepts.

15.12.1 #DE (Divide By Zero)

The EXITINFO1 and EXITINFO2 fields are undefined.

15.12.2 #DB (Debug)

The #DB exception can have fault-type (e.g., instruction breakpoint) or trap-type (e.g., data breakpoint) behavior; accordingly the intercept differs in what state is saved in the VMCB (see section 15.7.1). In either case, however, the value saved for DR6 and DR7 matches what would be visible to a #DB exception handler (i.e., both #DB faults and traps are permitted to write DR6 and DR7 before the intercept). The EXITINFO1 and EXITINFO2 fields are undefined.

Fault-type #DB exceptions, whether indicated in EXITCODE or EXITINTINFO, cause the CS:rIP saved in the VMCB to indicate the instruction that caused the #DB exception. Trap-type #DB exceptions cause the VMCB's CS:rIP to indicate the instruction following the instruction that caused the exception. A vector 1 exception generated by the single byte INT1 instruction (also known as ICEBP) does not trigger the #DB intercept. Software should use the dedicated ICEBP intercept to intercept ICEBP (see section 15.9).

15.12.3 Vector 2 (Reserved)

This intercept bit is not implemented; use the NMI intercept (section 15.13.2) instead. The effect of setting this bit is undefined.

15.12.4 #BP (Breakpoint)

This intercept applies to the trap raised by the single byte INT3 (opcode CCh) instruction. The EXITINFO1 and EXITINFO2 fields are undefined. The CS:rIP reported on #VMEXIT are those of the INT3 instruction.

15.12.5 #OF (Overflow)

This intercept applies to the trap raised by the INTO (opcode CEh) instruction. The EXITINFO1 and EXITINFO2 fields are undefined.

15.12.6 #BR (Bound-Range)

This intercept applies to the fault raised by the BOUND instruction. The EXITINFO1 and EXITINFO2 fields are undefined.

15.12.7 #UD (Invalid Opcode)

The EXITINFO1 and EXITINFO2 fields are undefined.

15.12.8 #NM (Device-Not-Available)

The EXITINFO1 and EXITINFO2 fields are undefined.

15.12.9 #DF (Double Fault)

The EXITINFO1 and EXITINFO2 fields are undefined. The rIP value saved in the VMCB is undefined (as is the case for the rIP value pushed on the stack for #DF exceptions). If a double fault is intercepted, the exceptions leading up to the double fault will have written any status registers normally written by those exceptions.

15.12.10 Vector 9 (Reserved)

This intercept is not implemented. The effect of setting this bit is undefined.

15.12.11 #TS (Invalid TSS)

The EXITINFO1 and EXITINFO2 fields are undefined. The rIP value saved in the VMCB may point to either the instruction causing the task switch, or to the first instruction of the incoming task. See section 15.14.1 for information on the EXITINFO1 and EXITINFO2 fields.

15.12.12 #NP (Segment Not Present)

The EXITINFO1 field contains the error code that would be pushed on the stack by a #NP exception. The EXITINFO2 field is undefined.

15.12.13 #SS (Stack Fault)

The EXITINFO1 field contains the error code that would be pushed on the stack by a #SS exception. The EXITINFO2 field is undefined.

15.12.14 #GP (General Protection)

The EXITINFO1 field contains the error code that would be pushed on the stack by a #GP exception.

15.12.15 #PF (Page Fault)

This intercept is tested *before* CR2 is written by the exception. The error code saved in EXITINFO1 is the same as would be pushed onto the stack by a non-intercepted #PF exception in protected mode. The faulting address is saved in the EXITINFO2 field in the VMCB. Even when the guest is running in paged real mode, the processor will deliver the (protected-mode) page-fault error code in EXITINFO1, for the VMM to use in analyzing the intercepted #PF. The processor may provide additional instruction decode assist information. (See section 15.8.4.)

15.12.16 #MF (X87 Floating Point)

This intercept is tested *after* the floating point status word has been written, as is the case for a normal FP exception. The EXITINFO1 and EXITINFO2 fields are undefined.

15.12.17 #AC (Alignment Check)

The EXITINFO1 field contains the error code that would be pushed on the stack by an #AC exception. The EXITINFO2 field is undefined.

15.12.18 #MC (Machine Check)

The SVM intercept is checked after all #MC-specific registers have been written, but before other guest state is modified. When #MC is being intercepted, a machine-check exits to the VMM, whenever possible, and shuts down the processor only when this is not a reasonable option. The EXITINFO1 and EXITINFO2 fields are undefined.

Note that in some processors, if the guest VM has disabled machine check handling (CR4.MCE=0) then all machine check errors that occur in the guest will result in a shutdown event. However in

processors where CPUID Fn8000_000A_EDX[HOST_MCE_OVERRIDE] (bit 23) = 1 the VMM may override this behavior by setting CR4.MCE=1 in the host. In this scenario, machine check errors that occur in the guest and which can be contained by the processor will always result in a #VMEXIT(MC).

15.12.19 #XF (SIMD Floating Point)

This intercept is tested after the SIMD status word (MXCSR) has been written, as is the case for a normal FP exception. The EXITINFO1 and EXITINFO2 fields are undefined.

15.12.20 #SX (Security Exception)

The EXITINFO1 field contains the error code that would be pushed on the stack by a #SX exception. The EXITINFO2 field is undefined.

15.12.21 #CP (Control Protection)

The EXITINFO1 field contains the error code that would be pushed on the stack by a #CP exception. The EXITINFO2 field is undefined.

15.13 Interrupt Intercepts

External interrupts, when intercepted, cause a #VMEXIT; the interrupt is held pending so that the interrupt can eventually be taken in the VMM. Exception intercepts do not apply to external or software interrupts, so it is not possible to intercept an interrupt by means of the exception intercepts, even if the interrupt should happen to use a vector in the range from 0 to 31.

15.13.1 INTR Intercept

This intercept affects physical, as opposed to virtual, maskable interrupts. See “Virtual Interrupt Intercept” on page 519 for virtualization of maskable interrupts.

15.13.2 NMI Intercept

This intercept affects non-maskable interrupts. NMI interrupts (and SMIs) may be blocked for one instruction following an STI.

15.13.3 SMI Intercept

This intercept affects System Management Mode Interrupts (SMIs); see “SMM Support” on page 521 for details on SMI handling.

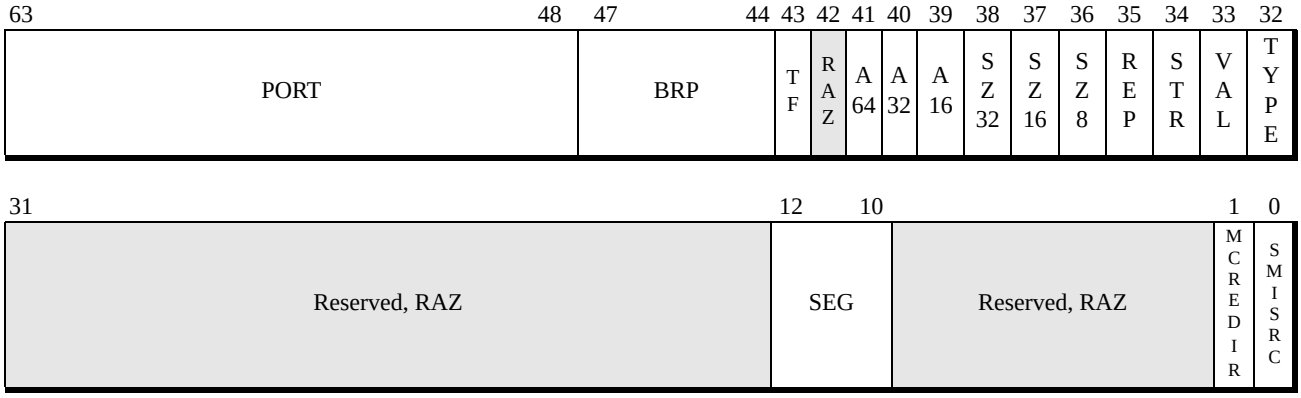
When this intercept triggers, bit 0 of the EXITINFO1 field distinguishes whether the SMI was caused internally by I/O Trapping (bit 0 = 0), or asserted externally (bit 0 = 1).

If the SMI was asserted while the guest was executing an I/O instruction, extra information (describing the I/O instruction) is saved in the upper 32 bits of EXITINFO1, and the rIP of the I/O instruction is

saved in EXITINFO2. EXITINFO1 indicates that SMI was asserted during an I/O instruction when the VALID bit is set.

If the SMI wasn't asserted during an I/O instruction, the extra EXITINFO1 and EXITINFO2 bits are undefined.

The SMI intercept is ignored when HWCR[SMMLOCK] is set.



Bits	Mnemonic	Description
63:48	PORT	Intercepted I/O port
47:44	BRP	I/O breakpoint matches
43	TF	EFLAGS TF value
42	—	Reserved, RAZ
41	A64	64-bit address
40	A32	32-bit address
39	A16	16-bit address
38	SZ32	32-bit operand size
37	SZ16	16-bit operand size
36	SZ8	8-bit operand size
35	REP	Repeated port access
34	STR	String based port access (INS, OUTS)
33	VAL	Valid (SMI was detected during an I/O instruction)
32	TYPE	Access Type (0 = OUT instruction, 1 = IN instruction)
31:13	—	Reserved, RAZ
12:10	SEG	Effective segment number (see section 15.9)
9:2	—	Reserved, RAZ
1	MCREDIR	SMI was due to a redirect machine check error (See “Interaction with SMI and #MC” on page 585)
0	SMISRC	SMI source (0 = internal, 1 = external)

Figure 15-3. EXITINFO1 for SMI Intercept

15.13.4 INIT Intercept

The INIT intercept allows the VMM to intercept the assertion of INIT while a guest is running. An intercepted INIT remains pending until the VMM sets GIF (see “Global Interrupt Flag, STGI and

CLGI Instructions” on page 514), at which point it either takes effect or is redirected. See section 15.21.8 for a discussion of the INIT redirection feature.

15.13.5 Virtual Interrupt Intercept

This intercept is taken just before a guest takes a virtual interrupt. When the intercept triggers, the virtual interrupt has not been taken, and remains pending in the guest's VMCB V_IRQ field. This intercept is not required for handling fixed local APIC interrupts, but may be used for emulating ExtINT interrupt delivery mode (which is not masked by the TPR), or legacy PICs in auto-EOI mode.

15.14 Miscellaneous Intercepts

The SVM architecture includes intercepts to handle task switches, processor freezes due to FERR, and shutdown operations.

15.14.1 Task Switch Intercept

Checked by—Any instruction or event that causes a task switch (e.g., JMP, CALL, exceptions, interrupts, software interrupts).

Priority—The intercept is checked before the task switch takes place but *after* the incoming TSS and task gate (if one was involved) have been checked for correctness.

Task switches can modify several resources that a VMM may want to protect (CR3, EFLAGS, LDT). However, instead of checking various intercepts (e.g., CR3 Write, LDTR Write) individually, task switches check only a single intercept bit.

On #VMEXIT, the following information is delivered in the VMCB:

- EXITINFO1[15:0] holds the segment selector identifying the incoming TSS.
- EXITINFO2[31:0] holds the error code to push in the new task, if applicable; otherwise, this field is undefined.
- EXITINFO2[63:32] holds auxiliary information for the VMM:
  - EXITINFO2[36]—Set to 1 if the task switch was caused by an IRET; else cleared to 0.
  - EXITINFO2[38]—Set to 1 if the task switch was caused by a far jump; else cleared to 0.
  - EXITINFO2[44]—Set to 1 if the task switch has an error code; else cleared to 0.
  - EXITINFO2[48]—The value of EFLAGS.RF that would be saved in the outgoing TSS if the task switch were not intercepted.

15.14.2 Ferr_Freeze Intercept

Checked when the processor freezes due to assertion of FERR (while IGNNE is deasserted, and legacy handling of FERR is selected in CR0.NE), i.e., while the processor is waiting to be unfrozen by an external interrupt.

15.14.3 Shutdown Intercept

When this intercept occurs, any condition that normally causes a shutdown causes a #VMEXIT to the VMM instead. After an intercepted shutdown, the state saved in the VMCB is undefined.

15.14.4 Pause Intercept Filtering

On processors that support Pause filtering (indicated by CPUID Fn8000_000A_EDX[PauseFilter] = 1), the VMCB provides a 16 bit PAUSE Filter Count value. On VMRUN this value is loaded into an internal counter. Each time a PAUSE instruction is executed, this counter is decremented until it reaches zero at which time a #VMEXIT is generated if PAUSE intercept is enabled. If the PAUSE Filter Count is set to zero and PAUSE Intercept is enabled, every PAUSE instruction will cause a #VMEXIT.

In addition, some processor families support Advanced Pause Filtering (indicated by CPUID Fn8000_000A_EDX[PauseFilterThreshold] = 1). In this mode, a 16-bit PAUSE Filter Threshold field is added in the VMCB. The threshold value is a cycle count that is used to reset the pause counter.

As with simple Pause filtering, VMRUN loads the PAUSE count VMCB value into an internal counter. Then, on each PAUSE instruction the hardware checks the elapsed number of cycles since the most recent PAUSE instruction against the PAUSE Filter Threshold. If the elapsed cycle count is greater than the PAUSE Filter Threshold, then the internal pause count is reloaded from the VMCB and execution continues. If the elapsed cycle count is less than the PAUSE Filter Threshold, then the internal pause count is decremented. If the count value is less than zero and PAUSE intercept is enabled, a #VMEXIT is triggered.

If Advanced Pause Filtering is supported and PAUSE Filter Threshold field is set to zero, the filter will operate in the simpler, count only mode.

See Section 3.3, “Processor Feature Identification,” on page 71 for more information on using the CPUID instruction.

15.15 VMCB State Caching

VMCB state caching allows the processor to cache certain guest register values in hardware between a #VMEXIT and subsequent VMRUN instructions and use the cached values to improve context-switch performance. Depending on the particular processor implementation, VMRUN loads each guest register value either from the VMCB or from the VMCB state cache, as specified by the value of the VMCB Clean field in the VMCB. Support for VMCB state caching is indicated by CPUID Fn8000_000A_EDX[VmcbClean] = 1.

The SVM architecture uses the physical address of the VMCB as a unique identifier for the guest virtual CPU for the purposes of deciding whether the cached copy belongs to the guest. For the purposes of VMCB state caching, the ASID is not a unique identifier for a guest virtual CPU.

15.15.1 VMCB Clean Bits

The VMCB Clean field (VMCB offset 0C0h, bits 31:0) controls which guest register values are loaded from the VMCB state cache on VMRUN. Each set bit in the VMCB Clean field allows the processor to load one guest register or group of registers from the hardware cache; each clear bit requires that the processor load the guest register from the VMCB. The clean bits are a hint, since any given processor implementation may ignore bits that are set to 1 on any given VMRUN, unconditionally loading the associated register value(s) from the VMCB. Clean bits that are set to zero are always honored.

This field is backward-compatible to CPUs that do not support VMCB state caching; older CPUs neither cache VMCB state nor read the VMCB Clean field.

Older hypervisors that are not aware of VMCB state caching and obey the SBZ property of undefined VMCB fields will not enable VMCB state caching.

15.15.2 Guidelines for Clearing VMCB Clean Bits

The hypervisor must clear specific bits in the VMCB Clean field every time it explicitly modifies the associated guest state in the VMCB. The guest's execution can cause cached state to be updated, but the hypervisor is not responsible for setting VMCB Clean bits corresponding to any state changes caused by guest execution.

The hypervisor must clear the entire VMCB field to 0 for a guest, under the following circumstances:

- This is the first time a particular guest is run.
- The hypervisor executes the guest on a different CPU core than one used the last time that guest was executed.
- The hypervisor has moved the guest's VMCB to a different physical page since the last time that guest was executed.

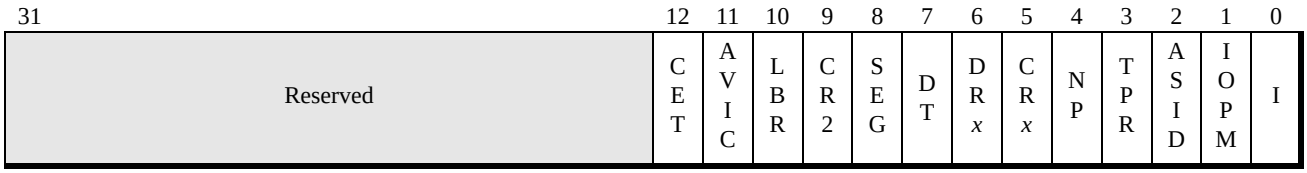
Failure to clear the VMCB Clean bits to zero in these cases may result in undefined behavior.

The CPU automatically treats the VMCB Clean field as zero on the current VMRUN when the hypervisor executes a guest that is not currently cached. The CPU compares the VMCB physical address against all cached VMCB physical addresses and treats the VMCB Clean field as zero, if no cached VMCB address matches.

SMM software (or any other agent external to the hypervisor that has access to VMCBs) that changes the contents of a VMCB needs to comprehend the clean bits and adjust them accordingly; otherwise the guest may not operate as intended.

15.15.3 VMCB Clean Field

The layout of the VMCB Clean field is illustrated in Figure 15-4 below.



Bits	Mnemonic	Description
31:13	—	Reserved
12	CET	S_CET, SSP, ISST_ADDR
11	AVIC	AVIC APIC_BAR; AVIC APIC_BACKING_PAGE, AVIC PHYSICAL_TABLE and AVIC LOGICAL_TABLE Pointers
10	LBR	DbgCtlMsr, br_from/to, lastint_from/to
9	CR2	CR2
8	SEG	CS/DS/SS/ES Sel/Base/Limit/Attr, CPL
7	DT	GDT/IDT Limit and Base
6	DR*x*	DR6, DR7
5	CR*x*	CR0, CR3, CR4, EFER
4	NP	Nested Paging: NCR3, G_PAT
3	TPR	V_TPR, V_IRQ, V_INTR_PRIO, V_IGN_TPR, V_INTR_MASKING, V_INTR_VECTOR (Offset 60h–67h)
2	ASID	ASID
1	IOPM	IOMSRPM: IOPM_BASE, MSRPM_BASE
0	I	Intercepts: all the intercept vectors, TSC offset, Pause Filter Count

Figure 15-4. Layout of VMCB Clean Field

Bits 31:12 are reserved for future implementations. For forward compatibility, if the hypervisor has not modified the VMCB, the hypervisor may write FFFF_FFFFh to the VMCB Clean Field to indicate that it has not changed any VMCB contents other than the fields described below as explicitly uncached. The hypervisor should write 0h to indicate that the VMCB is new or potentially inconsistent with the CPU's cached copy, as occurs when the hypervisor has allocated a new location for an existing VMCB from a list of free pages and does not track whether that page had recently been used as a VMCB for another guest. If any VMCB fields (excluding explicitly uncached fields) have been modified, all clean bits that are undefined (within the scope of the hypervisor) must be cleared to zero.

Bit 31 is a special bit reserved for the host that the CPU will never use for a clean bit.

The following are explicitly not cached and not represented by Clean bits:

- TLB_Control
- Interrupt shadow
- VMCB status fields (Exitcode, EXITINFO1, EXITINFO2, EXITINTINFO, Decode Assist, etc.)
- Event injection
- RFLAGS, RIP, RSP, RAX

15.16 TLB Control

TLB entries are tagged with *Address Space Identifier* (ASID) bits to distinguish different guest virtual address spaces when shadow page tables are used, or different guest physical address spaces when nested page tables are used. The VMM can choose a software strategy in which it keeps multiple shadow page tables, and/or multiple nested page tables in processors that support nested paging, up-to-date; the VMM can allocate a different ASID for each shadow or nested page table. This allows switching to a new process in a guest under shadow paging (changing CR3 contents), or to a new guest under nested paging (changing nCR3 contents), without flushing the TLBs. (See section 15.25 for a complete explanation of nested paging operation.)

With shadow paging, the VMM is responsible for setting up a shadow page table for each guest linear address space that maps it to system physical addresses. These are used as the active page tables in place of the guest OS's page tables. The VMM sets the CR3 field in the guest VMCB to point to the system physical address of the desired shadow page table. The VMM is responsible for updating the shadow page table when the guest changes its page table or paging control state, and the VMM updates the access and dirty bits of the guest page table.

The VMRUN instruction and #VMEXIT write the CR0, CR3, CR4 and EFER registers, but these writes do *not* flush the TLB. The VMM is responsible for explicitly invalidating any guest translations that may be affected by its actions. There are two mechanisms available for this described in the next two sections.

When running with SVM enabled, global page table entries (PTEs) are global only *within* an ASID, not across ASIDs.

Software Rule. When the VMM changes a guest’s paging mode by changing entries in the guest’s VMCB, the VMM must ensure that the guest’s TLB entries are flushed from the TLB. The relevant VMCB state includes:

- CR0—PG, WP, CD, NW.
- CR3—Any bit.
- CR4—PGE, PAE, PSE.
- EFER—NXE, LMA, LME.

15.16.1 TLB Flush

TLB flush operations function identically whether or not SVM is enabled (e.g., MOV-TO-CR3 flushes non-global mappings, whereas MOV-TO-CR4 flushes global and non-global mappings). TLB flush operations must not be assumed to affect all ASIDs. If a VMM sets the intercept bit for any guest action that would have flushed the TLB, the #VMEXIT intercept occurs and the TLB is not flushed; it is the VMM's responsibility to flush the TLB appropriately. In implementations that do not provide a way to selectively flush all translations of a single specified ASID, software may effectively flush the guest's TLB entries by allocating a new ASID for the guest and not reusing the old ASID until the entire TLB has been flushed at least once.

The TLB_CONTROL field in the VMCB provides the commands specified by the control byte encodings shown in Table 15-9. The first two commands are available on all processors that support SVM; support for the other commands is optional and is indicated by CPUID Fn8000_000A_EDX[FlushByAsid] = 1.

Table 15-9. TLB Control Byte Encodings

Encoding	Function Definition
00h	Do not flush
01h	Flush entire TLB (Should be used only on legacy hardware.)
03h	Flush this guest's TLB entries
07h	Flush this guest's non-global TLB entries
Note: All encodings not defined in this table are reserved.	

When the VMM sets the TLB_CONTROL field to 1, the VMRUN instruction flushes the TLB for all ASIDs, for both global and non-global pages. The VMRUN instruction reads, but does not change, the value of the TLB_CONTROL field.

A MOV-to-CR3, a task switch that changes CR3, or clearing or setting CR0.PG or bits PGE, PAE, PSE of CR4 affects only the TLB entries belonging to the current ASID, regardless of whether the operation occurred in host or guest mode. The current ASID is 0 when the CPU is not inside a guest context.

All TLB entries belonging to all ASIDs are flushed by SMI, RSM, MTRR modifications, IORR modifications, and access to other system MSRs that affect address translation.

If a hypervisor modifies a nested page table by decreasing permission levels, clearing present bits, or changing address translations and intends to return to the same ASID, it should use either TLB command 011b or 001b.

15.16.2 Invalidate Page, Alternate ASID

The INVLPGA instruction allows the VMM to selectively invalidate the TLB mapping for a given guest virtual page within a given ASID. The linear address is specified in the implicit register operand rAX; the ASID is specified in ECX. The input address is always interpreted as a guest virtual address, so INVLPGA is typically meaningful only when used with shadow page tables; it does not provide a means to invalidate a nested translation by guest physical address.

15.17 Global Interrupt Flag, STGI and CLGI Instructions

The global interrupt flag (GIF) is a bit that controls whether interrupts and other events can be taken by the processor. The STGI and CLGI instructions set and clear, respectively, the GIF. Table 15-10 shows how the value of the GIF affects how interrupts and exceptions are handled. Implementations may

provide hardware support for virtualizing the GIF in nested virtualization scenarios; see section 15.33, for details.

Table 15-10. Effect of the GIF on Interrupt Handling

Interrupt source	GIF==0	GIF ==1
Debug exception or trap, due to breakpoint register match	Ignored and discarded	Normal operation
Debug trace trap due to EFLAGS.TF	Normal operation	Normal operation
RESET	Normal operation	Normal operation
INIT	Held pending until GIF==1	Normal operation, see Table 15-12
NMI	Held pending until GIF==1	Normal operation, see Table 15-13
External SMI	Held pending until GIF==1	Normal operation, see Table 15-14
Internal SMI (I/O Trapping)	Ignored and discarded	Normal operation, see Table 15-14
INTR and vINTR	Held pending until GIF==1	Normal operation
#SX (Security Exception)	n/a[1]	Normal operation
Machine Check	If possible (implementation-dependent), held pending until GIF==1, otherwise shutdown.	Normal operation
DBREQ# (external debug request)	Normal operation	Normal operation
	(VM_CR.DPD always controls DBREQ)	
A20M	Normal operation	Normal operation
	(VM_CR.DIS_A20M controls A20 masking)	
Other implementation-specific but non-architecturally-visible interrupts (STPCLK, IGNNE toggle, ECC scrub)	Normal operation	Normal operation

Note:

1. #SX is caused only by an INIT signal that has been "redirected" (i.e., converted to an #SX; see section 15.28); the conversion only happens when GIF==1, as the INIT is simply held pending otherwise.

15.18 VMMCALL Instruction

This instruction is meant as a way for a guest to explicitly call the VMM. No CPL checks are performed, so the VMM can decide whether to make this instruction legal at the user-level or not.

If VMMCALL instruction is not intercepted, the instruction raises a #UD exception.

15.19 Paged Real Mode

To facilitate virtualization of real mode, the VMRUN instruction may legally load a guest CR0 value with PE = 0 but PG = 1. Likewise, the RSM instruction is permitted to return to paged real mode. This

processor mode behaves in every way like real mode, with the exception that paging is applied. The intent is that the VMM run the guest in paged-real mode at CPL0, and with page faults intercepted. The VMM is responsible for setting up a shadow page table that maps guest *physical* memory to the appropriate system physical addresses.

The behavior of running a guest in paged real mode without intercepting page faults to the VMM is undefined.

15.20 Event Injection

The VMM can inject exceptions or interrupts (collectively referred to as events) into the guest by setting bits in the VMCB's EVENTINJ field prior to executing the VMRUN instruction. The format of the field is shown in Table 15-5. The encoding matches that of the EXITINTINFO field. When an event is injected by means of this mechanism, the VMRUN instruction causes the guest to take the specified exception or interrupt unconditionally before executing the first guest instruction.

Injected events are treated in every way as though they had occurred normally in the guest (in particular, they are recorded in EXITINTINFO) with the following exceptions:

- Injected events are not subject to intercept checks. (Note, however, that if secondary exceptions occur during delivery of an injected event, those exceptions *are* subject to exception intercepts.)
- An injected NMI does not block delivery of further NMIs.
- If the VMM attempts to inject an event that is impossible for the guest mode (e.g., a #BR exception when the guest is in 64-bit mode), the event injection will fail and no guest state instructions will be executed; VMRUN will immediately exit with an error code of VMEXIT_INVALID.
- Injecting an exception (TYPE = 3) with vectors 3 or 4 behaves like a trap raised by INT3 and INTO instructions, respectively, in which case the processor checks the DPL of the IDT descriptor before dispatching to the handler.
- Software interrupts cannot be properly injected if the processor does not support the NextRIP field. Support is indicated by CPUID Fn8000_000A_EDX[NRIPS] = 1. Hypervisor software should emulate the event injection of software interrupts if NextRIP is not supported.
- Event injection does not support injection of intercepted #DB faults that are the result of a guest ICEBP instruction. ICEBP does not perform DPL checks, as does INT*n* injection. Hypervisor software should emulate the injection of ICEBP.

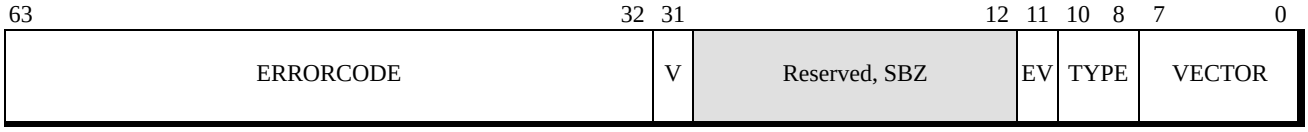


Figure 15-5. EVENTINJ Field in the VMCB

The fields in EVENTINJ are as follows:

- *VECTOR*—Bits 7:0. The 8-bit IDT vector of the interrupt or exception. If TYPE is 2 (NMI), the VECTOR field is ignored.
- *TYPE*—Bits 10:8. Qualifies the guest exception or interrupt to generate. Table 15-11 shows possible values and their corresponding interrupt or exception types. Values not indicated are unused and reserved.

Table 15-11. Guest Exception or Interrupt Types

Value	Type
0	External or virtual interrupt (INTR)
2	NMI
3	Exception (fault or trap)
4	Software interrupt (INT*n* instruction)

- *EV (Error Code Valid)*—Bit 11. Set to 1 if the exception should push an error code onto the stack; clear to 0 otherwise.
- *V (Valid)*—Bit 31. Set to 1 if an event is to be injected into the guest; clear to 0 otherwise.
- *ERRORCODE*—Bits 63:32. If EV is set to 1, the error code to be pushed onto the stack, ignored otherwise.

VMRUN exits with VMEXIT_INVALID error code if either:

- Reserved values of TYPE have been specified, or
- TYPE = 3 (exception) has been specified with a vector that does not correspond to an exception (this includes vector 2, which is an NMI, not an exception).

15.21 Interrupt and Local APIC Support

SVM hardware support is designed to ensure efficient virtualization of interrupts.

15.21.1 Physical (INTR) Interrupt Masking in EFLAGS

To prevent the guest from blocking maskable interrupts (INTR), SVM provides a VMCB control bit, V_INTR_MASKING, which changes the operation of EFLAGS.IF and accesses to the TPR by means of the CR8 register. While running a guest with V_INTR_MASKING cleared to zero:

- EFLAGS.IF controls both virtual and physical interrupts.

While running a guest with V_INTR_MASKING set to 1:

- The host EFLAGS.IF at the time of the VMRUN is saved and controls physical interrupts while the guest is running.
- The guest value of EFLAGS.IF controls virtual interrupts only.

15.21.2 Virtualizing APIC.TPR

SVM provides a virtual TPR register, V_TPR, for use by the guest; its value is loaded from the VMCB by VMRUN and written back to the VMCB by #VMEXIT. The APIC's TPR always controls the task priority for physical interrupts, and the V_TPR always controls virtual interrupts.

While running a guest with V_INTR_MASKING cleared to 0:

- Writes to CR8 affect both the APIC's TPR and the V_TPR register.
- Reads from CR8 operate as they would without SVM.

While running a guest with V_INTR_MASKING set to 1:

- Writes to CR8 affect only the V_TPR register.
- Reads from CR8 return V_TPR.

15.21.3 TPR Access in 32-Bit Mode

The mechanism for TPR virtualization described in section 15.21.2 applies only to accesses that are performed using the CR8 register. However, in 32-bit mode, the TPR is traditionally accessible only by using a memory-mapped register. Typically, a VMM virtualizes such TPR accesses by not mapping the APIC page addresses in the guest. A guest access to that region then causes a #PF intercept to the VMM, which inspects the guest page tables to determine the physical address and, after recognizing the physical address as belonging to the APIC, finally invokes software emulation code.

To improve the efficiency of TPR accesses in 32-bit mode, SVM makes CR8 available to 32-bit code by means of an alternate encoding of MOV TO/FROM CR8 (namely, MOV TO/FROM CR0 with a LOCK prefix). To achieve better performance, 32-bit guests should be modified to use this access method, instead of the memory-mapped TPR. (For details, see “MOV CRn” on page 377 of the *AMD64 Programmer’s Reference Volume 3: General Purpose and System Instructions*, order# 24594.)

The alternate encodings of the MOV TO/FROM CR8 instructions are available even if SVM is disabled in EFER.SVME. They are available in both 64-bit and 32-bit mode.

15.21.4 Injecting Virtual (INTR) Interrupts

Virtual Interrupts allow the host to pass an interrupt (#INTR) to a guest. While inside a guest, the virtual interrupt follows the same rules that a real interrupt follows (virtual #INTR is not taken until EFLAGS.IF is 1, the guest's TPR has enabled interrupts at the same priority as that of the pending virtual interrupt).

SVM provides an efficient mechanism by which the VMM can inject virtual interrupts into a guest:

- As described in Section 15.13.1, the VMM can intercept physical interrupts that arrive while a guest is running, by activating the INTR intercept in the VMCB.
- As described in Section 15.21.4, the VMM can virtualize the interrupt masking logic by setting the V_INTR_MASKING bit in the VMCB.

- The three VMCB fields V_IRQ, V_INTR_PRIO, and V_INTR_VECTOR indicate whether there is a virtual interrupt pending, and, if so, what its vector number and priority are. The VMRUN instruction loads this information into corresponding on-chip registers.
- The processor takes a virtual INTR interrupt if
  - V_IRQ and V_INTR_PRIO indicate that there is a virtual interrupt pending whose priority is greater than the value in V_TPR,
  - interrupts are enabled in EFLAGS.IF,
  - interrupts are enabled using GIF, and
  - the processor is not in an interrupt shadow (see Section 15.21.5).

  The only other difference between virtual INTR handling and normal interrupt handling is that, in the latter case, the interrupt vector is obtained from the V_INTR_VECTOR register (as opposed to running an INTACK cycle to the local APIC).
- The V_IGN_TPR field in the VMCB can be set to indicate that the currently pending virtual interrupt is not subject to masking by TPR. The priority comparison against V_TPR is omitted in this case. This mechanism can be used to inject ExtINT-type interrupts into the guest.
- When the processor dispatches a virtual interrupt (through the IDT), V_IRQ is cleared after checking for intercepts of virtual interrupts and before the IDT is accessed.
- On #VMEXIT, V_IRQ is written back to the VMCB, allowing the VMM to track whether a virtual interrupt has been taken.
- Physical interrupts take priority over virtual interrupts, whether they are taken directly or through a #VMEXIT.
- On #VMEXIT, the processor clears its internal copies of V_IRQ and V_INTR_MASKING, so virtual interrupts do not remain pending in the VMM, and interrupt control reverts to normal.

15.21.5 Interrupt Shadows

The x86 architecture defines the notion of an *interrupt shadow*—a single-instruction window during which interrupts are not recognized. For example, the instruction after an STI instruction that sets EFLAGS.IF (from zero to one) does not recognize interrupts or certain debug traps. The VMCB INTERRUPT_SHADOW field indicates whether the guest is currently in an interrupt shadow. This information is saved on #VMEXIT and loaded on VMRUN.

15.21.6 Virtual Interrupt Intercept

When virtualizing interrupt handling, a VMM typically needs only gain control when new interrupts for a guest arrive or are generated, and when the guest issues an EOI (end-of-interrupt). In some circumstances, it may also be necessary for the VMM to gain control at the moment interrupts become enabled in the guest (i.e., just before the guest takes a virtual interrupt). The VMM can do so by enabling the VINTR intercept.

15.21.7 Interrupt Masking in Local APIC

When guests have direct access to devices, interrupts arriving at the local APIC can usually be dismissed only by the guest that owns the device causing the interrupt. To prevent one guest from blocking other guests' interrupts (by never processing their own), the VMM can mask pending interrupts in the local APIC, so they do not participate in the prioritization of other interrupts.

SVM introduces the following APIC features:

- A 256-bit IER (interrupt enable) register is added to the local APIC. This register resets to all ones (enabling all 256 vectors). Software can read and write the IER by means of the memory-mapped APIC page.
- Only vectors that are enabled in the IER participate in the APIC computation of the highest-priority pending interrupt.
- The VMM can issue specific end-of-interrupt (EOI) commands to the local APIC, allowing the VMM to clear pending interrupts in any order, rather than always targeting the interrupt with highest-priority.

15.21.8 INIT Support

The INIT signal interrupts the processor at the next instruction boundary and causes an unconditional control transfer. INIT reinitializes the control registers, segment registers and GP registers in a manner similar to RESET, but does not alter the contents of most MSRs, caches or numeric coprocessor (x87 or SSE) state, and then transfers control to the same instruction address as RESET (physical address FFFFFFF0h). Unlike RESET, INIT is not expected to be visible to the memory controller, and hence will not trigger automatic clearing of trusted memory pages by memory controller hardware.

To maintain the security of such pages, the VMM can request that INITs be redirected and turned into #SX exceptions by setting the R_INIT bit in the VM_CR MSR (see Section 15.30.1). This allows the VMM to gain control when an INIT is requested and scrub any sensitive context. The VMM may then disable the redirection of INIT and cause the platform to reassert INIT (see the relevant BKDG or PPR documentation for details), at which point the processor will respond in the normal manner. The actions initiated by the INIT pin may also be initiated by an incoming APIC INIT interrupt; the mechanisms described here apply in either case. Table 15-12 summarizes the handling of INITs.

Table 15-12. INIT Handling in Different Operating Modes

GIF	INIT Intercept	INIT Redirect	Processor Response to INIT
0	X	X	Hold pending until GIF = 1.
1	1	X	#VMEXIT(INIT), INIT is still pending.
	0	0	Taken normally.
		1	#SX, INIT is no longer pending.

If redirection is enabled without the INIT intercept being enabled, an INIT that asserts during guest execution will result in #SX being asserted within the guest, with the INIT being cleared. The VMM may intercept the assertion of #SX as described in “Intercept Operation” on page 493. Note that when a VMM has intercepted an INIT assertion, it may modify R_INIT any time before setting GIF to control the behavior when GIF is ultimately set, or the VMM may instead return to a guest VM with the intercept disabled and redirection enabled to effectively hand off the INIT to the guest as a #SX exception.

15.21.9 NMI Support

The VMM can intercept non-maskable interrupts (NMI) using a VMCB control bit (see Table 15-13). When intercepted, NMIs cause an exit from the guest and are held pending.

Table 15-13. NMI Handling in Different Operating Modes

GIF	NMI Intercept	Processor Response to NMI
0	X	Hold pending until GIF=1.
1	1	#VMEXIT(NMI), NMI is still pending.
	0	Taken normally.

15.22 SMM Support

This section describes SVM support for virtualization of System Management Mode (SMM).

15.22.1 Sources of SMI

Various events can cause an assertion of a system management interrupt (SMI); these are classified into three categories

- Internal, synchronous (also known as I/O Trapping)—implementation-specific IOIO or config space trapping in the CPU itself; always synchronous in response to an IN or OUT instruction. I/O Trapping is set up by means of MSRs and can be brought under the control of the VMM by intercepting guest access to those MSRs.
- External, synchronous—IOIO trapping in response to (and synchronous with) IN or OUT instructions, but generated by an external agent (typically the Southbridge).
- External, asynchronous—generated externally in response to an external, physical event, e.g., closing a laptop lid, temperature sensor triggering, etc.

15.22.2 Response to SMI

How hardware responds to SMIs is a function of whether SMM interrupts are being intercepted and whether interrupts are enabled globally, as shown in Table 15-14.

Table 15-14. SMI Handling in Different Operating Modes

GIF	Intercept SMI	Internal SMI	External SMI
0	x	Lost.	Hold pending until GIF=1.
1	1	Exit guest, code #VMEXIT(SMI), SMI is not pending.	#VMEXIT(SMI), SMI is still pending.
	0	Taken normally.	Taken normally.

By intercepting SMIs, the VMM can gain control before the processor enters SMM.

15.22.3 Containerizing Platform SMM

In some usage scenarios, the VMM may not trust the existing platform SMM code, or may otherwise want to ensure that the SMM does not operate in the context of certain guests or the hypervisor. To address these cases, SVM provides the ability to *containerize* SMM code, i.e., run it inside a guest, with the full protection mechanisms of the VMM in place. In other scenarios, the VMM may not want to exert control over SMM.

There are three solutions for the VMM to control SMM handlers:

- The simplest solution is to not intercept SMI signals. SMIs encountered while in a guest context are taken from within the guest context. In this case, the SMM handler is not subject to any intercepts set up by the VMM and consequently runs outside of the virtualization controls. The state saved in the SMM State-Save area as seen by the SMM handler reflects the state of the guest that had been running at the time the SMI was encountered. When the SMM handler executes the RSM instruction, the processor returns to executing in the guest context, and any modifications to the SMM State-Save area made by the SMM handler are reflected in the guest state.
- A hypervisor may want to emulate all SMI-based I/O interceptions for a guest and to take SMI signals only in the hypervisor context. The hypervisor should set all IOIO intercept bits and the SMI intercept bit for the guest to ensure that there is no possibility of encountering synchronous (internal or external) SMI signals while running the guest. Any #VMEXIT(SMI) encountered is then known to be due to an external, asynchronous SMI. The hypervisor may respond to the #VMEXIT(SMI) by executing the STGI instruction, which causes the pending SMI to be taken immediately. When an SMI due to an I/O instruction is pending, the effect of executing STGI in the hypervisor is undefined. To handle a pending SMI due to an I/O instruction, the hypervisor must either containerize SMM or not intercept SMI.
- The most involved solution is to containerize SMM by placing it in a guest. Containerizing gives the VMM full control over the state that the SMM handler can access.

Containerizing Platform SMM. A VMM can containerize SMM by creating its own trusted SMM hypervisor and use that handler to run the platform SMM code in a container. The SMM hypervisor may be the same code as the VMM itself, or may be an entirely different set of code. The trusted SMM hypervisor sets up a guest context to run the platform SMM as a guest. The guest context consists of a VMCB and related state and the guest's (real or virtual) SMM save area. The SMM hypervisor

emulates SMM entry, including setup of the SMM save area, and emulates RSM at the end of SMM operation. The guest executes the platform SMM code in paged real mode with appropriate SVM intercepts in place, thus ensuring security.

For this approach to work, the VMM may need to write the SMM_BASE MSR, as well as related SMM control registers. As part of the emulation of SMM entry and RSM, the VMM needs to access the SMM_CTL MSR (see Section 15.30.3). However, these actions conflict with any platform firmware that locks SMM control registers.

A VMM can determine if it is running with a compatible firmware setup by checking the SMMLOCK bit in the HWCR MSR (described in the *BIOS and Kernel Developer's Guide (BKDG)* or *Processor Programming Reference Manual* applicable to your product). If the bit is 1, firmware has locked the SMM control registers and the VMM is unable to move them or insert its own SMM hypervisor.

As the processor physically enters SMM, the SMRAM regions are remapped. The VMM design must ensure that none of its code or data disappears when the SMRAM areas are mapped or unmapped. Also note that the ASEG region of the SMRAM overlaps with a portion of video memory, so the SMM hypervisor should not attempt to write diagnostic messages to the screen. Any attempt by guests to relocate any of the SMRAM areas (by means of certain MSR writes) must also be intercepted to prevent malicious SMM code from interfering with VMM operation.

Writes to the SMM_CTL MSR cause a #GP if firmware has locked the SMM control registers.

15.23 Last Branch Record Virtualization

The debug control MSR (DebugCtl) provides control of control-transfer recording and other debug facilities. (See Chapter 13, "Software Debug and Performance Resources," on page 385, for more information on using the debug control MSR.) Software sets the last-branch record (DebugCtl[LBR]) bit to 1 to cause the processor to record the source and target addresses of the last control transfer taken before a debug exception. These control transfers include branch instructions, interrupts, and exceptions. Recorded information is stored in four MSRs:

- LastBranchFromIP
- LastBranchToIP
- LastIntFromIP
- LastIntToIP

Under SVM, to virtualize the function of these MSRs, the VMM must save the contents of the control-transfer recording MSRs on #VMEXIT and restore them prior to the VMRUN for each guest. If control-transfer recording is to be used in host state as well the values of these registers must be exchanged between values tracked by host and guest.

15.23.1 Hardware Acceleration for LBR Virtualization

Processors optionally support hardware acceleration for LBR virtualization. The following fields are allocated in the VMCB state save area to hold the contents of the DebugCTL and control-transfer recording MSRs:

- DBGCTL—Holds the guest value of the DebugCTL MSR.
- BR_FROM—Holds the guest value of the LastBranchFromIP MSR.
- BR_TO—Holds the guest value of the LastBranchToIP MSR.
- LASTEXCPFROM—Holds the guest value of the LastIntFromIP MSR.
- LASTEXCPTO—Holds the guest value of the LastIntToIPLastIntToIP MSR.

When VMCB.LBR_VIRTUALIZATION_ENABLE is set, VMRUN saves all five host control-transfer MSRs in the host save area, and then loads the same five MSRs for the guest from the VMCB save area. Similarly, #VMEXIT saves the guest's MSRs and loads the host's MSRs to and from their respective save areas.

15.23.2 LBR Virtualization CPUID Feature Detection

CPUID Fn8000_000A_EDX[LbrVirt] = 1 indicates support for the LBR virtualization acceleration feature on AMD64 processors. See Section 3.3, “Processor Feature Identification,” on page 71 for more information on using the CPUID instruction.

15.24 External Access Protection

By securing the virtual address translation mechanism, the VMM can restrict guest CPU accesses to memory. However, should the guest have direct access to DMA-capable devices, an additional protection mechanism is required. SVM provides multiple protection domains which can restrict device access to physical memory on a per-page basis. This is accomplished via control logic in the northbridge’s host bridge which governs any external access port (e.g., PCI or HyperTransport™ technology interfaces).

15.24.1 Device IDs and Protection Domains

The northbridge’s host bridge provides a number of protection domains. Each protection domain has associated with it a device exclusion vector (DEV) that specifies the per-page access rights of devices in that domain. Devices are identified by a HyperTransport™ bus/unitID (device ID) and the host bridge contains a lookup table of fixed size that maps device IDs to a protection domain.

15.24.2 Device Exclusion Vector (DEV)

A DEV is a contiguous array of bits in physical memory; each bit in the DEV (in little-endian order) corresponds to one 4-Kbyte page in physical memory.

The physical address of the base of a DEV must be 4-Kbyte-aligned and stored in one of the DEVBASE registers, which are accessed through an indirection mechanism in the DEVCTL PCI

Configuration Space function block in the host bridge (see “DEV Control and Status Registers” on page 528). The DEV protection hardware is not operational until enabled by setting a control bit in the DEV Control Register, also in the DEVCTL function block.

The DEV may have to cover part of MMIO space beyond the DRAM. Especially in 64-bit systems, the operating system should map MMIO space starting immediately after the DRAM area and building up, as opposed to starting down from the maximum physical address.

Host Bridge and Processor DEV Caching. For improved performance, the host bridge may cache portions of the DEV. Any such cached information can be invalidated by setting the DEV_FLUSH flag in the DEV control register to 1. Software must set this flag after modifying DEV contents to ensure that the protection logic uses the updated values. The host bridge automatically clears this flag when the flush operation completes. After setting this flag, software should monitor it until it has cleared, in order to synchronize DEV updates with subsequent activity.

By default, the host bridge probes the processor caches for the latest data when it accesses the DEV in DRAM. However, it is possible to disable probing by means of the DEV_CR register (“DEV_CR Register” on page 528); this is recommended in the case of unified memory architecture (UMA) graphics systems. If cache probing is disabled, host bridge reads of the DEV will not check processor caches for more recent copies. This requires software on the CPU to map the memory containing the DEV as uncacheable (UC) or write-through (WT). Alternatively, software must perform a CLFLUSH before it can expect a change to the DEV to be visible by the northbridge (and before software flushes the DEV cache in the host controller).

Multiprocessor Issues. Device-originated memory requests are checked against the DEV at the point of entry to the system—the northbridge to which the device is physically attached. Each northbridge can have its own set of domains, device-to-domain mappings, and DEV tables (e.g., domain #2 on one node can encompass different devices, and can have different access rights than domain #2 on another node). Thus, the number of protection domains available to software can scale with the number of northbridges in the system.

15.24.3 Access Checking

Memory Space Accesses. When a memory-space read or write request is received on an external host bridge port, the host bridge maps the HyperTransport bus device ID to a protection domain number, which in turn selects the DEV defining the access permissions for the device (see Figure 15-6). The host bridge then checks the memory address against the DEV contents by indexing into the DEV with the PFN portion of the address (bits 39:12). The PFN is used as a bit index within the DEV. If the bit read from the DEV is set to 1, the host bridge inhibits the access by returning all ones for the data for a read request, or suppressing the store operation on a write request. A Master Abort error response will be returned to the requesting device.

Peer-to-peer memory accesses routed up to the host bridge are also subjected to checks against the DEV. Peer-to-peer transfers that may be occurring behind bridges are not checked.

DEV checks are applied before addresses are translated by the GART. The DEV table is never consulted by accesses originating in the CPU.

I/O Space Accesses. The host bridge can be configured to reject all I/O space accesses from devices, by setting the IOSPE bit in the DEV_CR control register (see “DEV_CR Register” on page 528). I/O space peer-to-peer transfers behind bridges are not checked.

Config Space Accesses. Major aspects of host bridge functionality are configured by means of control registers that are accessed through PCI configuration space. Because this is potentially accessible by means of device peer-to-peer transfers, the host bridge always blocks access to this space from anything other than the CPU.

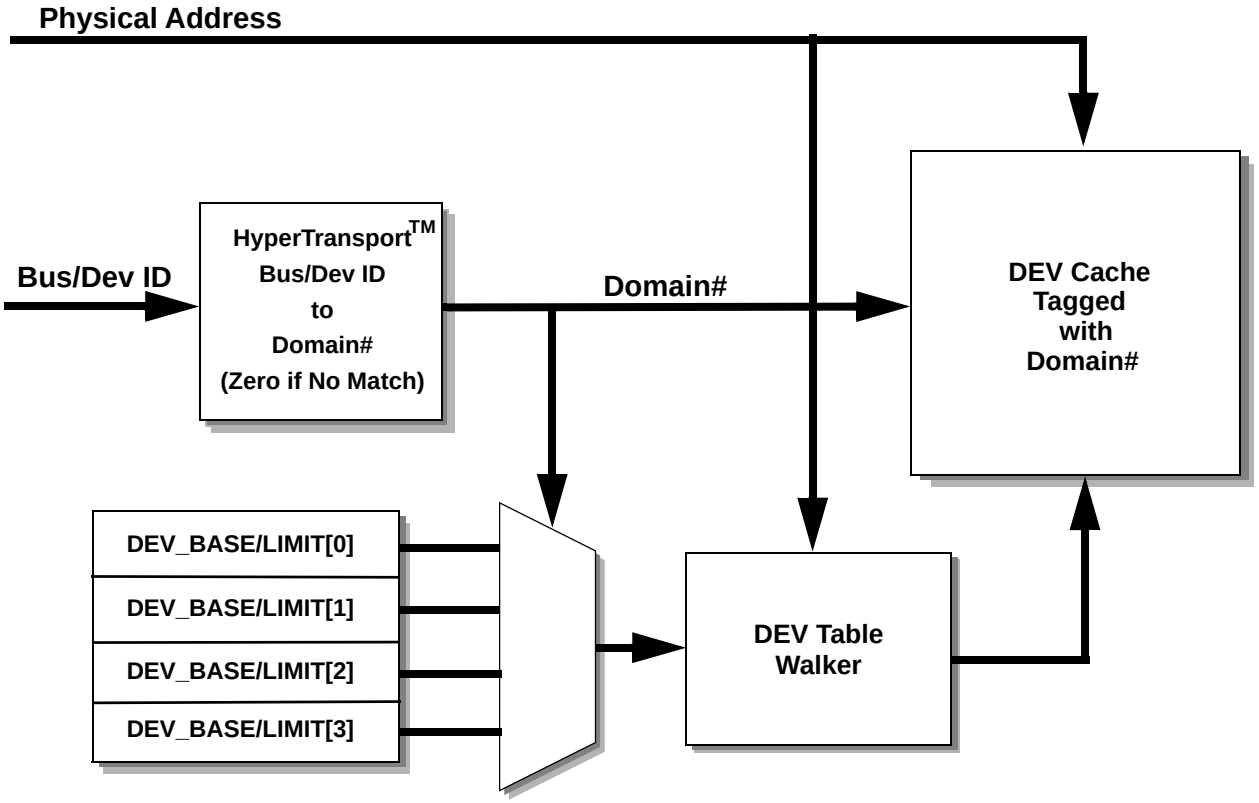

Figure 15-6. Host Bridge DMA Checking

15.24.4 DEV Capability Block

The presence of DEV support is indicated through a new PCI capability block. The capability block also provides access to the registers that control operation of the DEV feature.

The DEV capability block in PCI space contains three 32-bit words: the capability header (DEV_HDR), and two registers (DEV_OP and DEV_DATA) which serve as an indirection mechanism for accessing the actual DEV control and status registers.

Table 15-15. DEV Capability Block, Overall Layout

Byte Offset	Register	Comments
0	DEV_HDR	Capability block header
4	DEV_OP	Selects control/status register to access
8	DEV_DATA	Read/write to access register selected in DEV_OP

DEV Capability Header. The DEV capability header (DEV_HDR) is defined in Table 15-16.

Table 15-16. DEV Capability Header (DEV_HDR) (in PCI Config Space)

Bit(s)	Definition
31:22	Reserved, MBZ
21	Interrupt Reporting Capability
20	Machine Check Exception Reporting Capability
19	Reserved, MBZ
18:16	DEV Capability Block Type; hardwired to 000b.
15:8	PCI Capability pointer; points to next capability in list
7:0	PCI Capability ID; hardwired to 0x0F

15.24.5 DEV Register Access Mechanism

The northbridge's DEV control and status registers are accessed through an indirection mechanism: writing the DEV_OP register selects which internal register is to be accessed, and the DEV_DATA register can be read or written to access the selected register.

Figure 15-7 shows the format of the DEV_OP register. The DEV_DATA register reflects the format of the DEV register selected in DEV_OP.

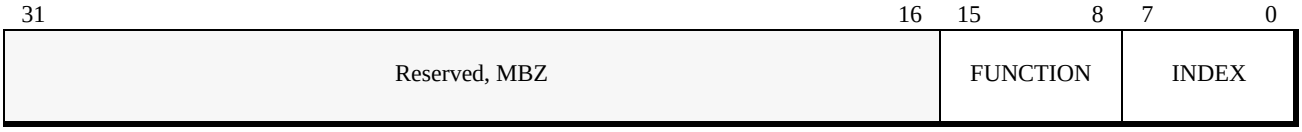

Figure 15-7. Format of DEV_OP Register (in PCI Config Space)

The FUNCTION field in the DEV_OP register selects the function/register to read or write according to the encoding in Table 15-17; for blocks of registers that have multiple instances (e.g., multiple DEV_BASE_HI/LO registers), the INDEX field selects the instance; otherwise it is ignored.

Table 15-17. Encoding of Function Field in DEV_OP Register

Function Code	RegisterType	Number of Instances
0	DEV_BASE_LO	multiple
1	DEV_BASE_HI	multiple
2	DEV_MAP	multiple
3	DEV_CAP	single
4	DEV_CR	single
5	DEV_ERR_STATUS	single
6	DEV_ERR_ADDR_LO	single
7	DEV_ERR_ADDR_HI	single

For example, to write the DEV_BASE_HI register for protection domain number 2, software sets DEV_OP.FUNCTION to 1, and DEV_OP.INDEX to 2, and then writes the desired 32-bit value into DEV_DATA. As the DEV_OP and DEV_DATA registers are accessed through PCI config space (ports 0CF8h–0CFFh), they may be secured from unauthorized access by software executing on the processor by appropriate settings in the SVM I/O protection bitmap. These registers are also protected by the host bridge from external access as described in “Config Space Accesses” on page 526.

15.24.6 DEV Control and Status Registers

The DEV control and status registers are accessible by means of the indirection mechanism; these registers are *not* directly visible in PCI config space.

DEV_CAP Register. Read-only register; holds implementation specific information: the number of protection domains supported, the number of DEV_MAP registers (which map device/unit IDs to domain numbers), and the revision ID.

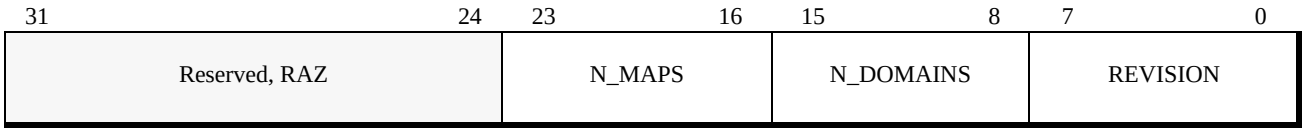

Figure 15-8. Format of DEV_CAP Register (in PCI Config Space)

The initial implementation provide four domains and three map registers.

DEV_CR Register. This is the main control register for the DEV mechanism; it is cleared to zero by RESET.

Table 15-18. DEV_CR Control Register

Bit(s)	Definition
31:7	Reserved, MBZ
6	DEV table walk probe disable. 0 = Use probe on DEV walk; 1 = Do not use probe
5	SL_DEV_EN. Enable bit for limited memory protection, see Section 15.24.8 on page 530. Set to “1” by SKINIT instruction, can be cleared by software.
4	Invalidate DEV cache. Software must set this bit to 1 to invalidate the DEV cache; cleared by hardware when invalidation is complete.
3	Enable MCE reporting. 0 = Do not generate MCE; 1 = Generate MCE on errors.
2	I/O space protection enable (IOSPEN) 0 = Allow upstream I/O cycles; 1 = Block.
1	Memory clear disable. If non-zero, memory-clearing on reset is disabled. This bit is not writable until the memory is enabled.
0	DEV global enable bit. If zero, DEV protection is turned off.

DEV_BASE Address/Limit Registers. The DEV base address registers (one set per domain) each point to the physical address of a DEV table corresponding to a protection domain. The address and size are encoded in a pair (high/low) of 32-bit registers. The N_DOMAINS field in DEV_CAP indicates how many (pairs of) DEV_BASE registers are implemented. The register format is as shown in Figures 15-9 and 15-10.

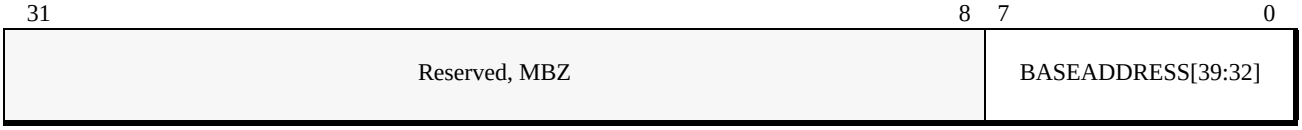

Figure 15-9. Format of DEV_BASE_HI[n] Registers

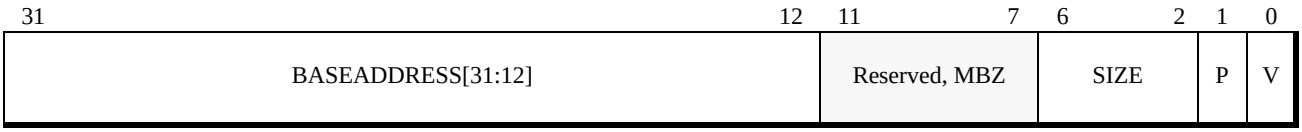

Figure 15-10. Format of DEV_BASE_LO[n] Registers

Fields of the DEV_BASE_HI and DEV_BASE_LO registers are defined as follows:

- *Valid (V)*—Bit 0. Indicates whether a DEV table has been defined for the given protection domain; if this bit is clear, software can leave the other fields undefined, and no protection checks are performed for memory references in this domain.

- *Protect (P)*—Bit 1. Indicates whether accesses to addresses beyond the address range covered by the DEV are legal (P=0) or illegal (P=1).
- *SIZE*—Bits 6:2. Specifies how much memory the DEV covers, expressed increments of 4GB * 2^{size}. In other words, a DEV table covers a minimum of 4GB, and can expand by powers of two.

DEV_MAP Registers. The DEV_MAP registers assign protection domain numbers to device-originated requests by matching the device ID (HT bus and unit number) associated with the request against bus and unit numbers in the registers. If no match is found in any of the registers, a domain number of zero is returned. The number of DEV_MAP registers implemented by the chip is indicated by the N_MAPS field in DEV_CAP.

The format of the DEV_MAP registers is shown in Figure 15-11.

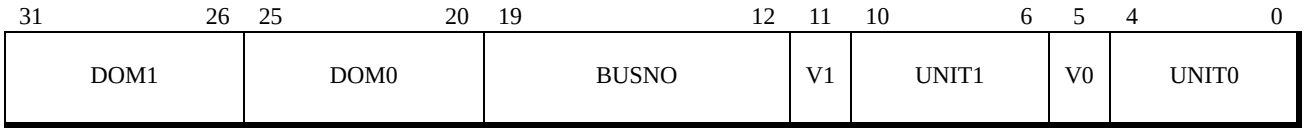

Figure 15-11. Format of DEV_MAP[n] Registers

The fields of the DEV_MAP[*n*] registers are defined as follows:

- UNIT0—Bits 4:0. Specifies the first of two HyperTransport link unit numbers on the bus number specified by the BUSNO field.
- V0—Bit 5. Indicates whether UNIT0 is valid (no matches occur on invalid entries).
- UNIT1—Bits 10:6. Specifies the second of two HyperTransport link unit numbers on the bus number specified by the BUSNO field.
- V1—Bit 11. Indicates whether UNIT1 is valid (no matches occur on invalid entries).
- BUSNO—Bits 19:12. Specifies a HyperTransport link bus number.
- DOM0—Bits 25:20. Specifies the protection domain for the first HyperTransport link unit.
- DOM1—Bits 31:26. Specifies the protection domain for the second HyperTransport link unit.

15.24.7 Unauthorized Access Logging

Any attempted unauthorized access by devices to DEV-protected memory is logged by the host bridge in the DEV_Error_Status and DEV_Error_Address registers for possible inspection by the VMM.

15.24.8 Secure Initialization Support

The host bridge contains additional logic that operates in conjunction with the SKINIT instruction to provide a limited form of memory protection during the secure startup protocol. This provides protection for a Secure Loader image in memory, allowing it to, among other things, set up full DEV protection. (See Section 15.27 for detailed operation of SKINIT.)

The host bridge logic includes a hidden (not accessible to software) SL_DEV_BASE address register. SL_DEV_BASE points to a 64KB-aligned 64KB region of physical memory. When SL_DEV_EN is 1, the 64KB region defined by SL_DEV_BASE is protected from external access (as if it were protected by the DEV), as well as from any access (both CPU and external accesses) via GART-translated addresses. Additionally, the SL_DEV mechanism, when enabled, blocks all device accesses to PCI Configuration space.

15.25 Nested Paging

The optional SVM nested paging feature provides for two levels of address translation, thus eliminating the need for the VMM to maintain shadow page tables.

15.25.1 Traditional Paging versus Nested Paging

Figure 15-12 shows how a page in the linear address space is mapped to a page in the physical address space in traditional (single-level) address translation. Control register CR3 contains the physical address of the base of the page tables (PT, represented by the shaded box in the figure), which governs the address translation.

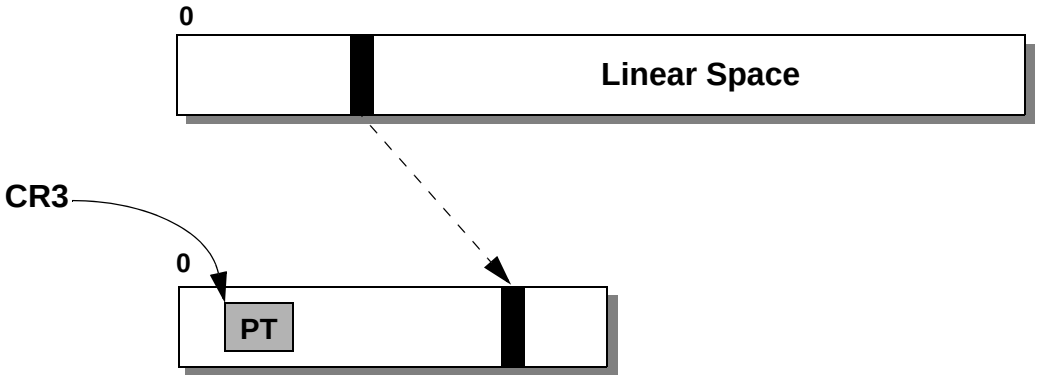

Figure 15-12. Address Translation with Traditional Paging

With nested paging enabled, *two* levels of address translation are applied; refer to Figure 15-13 below.

- Both guest and host levels have their own copy of CR3, referred to as gCR3 and nCR3, respectively.
- Guest page tables (gPT) map guest linear addresses to guest physical addresses. The guest page tables are in guest physical memory, and are pointed to by gCR3.
- Nested page tables (nPT) map guest physical addresses to system physical addresses. The nested page tables are in system physical memory, and are pointed to by nCR3.
- The most-recently used translations from guest linear to system physical address are cached in the TLB and used on subsequent guest accesses.

It is important to note that gCR3 and the guest page table entries contain guest physical addresses, not system physical addresses. Hence, before accessing a guest page table entry, the table walker first translates that entry's guest physical address into a system physical address.

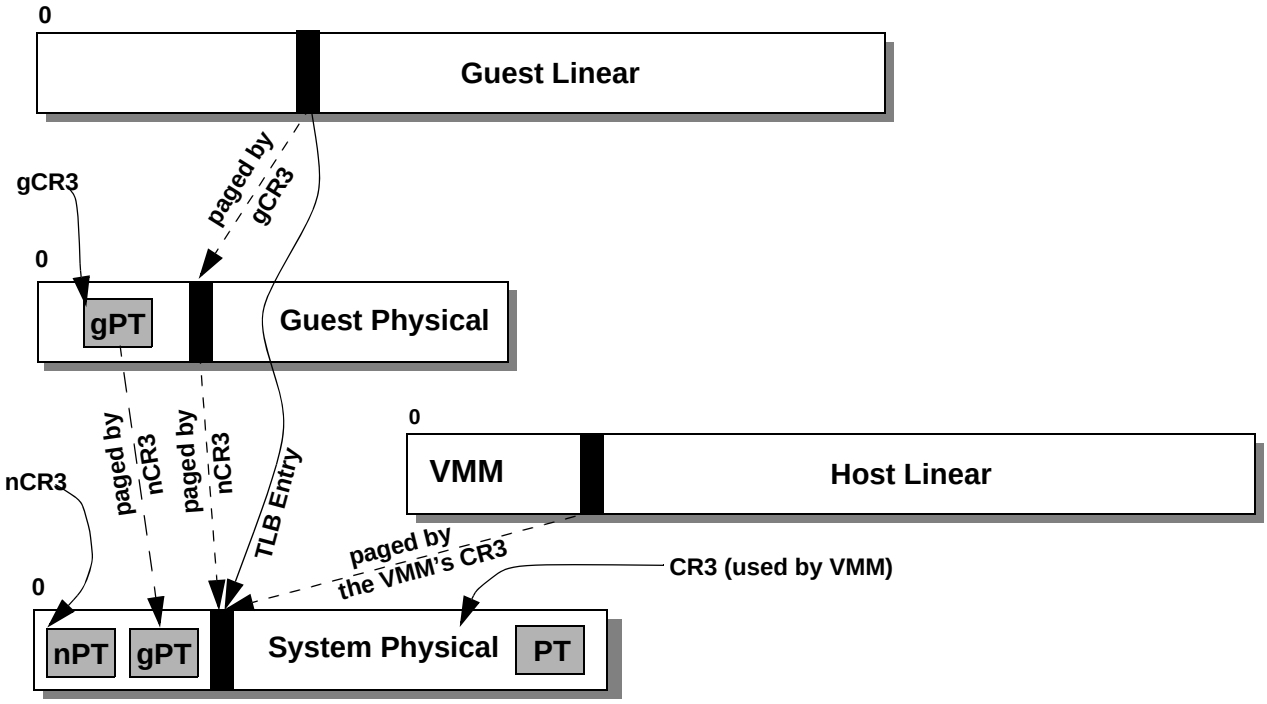

Figure 15-13. Address Translation with Nested Paging

The VMM can give each guest a different ASID, so that TLB entries from different guests can coexist in the TLB. The ASID value of zero is reserved for the host; if the VMM attempts to execute VMRUN with a guest ASID of zero, the result is #VMEXIT(VMEXIT_INVALID). Note that because an ASID is associated with the guest's physical address space, it is common across all of the guest's virtual address spaces within a processor. This differs from shadow page tables where ASIDs tag individual guest virtual address spaces. Note also that the same ASID may or may not be associated with the same address space across all processors in a multiprocessor system, for either nested tables or shadow tables; this depends on how the VMM manages ASID assignment.

15.25.2 Replicated State

Most processor state affecting paging is replicated for host and guest. This includes the paging registers CR0, CR3, CR4, EFER and PAT. CR2 is not replicated but is loaded by VMRUN. The MTRRs are not replicated.

While nested paging is enabled, all (guest) references to the state of the paging registers by x86 code (MOV to/from CR*n*, etc.) read and write the guest copy of the registers; the VMM's versions of the

registers are untouched and continue to control the second level translations from guest physical to system physical addresses. In contrast, when nested paging is disabled, the VMM's paging control registers are stored in the host state save area and the paging control registers from the guest VMCB are the only active versions of those registers.

15.25.3 Enabling Nested Paging

The VMRUN instruction enables nested paging when the NP_ENABLE bit in the VMCB is set to 1. The VMCB contains the hCR3 value for the page tables for the extra translation. The extra translation uses the same paging mode as the VMM used when it executed the most recent VMRUN.

Nested paging is automatically disabled by #VMEXIT.

Nested paging is allowed only if the host has paging enabled. Support for nested paging is indicated by CPUID Fn8000_000A_EDX[NP] = 1. If VMRUN is executed with hCR0.PG cleared to zero and NP_ENABLE set to 1, VMRUN terminates with #VMEXIT(VMEXIT_INVALID). See Section 3.3, “Processor Feature Identification,” on page 71 for more information on using the CPUID instruction.

15.25.4 Nested Paging and VMRUN/#VMEXIT

When VMRUN is executed with nested paging enabled (NP_ENABLE = 1), the paging registers are affected as follows:

- VMRUN saves the VMM’s CR3 in the host save area.
- VMRUN loads the guest paging state from the guest VMCB into the guest registers (i.e., VMRUN loads CR3 with the VMCB CR3 field, etc.). The guest PAT register is loaded from G_PAT field in the VMCB.
- VMRUN loads nCR3, the version of CR3 to be used while the nested-paging guest is running, from the N_CR3 field in the VMCB. The other host paging-control bits (hCR4.PAE, etc.) remain the same as they were in the VMM at the time VMRUN was executed.

When VMRUN is executed with nested paging enabled (NP_ENABLE = 1), the following conditions are considered illegal state combinations, in addition to those mentioned in “Canonicalization and Consistency Checks” on page 489:

- Any MBZ bit of nCR3 is set.
- Any G_PAT.PA field has an unsupported type encoding or any reserved field in G_PAT has a non-zero value. (See Section 7.8.1, “PAT Register,” on page 218.)

When #VMEXIT occurs with nested paging enabled:

- #VMEXIT writes the guest paging state (gCR3, gCR0, etc.) back into the VMCB. nCR3 is not saved back into the VMCB.
- #VMEXIT need not reload any host paging state other than CR3 from the host save area, though an implementation is free to do so.

15.25.5 Nested Table Walk

When the guest is running with nested paging enabled, a TLB miss causes several nested table walks:

- Guest Page Tables—the gCR3 register specifies a guest physical address, as do the entries in the guest's page tables. These guest physical addresses must be translated to system physical addresses using the nested page tables. Nested page table level faults can occur on these accesses, including write faults due to setting of accessed and dirty bits in the guest page table.
- Final Guest-Physical Page—once a guest linear to guest physical mapping is known, guest permissions can be checked. If the guest page tables allow the access, the guest physical address is walked in the nested page tables to find the system physical address.

Table walks for guest page tables are always treated as user writes at the nested page table level. For this reason,

- the page must be writable by user at the nested page table level, or else a #VMEXIT(NPF) is raised, and
- the dirty and accessed bits are always set in the nested page table entries that were touched during nested page table walks for guest page table entries.

A table walk for the guest page itself is always treated as a user access at the nested page table level, but is treated as a data read, data write, or code read, depending on the guest access.

If the guest has paging disabled (gCR0.PG = 0), there are no guest page table entries to be translated in the nested page tables. In this case, the final guest-physical address is equal to the guest-linear address, and is still translated in the nested page tables.

15.25.6 Nested versus Guest Page Faults, Fault Ordering

In nested paging, page faults can be raised at either the guest or nested page table level. Nested walks proceed in the following order; faults are generated in the same order:

1. Walk the guest page table entries in the nested page table. Dirty/Accessed bits are set as needed in the nested page table. Any nested page table faults result in #VMEXIT(NPF).
2. As the guest page table walk proceeds from the top of the page table to the last entry, any not-present entries or reserved bits in the guest page table entries at each level of the guest walk cause #PF in the guest. Guest dirty and accessed bits are set as needed in the guest page tables during the walk. Steps 1 and 2 are repeated for each level of the guest page table that is traversed.
3. Once the guest physical address for the guest access has been determined, check the guest permissions; any fault at this point causes a #PF in the guest.
4. Perform the final translation from guest physical to system physical using the nested page table; any fault during this translation results in a #VMEXIT(NPF).

Nested page faults are entirely a function of the nested page table and VMM processor mode. Nested faults cause a #VMEXIT(NPF) to the VMM. The faulting guest physical address is saved in the VMCB's EXITINFO2 field; EXITINFO1 delivers an error code similar to a #PF error code:

- Bit 0 (P)—cleared to 0 if the nested page was not present, 1 otherwise
- Bit 1 (RW)—set to 1 if the nested page table level access was a write. Note that host table walks for guest page tables are always treated as data writes.
- Bit 2 (US)—set to 1 if the nested page table level access was a user access. Note that nested page table accesses performed by the MMU are treated as user accesses unless there are features enabled that override this.
- Bit 3 (RSV)—set to 1 if reserved bits were set in the corresponding nested page table entry
- Bit 4 (ID)—set to 1 if the nested page table level access was a code read. Note that nested table walks for guest page tables are always treated as data writes, even if the access itself is a code read
- Bit 6 (SS) - set to 1 if the fault was caused by a shadow stack access.

In addition, the VMCB contents for nested page faults indicate whether the page fault was encountered during the nested page table walk for a guest page TLB entry, or for the final nested walk for the guest physical address, as indicated by EXITINFO1[33:32]:

- Bit 32—set to 1 if nested page fault occurred while translating the guest's final physical address
- Bit 33—set to 1 if nested page fault occurred while translating the guest page tables
- Bit 37—set to 1 if the page was marked as a supervisor shadow stack page in the leaf node of the nested page table and the shadow stack check feature is enabled in VMCB offset 90h.

Guest faults are entirely a function of the guest page tables and processor mode; they are delivered to the guest as normal #PF exceptions without any VMM intervention, unless the VMM is intercepting guest #PF exceptions. Bits 32 and 33 of EXITINFO1 are written during nested page faults to indicate whether the page fault was encountered during the nested page table walk for a guest page table's table entries, or if the fault was encountered during the nested page table walk for the translation of the final guest physical address.

The processor may provide additional instruction decode assist information. (See section 15.10.)

15.25.7 Combining Nested and Guest Attributes

Any access to guest physical memory is subjected to a permission check by examining the mapping of the guest physical address in the nested page table.

A page is considered writable by the guest only if it is marked writable at both the guest and nested page table levels. Note that the guest's gCR0.WP affects only the interpretation of the guest page table entry; setting gCR0.WP cannot make a page writable at any CPL in the guest, if the page is marked read-only in the nested page table. The host hCR0.WP bit is ignored under nested paging.

A page is considered executable by the guest only if it is marked executable at both the guest and nested page table levels. If the EFER.NXE bit is cleared for the guest, all guest pages are executable at the guest level. Similarly, if the EFER.NXE bit is cleared for the host, all nested page table mappings are executable at the underlying nested level.

Some attributes are taken from the guest page tables and operating modes only. A page is considered global within the guest only if is marked global in the guest page tables; the nested page table entry and host hCR4.PGE are irrelevant. Global pages are only global within their ASID.

A page is considered user in the guest only if it is marked as user at the guest level. The page must be marked user in the nested page table to allow any guest access at all.

15.25.8 Combining Memory Types, MTRRs

When nested paging is disabled, the processor behaves as though there is no gPAT register.

The host PAT MSR determines memory type attributes for the current VM, and guest writes to the PAT MSR that aren't intercepted by the VMM will alter the host PAT MSR. The hypervisor is responsible for context-switching the PAT MSR contents on world switches between VM's.

When nested paging is enabled, the processor combines guest and nested page table memory types. Registers that affect memory types include:

- The PCD/PWT/PAT*i* bits in the nested and guest page table entries.
- The PCD/PWT bits in the nested CR3 and guest CR3 registers.
- The guest PAT type (obtained by appropriately indexing the gPAT register).
- The host PAT type (obtained by appropriately indexing the host’s PAT register).
- The MTRRs (which are referenced based only on system physical address).
- gCR0.CD and hCR0.CD.

Note that there is no hardware support for guest MTRRs; the VMM can simulate their effect by altering the memory types in the nested page tables. Note that the MTRRs are only applied to system physical addresses.

The rules for combining memory types when constructing a guest TLB entry are:

- Nested and guest PAT types are combined according to Table 15-19, producing a “combined PAT type.”
- Combined PAT type is further combined with the MTRR type according to Table 15-20, where the relevant MTRRs are determined by the system physical address.
- Either gCR0.CD or hCR0.CD can disable caching.

Memory Consistency Issues. Because the guest uses extra fields to determine the memory type, the VMM may use a different memory type to access a given piece of memory than does the guest. If one access is cacheable and the other is not, the VMM and guest could observe different memory images, which is undesirable. (MP systems are particularly sensitive to this problem when the VMM desires to migrate a virtual processor from one physical processor to another.)

To address this issue, the following mechanisms are provided:

- VMRUN and #VMEXIT flush the write combiners. This ensures that all writes to WC memory by the guest are visible to the host (or vice-versa) regardless of memory type. (It does not ensure that cacheable writes by one agent are properly observed by WC reads or writes by the other agent.)
- A new memory type *WC+* is introduced. WC+ is an uncacheable memory type, and combines writes in write-combining buffers like WC. Unlike WC (but like the CD memory type), accesses to WC+ memory also snoop the caches on all processors (including self-snooping the caches of the processor issuing the request) to maintain coherency. This ensures that cacheable writes are observed by WC+ accesses.
- When combining nested and guest memory types that are incompatible with respect to caching, the WC+ memory type is used instead of WC (and Table 15-20 ensures that the snooping behavior is retained regardless of the host MTRR settings). Refer to Table 15-19 or details.

Table 15-19 shows how guest and host PAT types are combined into an effective PAT type. When interpreting this table, recall (a) that guest and host PAT types are not combined when nested paging is disabled and (b) that the intent is for the VMM to use its PAT type to simulate guest MTRRs.

Table 15-19. Combining Guest and Host PAT Types

		Host PAT Type					
		UC	**UC–**	**WC**	**WP**	**WT**	**WB**
Guest PAT Type	**UC**	UC	UC	UC	UC	UC	UC
	UC–	UC	UC–	WC	UC	UC	UC
	WC	WC	WC	WC	WC+	WC+	WC+
	WP	UC	UC	UC	WP	UC	WP
	WT	UC	UC	UC	UC	WT	WT
	WB	UC	UC	WC	WP	WT	WB

The existing AMD64 table that defines how PAT types are combined with the physical MTRRs is extended to handle CD and WC+ PAT types as shown in Table 15-20.

Table 15-20. Combining PAT and MTRR Types

		MTRR Type				
		UC	**WC**	**WP**	**WT**	**WB**
Effective PAT Type	**UC**	UC	CD	CD	CD	CD
	UC–	UC	WC	CD	CD	CD
	WC	WC	WC	WC	WC	WC
	WC+	WC	WC	WC+	WC+	WC+
	WP	UC	CD	WP	CD	WP
	WT	UC	CD	CD	WT	WT
	WB	UC	WC	WP	WT	WB

15.25.9 Page Splintering

When an address is mapped by guest and nested page table entries with different page sizes, the TLB entry that is created matches the size of the smaller page.

15.25.10 Legacy PAE Mode

The behavior of PAE mode in a nested-paging guest differs slightly from the behavior of (host-only) legacy PAE mode, in that the guest's four PDPEs are not loaded into the processor at the time CR3 is written. Instead, the PDPEs are accessed on demand as part of a table walk. This has the side-effect that illegal bit combinations in the PDPEs are not signaled at the time that CR3 is written, but instead when the faulty PDPE is accessed as part of a table walk.

This means that an operating system cannot rely on the behavior when the in-memory PDPEs are different than the in-processor copy.

15.25.11 A20 Masking

There is no provision for applying A20 masking to guest physical addresses; the VMM can emulate A20 masking by changing the nested page mappings accordingly.

15.25.12 Detecting Nested Paging Support

Nested Paging is an optional feature of SVM and is not available in all implementations of SVM-capable processors. The CPUID instruction should be used to detect nested paging support on a particular processor. See Section 3.3, "Processor Feature Identification," on page 71 for more information on using the CPUID instruction.

15.25.13 Guest Mode Execute Trap Extension

The Guest Mode Execute Trap (GMET) extension allows a hypervisor to cause nested page faults on attempts by a guest to execute code at CPL0, 1 or 2 from pages designated by the hypervisor. The presence of the GMET extension is indicated by CPUID Fn8000_000A EDX[17]=1. The GMET mode is selected for a targeted guest by setting bit 3 of VMCB offset 090h to 1. For processors that don't support GMET this bit is ignored.

On GMET capable processors, when this bit is set to 1 on a VMRUN, the processor changes how the U/S bit in the nested page table is interpreted. The NX bit still prohibits execution of code at any privilege level when set to 1. However, with GMET enabled and the effective NX bit =0, if the effective U/S bit =1 and the page is being accessed for execution at CPL0, 1 or 2, a nested page fault #VMEXIT(NPF) is generated. If the effective NX bit =0 and the effective U/S bit =0 then the

translation is allowed for the code page. The following table summarizes the behavior when GMET is enabled.

Table 15-21. GMET Page Configuration

nPT NX Bit	nPT U/S Bit	Guest User-Mode Code	Guest Supervisor-Mode Code
1	X	No Execute	No Execute
0	1	Execute	No Execute
0	0	Execute	Execute

The EXITINFO1 field for the nested page fault contains the page fault error code describing attributes of the attempted translation that caused the fault. A GMET violation is not explicitly indicated with a separate bit. It is up to software to determine if it was NX based or GMET based by inspecting this error code along with the faulting page's effective NX and U/S settings.[1]

15.25.14 Supervisor Shadow Stacks

The Supervisor Shadow Stack (SSS) feature is an extension to nested paging which allows a hypervisor to restrict which guest physical addresses may be used for a guest supervisor shadow stack. Supervisor shadow stack accesses made by the guest to pages not designated as SSS pages in the nested page tables result in a #VMEXIT(NPF).

Determining Support for SSS. Support for the SSS feature is indicated CPUID Fn8008_000A_EDX[19](SupervisorShadowStack)=1.

Enabling SSS. The SSS feature is enabled by setting bit 4 in VMCB offset 90h (See Table B-1. VMCB Layout, Control Area). The SSS feature can be enabled only if nested paging is enabled in the VMCB and the PAE and No Execute paging modes (EFER.NXE=1) are enabled in the host.

- Attempting to execute a VMRUN with SSS enabled and nested paging disable result in a VMEXIT(INVALID).
- If the host is not legacy non-PAE mode or EFER.NXE=0, attempts to enable the SSS feature are silently ignored.

The SSS feature can be enabled regardless of whether the guest has enabled shadow stacks or not.

Designating SSS Pages. When the SSS feature is enabled, the hypervisor indicates a page may be used for a supervisor shadow stack using following combination of nested page table bits:

- NX=1 and U/S=0 in the final nested page table entry used to translate the address.
- R/W=1 in all other nested non-leaf page table entries leading to the final nested page table entry.

Although is not enforced by the SSS feature, R/W should be 0 in the final nested page table entry in order to achieve the desired security functionality.

[1] The guest user/supervisor indication is normally provided in ExitInfo1, however on some implementations a GMET erratum may require CPL to be read from the guest VMCB.

SSS Access Checking. When the SSS feature is enabled, guest supervisor shadow stack accesses are allowed only to physical pages designated as SSS pages in the nested page tables. Note that supervisor shadow stack writes to SSS pages are allowed to complete even though R/W=0 in the final nested page table entry.

The following accesses to SSS pages are not allowed:

- Supervisor shadow accesses made to non-SSS pages. These result in a #VMEXIT(NPF) with the SS bit set in the EXITINFO1 error code.
- Attempting to execute code from an SSS page. This results in a VMEXIT(#NPF) the same as any page with NX=1.

See Chapter 15.25.6, “Nested versus Guest Page Faults, Fault Ordering,” on page 534 for more information on EXITINFO1 error codes for nested page faults.

15.26 Security

SVM provides additional hardware support that is designed to facilitate the construction of trusted software systems. While the security features described in this section are orthogonal to SVM’s virtualization support (and are not required for processor virtualization), the two form building blocks for trusted systems.

SKINIT Instruction. The SKINIT instruction and associated system support (the Trusted Platform Module or TPM) are designed to allow for verifiable startup of trusted software (such as a VMM), based on secure hash comparison.

Security Exception. A security exception (#SX) is used to signal certain security-critical events.

15.27 Secure Startup with SKINIT

The SKINIT instruction is one of the keys to creating a “root of trust” starting with an initially untrusted operating mode. SKINIT reinitializes the processor to establish a secure execution environment for a software component called the secure loader (SL) and starts execution of the SL in a way that cannot be tampered with. SKINIT also copies the secure loader executable image to an external device, such as a Trusted Platform Module (TPM) for verification using unique bus transactions that preclude SKINIT operation from being emulated by software in a way that the TPM could not readily detect. (Detailed operation is described in Section 15.27.4.)

15.27.1 Secure Loader

A secure loader (SL) typically initializes SVM hardware mechanisms and related data structures, and initiates execution of a trusted piece of software such as a VMM (referred to as a Security Kernel, or SK, in this document), after first having validated the identity of that software.

SKINIT allows SVM protections to be reliably enabled after the system is already up and running in a non-trusted mode — there is no requirement to change the typical x86 platform boot process.

Exact details of the handoff from the SL to an SK are dependent on characteristics of the SL, SK and the initial untrusted operating environment. However, there are specific requirements for the SL image, as described in Section 15.27.2.

15.27.2 Secure Loader Image

The secure loader (SL) image contains all code and initialized data sections of a secure loader. This code and initial data are used to initialize and start a security kernel in a completely safe manner, including setting up DEV protection for memory allocated for use by SL and SK. The SL image is loaded into a region of memory called the secure loader block (SLB) and can be no larger than 64Kbyte (see Section 15.27.3). The SL image is defined to start at byte offset 0 in the SLB.

The first word (16 bits) of the SL image must specify the SL entry point as an unsigned offset into the SL image. The second word must contain the length of the image in bytes; the maximum length allowed is 65535 bytes. These two values are used by the SKINIT instruction. The layout of the rest of the image is determined by software conventions. The image typically includes a digital signature for validation purposes. The digital signature hash must include the entry point and length fields. SKINIT transfers the SL image to the TPM for validation prior to starting SL execution (see Section 15.27.6 for further details of this transfer). The SL image for which the hash is computed must be ready to execute without prior manipulation.

15.27.3 Secure Loader Block

The secure loader block is a 64Kbyte range of physical memory which may be located at any 64Kbyte-aligned address below 4Gbyte. The SL image must have been loaded into the SLB starting at offset 0 before executing SKINIT. The physical address of the SLB is provided as an input operand (in the EAX register) to SKINIT, which sets up special protection for the SLB against device accesses (i.e., the DEV need not be activated yet).

The SL must be written to execute initially in flat 32-bit protected mode with paging disabled. A base address can be derived from the value in EAX to access data areas within the SL image using base+displacement addressing, to make the SL code position-independent.

Memory between the end of the SL image and the end of the SLB may be used immediately upon entry by the SL as secure scratch space, such as for an initial stack, before DEV protections are set up for the rest of memory. The amount of space required for this will limit the maximum size of the SL image, and will depend on SL implementation. SKINIT sets the ESP register to the appropriate top-of-stack value (EAX + 10000h).

Figure 15-14 illustrates the layout of the SLB, showing where EAX and ESP point after SKINIT execution. Labels in italics indicate suggested uses; other labels reflect required items.

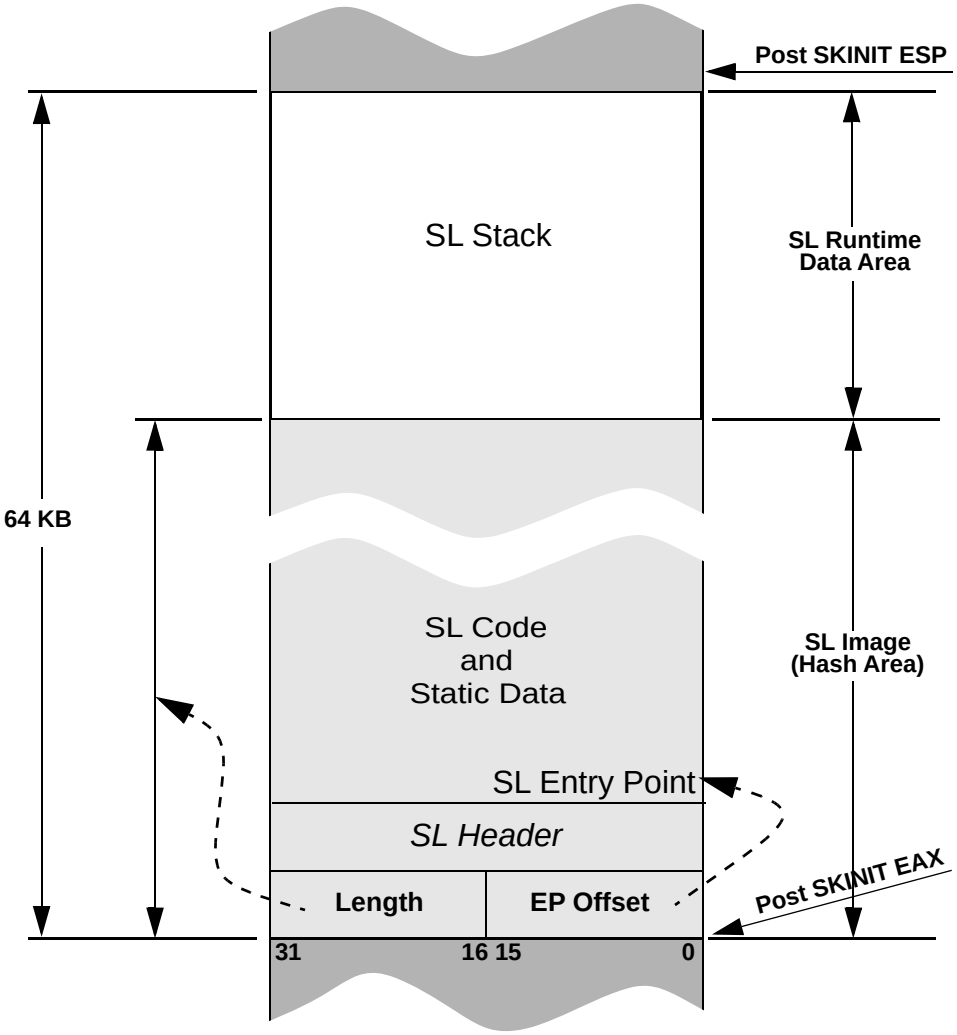

Figure 15-14. SLB Example Layout

15.27.4 Trusted Platform Module

The trusted platform module, or TPM, is an essential part of full trusted system initialization. This device is attached to an LPC link off the system I/O hub. It recognizes special SKINIT transactions, receives the SL image sent by SKINIT and verifies the signature. Based on the outcome, the device decides whether or not to cooperate with the SL or subsequent SK. The TPM typically contains sealed storage containing cryptographic keys and other high-security information that may be specific to the platform.

15.27.5 System Interface, Memory Controller and I/O Hub Logic

SKINIT uses special support logic in the processor's system interface unit, the internal controller and the I/O hub to which the TPM is attached. SKINIT uses special transactions that are unique to SKINIT, along with this support logic, designed to securely transmit the SL Image to the TPM for validation.

The use of this special protocol is intended to allow the TPM to detect true execution, as opposed to emulation, of a trusted Secure Loader, which in turn provides a means for verifying the subsequent loading and startup of a trusted Security Kernel.

15.27.6 SKINIT Operation

The SKINIT instruction is intended to be used primarily in normal mode prior to the VMM taking control.

SKINIT takes the physical base address of the SLB as its only input operand in EAX, and performs the following steps:

1. Reinitialize processor state in the same manner as for the INIT signal, then enter flat 32-bit protected mode with paging off. The CS selector is set to 8h and CS is read only. The SS selector is set to 10h and SS is read/write and expand-up. The CS and SS bases are cleared to 0 and limits are set to 4G. DS, ES, FS and GS are left as 16-bit real mode segments and the SL must reload these with protected mode selectors having appropriate GDT entries before using them. Initialized data in the SLB may be referenced using the SS segment override prefix until DS is reloaded. The general purpose registers are cleared except for EAX, which points to the start of the secure loader, EDX, which contains model, family and stepping information, and ESP, which contains the initial stack pointer for the secure loader. Cache contents remain intact, as do the x87 and SSE control registers. Most MSRs also retain their values, except those which might compromise SVM protections. The EFER MSR, however, is cleared. The DPD, R_INIT and DIS_A20M flags in the VM_CR register are unconditionally set to 1.
2. Form the SLB base address by clearing bits 15:0 of EAX (EAX is updated), and enable the SL_DEV protection mechanism (see Section 15.24.8) to protect the 64-Kbyte region of physical memory starting at the SLB base address from any device access.
3. In multiprocessor operation, perform an interprocessor handshake as described in section 15.27.8.
4. Read the SL image from memory and transmit it to the TPM in a manner that cannot be emulated by software.
5. Signal the TPM to complete the hash and verify the signature. If any failures have occurred along the way, the TPM will conclude that no valid SL was started.
6. Clear the Global Interrupt Flag. This disables all interrupts, including NMI, SMI and INIT and ensures that the subsequent code can execute atomically. If the processor enters the shutdown state (due to a triple fault for instance) while GIF is clear, it can only be restarted by means of a RESET.
7. Update the ESP register to point to the first byte beyond the end of the SLB (SLB base + 65536), so that the first item pushed onto the stack by the SL will be at the top of the SLB.

8. Add the unsigned 16-bit entry point offset value from the SLB to the SLB base address to form the SL entry point address, and jump to it.

The validation of the SL image by the TPM is a one-way transaction as far as SKINIT is concerned. It does not depend on any response from the TPM after transferring the SL image before jumping to the SL entry point, and initiates execution of the Secure Loader unconditionally. Because of the processor initialization performed, SKINIT does not honor instruction or data breakpoint traps, or trace traps due to EFLAGS.TF.

Pending interrupts. Device interrupts that may be pending prior to SKINIT execution due to EFLAGS.IF being clear, or that assert during the execution of SKINIT, will be held pending until software subsequently sets GIF to 1. Similarly, SMI, INIT and NMI interrupts that assert after the start of SKINIT execution will also be held pending until GIF is set to 1.

Debug Considerations. SKINIT automatically disables various implementation-specific hardware debug features. A debug version of the SL can reenable those features by clearing the VM_CR.DPD flag immediately upon entry.

15.27.7 SL Abort

If the SL determines that it cannot properly initialize a valid SK, it must cause GIF to be set to 1 and clear the VM_CR MSR to re-enable normal processor operation.

15.27.8 Secure Multiprocessor Initialization

The following standard APIC features are used for secure MP initialization:

- The concept of a single Bootstrap Processor (BSP) and multiple Application Processors (APs).
- The INIT interprocessor interrupt (IPI), which puts the target processors into a halted state (INIT state) which is responsive only to a subsequent Startup IPI.
- The Startup IPI causes target processors to begin execution at a location in memory that is specified by the Boot Processor and conveyed along with the Startup IPI. The operation of the processor in response to a Startup IPI is slightly modified to support secure initialization, as described below.

A Startup IPI normally causes an AP to start execution at a location provided by the IPI. To support secure MP startup, each AP responds to a startup IPI by additionally clearing its GIF and setting the DPD, R_INIT and DIS_A20M flags in the VM_CR register if, and only if, the BSP has indicated that it has executed an SKINIT. All other aspects of Startup IPI behavior remain unchanged.

Software Requirements for Secure MP initialization. The driver that starts the SL must execute on the BSP. Prior to executing the SKINIT instruction, the driver must save any processor-specific system register contents to memory for restoration after reinitialization of the APs. The driver should also put all APs in an idle state. The driver must first confirmed that all APs are idle and then it must issue an INIT IPI to all APs and wait for its local APIC busy indication to clear. This places the APs into a halted state which is responsive only to a subsequent Startup IPI. APs will still respond to snoops for cache coherency. The driver may execute SKINIT at any time after this point. Depending on processor

implementation, a fixed delay of no more than 1000 processor cycles may be necessary before executing SKINIT to ensure reliable sensing of APIC INIT state by the SKINIT.

AP Startup Sequence. While the SL starts executing on the BSP, the APs remain halted in APIC INIT state. Either the SL or the SK may issue the Startup IPI for the APs at whatever point is deemed appropriate. The Startup IPI conveys an 8-bit vector specified by the software that issues the IPI to the APs. This vector provides the upper 8 bits of a 20-bit physical address. Therefore, the AP startup code must reside in the lower 1Mbyte of physical memory—with the entry point at offset 0 on that particular page.

In response to the Startup IPI, the APs start executing at the specified location in 16-bit real mode. This AP startup code must set up protections on each processor as determined by the SL or SK. It must also set GIF to re-enable interrupts, and restore the pre-SKINIT system context (as directed by the SL or SK executing on the BSP), before resuming normal system operation.

The SL must ensure the integrity of the AP startup sequence, for example by including the startup code in the hashed SL image and setting up DEV protection for it before copying it to the desired area. The AP startup code does not need to (and should not) execute SKINIT. Care must also be taken to avoid issuing another INIT IPI from any processor after the BSP executes SKINIT and before all APs have received a Startup IPI, as this could compromise the integrity of AP initialization.

Pending interrupts. Device interrupts that may be pending on an AP prior to the APIC INIT IPI due to EFLAGS.IF being clear, or that assert any time after the processor has accepted the INIT IPI, will be held pending through the subsequent Startup IPI, and remain pending until software sets GIF to 1 on that AP. Similarly, SMI, INIT, and NMI interrupts that assert after the processor has accepted the INIT IPI will also be held pending until GIF is set to 1.

Aborting MP initialization. In the event that the SL or SK on the BSP decides to abort SVM system initialization for any reason, the following clean-up actions must be performed by SL code executing on each processor before returning control to the original operating environment:

- The BSP and all APs that responded to the Startup IPI must restore GIF and clear VM_CR on each processor for normal operation.
- For each processor that has a distinct memory controller associated with it, the SL_DEV_EN flag in the DEV control register must be cleared in order to restore normal device accessibility to the 64KB SL memory range.

Any secure context created by the SL that should not be exposed to untrusted code should be cleaned up as appropriate before these steps are taken.

15.28 Security Exception (#SX)

The Security Exception fault signals security-sensitive events that occur while executing the VMM, in the form of an exception so that the VMM may take appropriate action. (A VMM would typically intercept comparable sensitive events in the guest.) Currently, the only use of the #SX is to redirect external INITs into an exception so that the VMM may — among other possibilities — destroy

sensitive information before re-issuing the INIT, this time without redirection. The INIT redirection is controlled by the VM_CR.R_INIT bit. (See “INIT Support” on page 520 for more details on INIT and #SX behavior). Note that INIT is gated by the Global Interrupt Flag (GIF), and so will be held pending if asserted while GIF is 0. When GIF transitions to 1, INIT will either take effect or be redirected to #SX, depending on the state of R_INIT.

The #SX exception dispatches to vector 30, and behaves like other fault-class exceptions such as General Protection Fault (#GP). The #SX exception pushes an error code. The only error code currently defined is 1, and indicates redirection of INIT has occurred.

The #SX exception is a contributory fault.

15.29 Advanced Virtual Interrupt Controller

The AMD Advanced Virtual Interrupt Controller (AVIC) is an important enhancement to AMD Virtualization™ Technology (AMD-V). In a virtualized environment, AVIC presents to each guest a virtual interrupt controller that is compliant with the local Advanced Programmable Interrupt Controller (APIC) architecture. See Chapter 16, “Advanced Programmable Interrupt Controller (APIC),” on page 601 for a detailed description of APIC.

15.29.1 Introduction

In a virtualized computer system, each guest operating system needs access to an interrupt controller to send and receive device and interprocessor interrupts. When there is no hardware acceleration, it falls to the virtual machine monitor (VMM) to intercept guest-initiated attempts to access the interrupt controller registers and provide direct emulation of the controller system programming interface allowing the guest to initiate and process interrupts. The VMM uses the underlying physical and virtual interrupt delivery mechanisms of the system to deliver interrupts from I/O devices and virtual processors to the target guest virtual processor and to handle any required end of interrupt processing.

Given the high rate of device and interprocessor interrupt generation in certain scenarios, in particular on server-class systems, the emulation of a local APIC can be a significant burden for the VMM. The AVIC architecture addresses the overhead of guest interrupt processing in a virtualized environment by applying hardware acceleration to the following components of interrupt processing:

- Providing a guest operating system access to performance-critical interrupt controller registers
- Initiating intra- and inter-processor interrupts (IPIs) in and between virtual processors in a guest

Software-initiated Interrupts. Modern operating systems use software interrupts (self-IPIs) to implement software event signalling, inter-process communication and the scheduling of deferred processing. System software sets up and initiates these interrupts by writing to control registers of the local APIC. AVIC hardware reduces VMM overhead by providing hardware assist for many of these operations.

Inter-processor Interrupts. Inter-processor interrupts (IPIs) are used extensively by modern operating systems to handle communication between processor cores within a machine (or, in a

virtualized environment, between virtual processors within a virtual machine). IPIs are also employed to provide signaling and synchronization for operations such as cross-processor TLB invalidations (also known as TLB shootdowns). AVIC provides hardware mechanisms that deliver the interrupt to the virtual interrupt controller of the target virtual processor without VMM intervention.

Device Interrupts. Acceleration of the delivery of virtual interrupts from I/O devices to virtual processors is not addressed directly by AVIC hardware. This acceleration would be provided by an I/O memory management unit (IOMMU). The AVIC architecture is compatible with the AMD I/O Memory Management Unit (IOMMU). For more information on the IOMMU architecture, see *AMD I/O Virtualization Technology (IOMMU) Specification* (order #48882). See “Device Interrupts” on page 561 for further details of device interrupt handling under the AVIC extension.

The following subsections describe the AVIC architecture in detail.

15.29.2 Local APIC Register Virtualization

The system programming interface for the local APIC comprises a set of memory-mapped registers. In a non-virtualized environment, system software directly reads and writes these registers to configure the interrupt controller and initiate and process interrupts. In a virtualized environment, each guest operating system still requires access to this system programming interface but does not own the underlying interrupt processing hardware. To provide this facility to the guest operating system, VMM-level software emulates the local APIC for each guest virtual processor.

The AVIC architecture provides an image of the local APIC called the guest virtual APIC (guest vAPIC) in the guest physical address (GPA) space of each virtual processor when the virtual machine for the guest is instantiated. This image is backed by a page in the system physical address (SPA) space called a vAPIC backing page. The backing page remains pinned in system memory as long as the virtual machine persists, even when the specific virtual processor associated with the backing page is not running. Accesses to the memory-mapped register set by the guest are redirected by AVIC hardware to this backing page.

The VMM reads configuration, control, and command information written by the guest from the backing page and writes status information to this page for the guest to read. The guest is allowed to read most registers directly without the need for VMM intervention. Most writes are intercepted allowing the VMM to process and act on the configuration, control, and command data from the guest. However, for certain frequently used command and control operations, specific hardware support allows the guest to directly initiate interrupts and complete end of interrupt processing, eliminating the need for VMM intervention in the execution of performance-critical operations.

15.29.3 AVIC Backing Page

AVIC hardware detects attempted accesses by the guest to its local APIC register set and redirects these accesses to the vAPIC backing page. This is illustrated in the figure below.

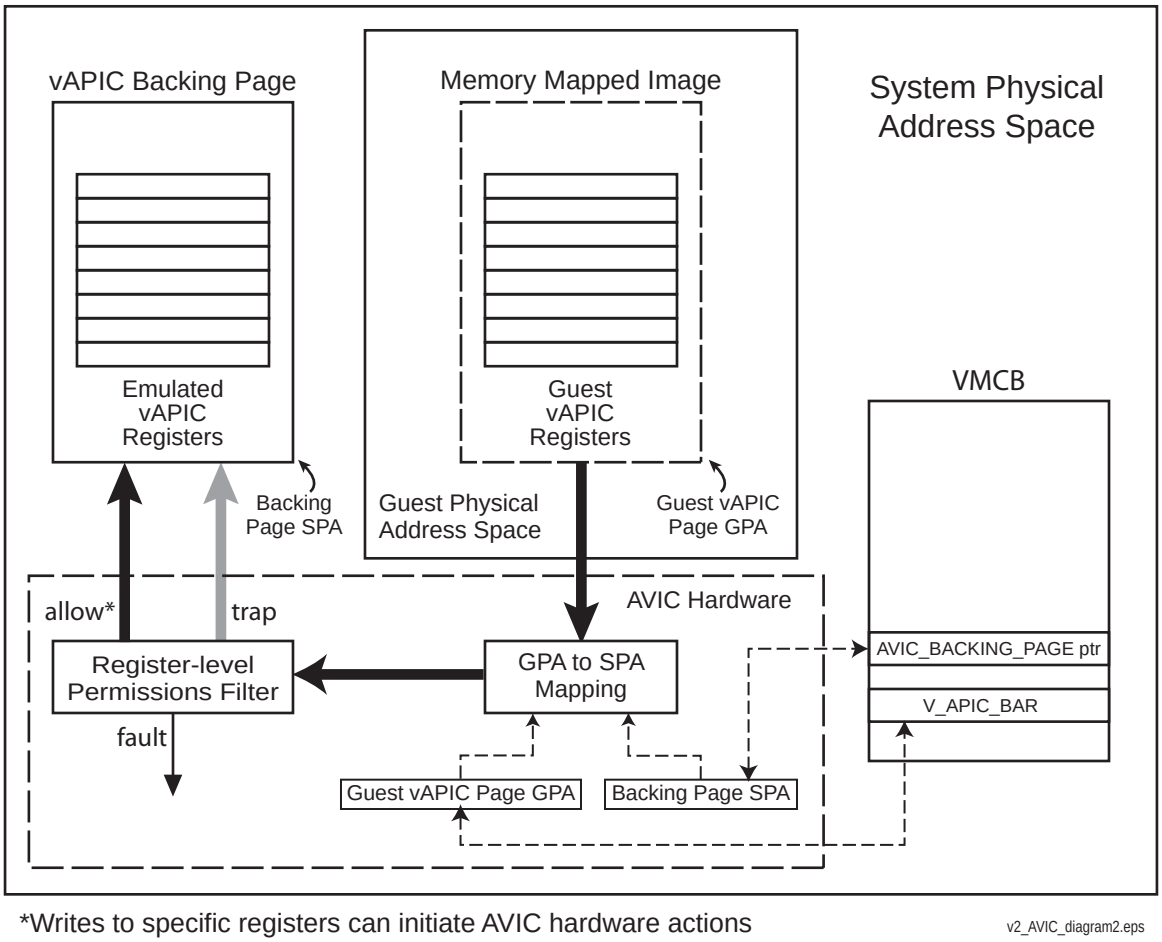

Figure 15-15. vAPIC Backing Page Access

To correctly redirect guest accesses of the guest vAPIC registers to the vAPIC backing page, the hardware needs two addresses. These are:

- vAPIC backing page address in the SPA space
- Guest vAPIC base address (APIC BAR) in the GPA space

System software is responsible for setting up a translation in the nested page table granting guest read and write permissions for accesses to the vAPIC Backing Page in SPA space. AVIC hardware walks the nested page table to check permissions, but does not use the SPA address specified in the leaf page table entry. Instead, AVIC hardware finds this address in the AVIC_BACKING_PAGE pointer field of the VMCB.

The VMM initializes the backing page with appropriate default APIC register values including items such as APIC version number. The vAPIC backing page address and the guest vAPIC base address are stored in the VMCB fields AVIC_BACKING_PAGE pointer and V_APIC_BAR respectively.

System firmware initializes the value of guest vAPIC base address (and VMCB.V_APIC_BAR) to FEE0_0000h. This is the address where the guest operating system expects to find the local APIC register set when it boots. If the guest attempts to relocate the local APIC register base address in GPA space by writing to the APIC Base Address Register (MSR 0000_001Bh), the VMM should intercept the write to update the V_APIC_BAR field of the guest's VMCB(s) and the GPA part of translation in the virtual machine's nested page tables.

The vAPIC backing page must be present in system physical memory for the life of the guest VM because some fields are updated even when the guest is not running.

15.29.3.1 Virtual APIC Register Accesses

AVIC hardware detects attempted guest accesses to the vAPIC registers in the backing page. These attempted accesses are handled by the register-level permissions filter in one of three ways:

- Allow—The access to the backing page is allowed to complete. Writes update the backing page value, while reads return the current value. In certain cases, a write results in specific hardware-based acceleration actions (summarized in Table 15-22 and described below).
- Fault—The processor performs an SVM intercept before the access. Causes a #VMEXIT.
- Trap— The processor performs an SVM intercept immediately after the access completes. Causes a #VMEXIT.

The details of this behavior for each of these registers are summarized in the following table:

Table 15-22. Guest vAPIC Register Access Behavior

Offset	Register Name	Result
20h	APIC ID Register	Read: Allowed Write: #VMEXIT (trap)
30h	APIC Version Register	Read: Allowed Write: #VMEXIT (fault)
80h	Task Priority Register (TPR)	Read: Allowed Write: Accelerated by AVIC
90h	Arbitration Priority Register (APR)	Read: #VMEXIT (fault) Write: #VMEXIT (fault)
A0h	Processor Priority Register (PPR)	Read: Allowed Write: #VMEXIT (fault)
B0h	End of Interrupt Register (EOI)	Read: Allowed Write: Accelerated by AVIC for edge-triggered interrupts or #VMEXIT (trap) for level triggered interrupts
C0h	Remote Read Register	Read: Allowed Write: #VMEXIT (trap)
D0h	Logical Destination Register	Read: Allowed Write: #VMEXIT (trap)
E0h	Destination Format Register	Read: Allowed Write: #VMEXIT (trap)

Table 15-22. Guest vAPIC Register Access Behavior (continued)

Offset	Register Name	Result
F0h	Spurious Interrupt Vector Register	Read: Allowed Write: #VMEXIT (trap)
100h–170h	In-Service Register (ISR)	Read: Allowed Write: #VMEXIT (fault)
180h–1F0h	Trigger Mode Register (TMR)	Read: Allowed Write: #VMEXIT (fault)
200h–270h	Interrupt Request Register (IRR)	Read: Allowed Write: #VMEXIT (fault)
280h	Error Status Register (ESR)	Read: Allowed Write: #VMEXIT (trap)
300h	Interrupt Command Register Low (bits 31:0)	Read: Allowed Write: Accelerated by AVIC or #VMEXIT (trap) for advanced functions.
310h	Interrupt Command Register High (bits 63:32)	Read: Allowed Write: Allowed
320h	Timer Local Vector Table Entry	Read: Allowed Write: #VMEXIT (trap)
330h	Thermal Local Vector Table Entry	Read: Allowed Write: #VMEXIT (trap)
340h	Performance Counter Local Vector Table Entry	Read: Allowed Write: #VMEXIT (trap)
350h	Local Interrupt 0 Vector Table Entry	Read: Allowed Write: #VMEXIT (trap)
360h	Local Interrupt 1 Vector Table Entry	Read: Allowed Write: #VMEXIT (trap)
370h	Error Vector Table Entry	Read: Allowed Write: #VMEXIT (trap)
380h	Timer Initial Count Register	Read: Allowed Write: #VMEXIT (trap)
390h	Timer Current Count Register	Read: #VMEXIT (fault) Write: #VMEXIT (fault)
3E0h	Timer Divide Configuration Register	Read: Allowed Write: #VMEXIT (trap)
400h–FFFh	Extended Registers	Read: #VMEXIT (fault) Write: #VMEXIT (fault)

Accesses to any other register locations not explicitly defined in this table are allowed to read and write the backing page.

All vAPIC registers are 32-bits wide and are located at 16-byte aligned offsets. The results of an attempted read or write of any bytes in the range [register_offset + 4:register_offset + 15] are undefined.

Guest writes to the Task Priority Register (TPR) and specific usage cases of writes to the End of Interrupt (EOI) Register and the Interrupt Command Register Low (ICRL) cause specific hardware actions. AVIC hardware allows guest writes to the Interrupt Command Register High (ICRH) since the writing of this register has no immediate hardware side-effect. AVIC hardware maintains and uses the value in the Processor Priority Register (PPR) to control the delivery of interrupts to guest virtual processors. The following sections discuss the handling of accesses by the guest to these registers in the vAPIC backing page.

Task Priority Register (TPR). When the guest operating system writes to the TPR, the value is updated in the backing page and the upper 4 bits of the value are automatically copied by the hardware to the V_TPR value in the VMCB. All reads from the TPR location return the value from the vAPIC backing page. Also, any TPR accesses using the MOV CR8 semantics update the backing page and V_TPR values.

The priority value stored in CR8 and V_TPR are not the same format as the APIC TPR register. Only the Task Priority bits of are maintained in the lower 4 bits of CR8 and V_TPR. The Task Priority Sub-class value is not stored. Writes to the memory-mapped TPR register update bits 3:0 of CR8 and V_TPR and writes to CR8 update the TPR backing page value bits 7:4 while bits 3:0 are set to zero.

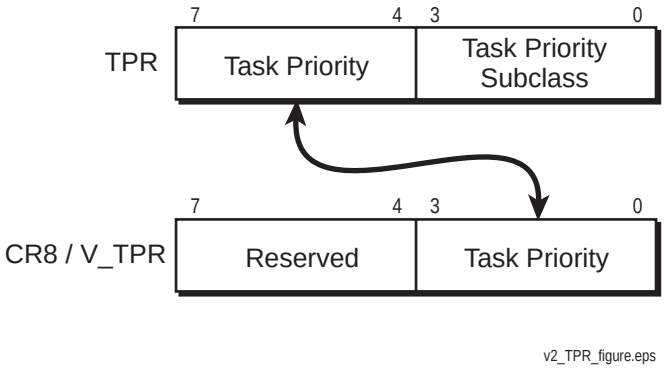

Figure 15-16. Virtual APIC Task Priority Register Synchronization

The synchronization between the Task Priority field of the TPR and the Task Priority field of CR8 is normal local APIC behavior which is emulated by AVIC. For more information on the APIC, see Chapter 16, “Advanced Programmable Interrupt Controller (APIC),” on page 601.

Processor Priority Register (PPR). Writes to the processor priority register by the guest cause a #VMEXIT without updating the value in the backing page. AVIC hardware maintains the PPR value in the backing page. AVIC hardware updates the PPR value in the backing page when either the TPR value or the highest in-service interrupt changes. This value is used to control the delivery of virtual interrupts to the guest. PPR reads by the guest are allowed.

End of Interrupt (EOI) Register. When the guest writes to the EOI register address, AVIC hardware clears the highest priority in-service interrupt (ISR) bit in the backing page and re-evaluates the interrupt state to determine if another pending interrupt should be delivered. If the highest priority in-service interrupt is set to level mode (in the corresponding TMR bit), the EOI write causes a #VMEXIT to allow the VMM to emulate the level-triggered behavior.

Interrupt Command Register Low (ICRL). Writes to the ICRL register have the side-effect of initiating the generation of an interprocessor interrupt (IPI) based on the values written to the fields in both the ICRL and ICRH registers. AVIC hardware handles the generation of IPIs when the specified Message Type is Fixed (also known as fixed delivery mode) and the Trigger Mode is edge-triggered. The hardware also supports self and broadcast delivery modes specified via the Destination Shorthand (DSH) field of the ICRL. Logical and physical APIC ID formats are supported. All other IPI types cause a #VMEXIT. For more information on AVIC's handling of IPI commands, see "Inter-processor Interrupts" on page 546.

15.29.4 VMCB Changes in Support of AVIC

The following paragraphs provide an overview of new VMCB fields defined as part of the AVIC architecture.

15.29.4.1 VMCB Control Word

AVIC adds the AVIC Enable bit to the VMCB control word at offset 60h:

Table 15-23. Virtual Interrupt Control (VMCB offset 60h)

VMCB offset	Bit(s)	Field Name	Description
060h	7:0	V_TPR	Virtual TPR for the guest [1] [2]
	8	V_IRQ	If nonzero; virtual INTR is pending [2] [3]
	15:9	—	Reserved, SBZ
	19:16	V_INTR_PRIO	Priority for virtual interrupt[3]
	20	V_IGN_TPR	If nonzero, the current virtual interrupt ignores the virtual TPR[3]
	23:21	—	Reserved, SBZ
	24	V_INTR_MASKING	Virtualized masking of INTR interrupts
	25	—	Reserved, SBZ
	31	AVIC Enable	If set, enables AVIC
	39:32	V_INTR_VECTOR	Vector to use for this interrupt[3]
	63:40	—	Reserved, SBZ

Note(s):
1. *Bits 3:0 are used for the 4-bit virtual TPR value; bits 7:4 are Reserved, SBZ.*
2. *This value is written back to the VMCB at #VMEXIT.*
3. *This field is ignored on VMRUN when AVIC is enabled.*

AVIC Enable—Virtual Interrupt Control, Bit 31. The AVIC hardware support may be enabled on a per virtual processor basis. This bit determines whether or not AVIC is enabled for a particular virtual processor. Any guest configured to use AVIC must also enable RVI (nested paging). Enabling AVIC implicitly disables the V_IRQ, V_INTR_PRIO, V_IGN_TPR, and V_INTR_VECTOR fields in the VMCB Control Word. Enabling AVIC also affects CR8 behavior independent of V_INTR_MASKING enable (bit 24): writes to CR8 affect the V_TPR and update the backing page and reads from CR8 return V_TPR.

15.29.4.2 Newly Defined VMCB Fields

AVIC utilizes a number of formerly reserved locations in the VMCB. Table 15-24 below lists the new fields defined by the architecture:

Table 15-24. New VMCB Fields Defined by AVIC

VMCB Offset	Bit(s)	Field Name	Description
098h	63:52	Reserved, SBZ	—
	51:12	V_APIC_BAR	Bits 51:12 of the GPA of the guest vAPIC register bank
	11:0	Reserved, SBZ	—
0E0h	63:52	Reserved, SBZ	—
	51:12	AVIC_BACKING_PAGE Pointer	Bits 51:12 of HPA of the vAPIC backing page
	11:0	Reserved, SBZ	—
0F0h	63:52	Reserved, SBZ	—
	51:12	AVIC_LOGICAL_TABLE Pointer	Bits 51:12 of HPA of the Logical APIC Table
	11:0	Reserved, SBZ	—
0F8h	63:52	Reserved, SBZ	—
	51:12	AVIC_PHYSICAL_TABLE Pointer	Bits 51:12 of HPA for the Physical APIC Table
	11:8	Reserved, SBZ	—
	7:0	AVIC_PHYSICAL_MAX_INDEX	Index of the last guest physical core ID for this guest

These fields are discussed further in the following paragraphs:

V_APIC_BAR—VMCB, Offset 098h. This entry is used to hold a copy of guest physical base address of its local APIC register block. The guest can change the GPA of its local APIC register block by writing to the guest version of the APIC Base Address Register (MSR 0000_001Bh). Writes to this MSR are intercepted by the VMM and the value is used to update the GPA in the nested page table entry for the vAPIC backing page and the value to be saved in this field of the VMCB.

APIC_BACKING_Page Pointer—VMCB, Offset 0E0h. This is a 52-bit HPA pointer to the vAPIC backing page for this virtual processor. The vAPIC backing page is described in more detail in the following section.

Logical APIC Table Pointer—VMCB, Offset 0F0h. This is a 52-bit HPA pointer to the Logical APIC ID Table for the virtual machine containing this virtual processor. This table is described in more detail in the following section.

Physical APIC Table Pointer—VMCB, Offset 0F8h. This is a 52-bit HPA pointer to the Physical APIC ID Table for the virtual machine containing this virtual processor. This table is described in more detail in the following section.

AVIC_PHYSICAL_MAX_INDEX—VMCB, Offset 0F8h. Bits [7:0]. This 8-bit value provides the index of the last guest physical core ID for this guest.

15.29.4.3 Restrictions on Physical Address Pointers

All of the physical addresses in the previous sections must point to legal, implementation-supported physical address ranges. These pointers are evaluated on VMRUN and cause a #VMEXIT if they are outside of the legal range. These memory ranges must be mapped as write-back cacheable memory type.

All the addresses point to 4-Kbyte aligned data structures. Bits 11:0 are reserved (except for offset 0F8h) and should be set to zero. The lower 8 bits of offset 0F8h are used for the field AVIC_PHYSICAL_MAX_INDEX.

Multiprocessor VM requirements. When running a VM which has multiple virtual CPUs, and the VMM runs a virtual CPU on a core which had last run a different virtual CPU from the same VM, regardless of the respective ASID values, care must be taken to flush the TLB on the VMRUN using a TLB_CONTROL value of 3h. Failure to do so may result in stale mappings misdirecting virtual APIC accesses to the previous virtual CPU's APIC backing page.

15.29.5 AVIC Memory Data Structures

The AVIC architecture defines three new memory-resident data structures. Each of these structures is defined to fit exactly in one 4-Kbyte page. Future implementations may expand the size.

15.29.5.1 Virtual APIC Backing Page

Each virtual processor in the system is assigned a virtual APIC backing page (vAPIC backing page). Accesses by the guest to the local APIC register block in the guest physical address space are redirected to the vAPIC backing page in system memory. The vAPIC backing page is used by AVIC hardware and the VMM to emulate the local APIC. See “Virtual APIC Register Accesses” on page 549 for a detailed description.

15.29.5.2 Physical APIC ID Table

The physical APIC ID table is set up and maintained by the VMM and is used by the hardware to locate the proper vAPIC backing page to be used to deliver interrupts based on the guest physical APIC ID. One physical APIC ID table must be provided per virtual machine.

The guest physical APIC ID is used as an index into this table. Each entry contains a pointer to the virtual processor's vAPIC backing page, a bit to indicate whether the virtual processor is currently scheduled on a physical core, and if so, the physical APIC ID of that core.

The length of this table is fixed at 4 Kbytes allowing a maximum of 512 virtual processors per virtual machine. However, in this version of the architecture the maximum number of virtual processors per guest is limited to 256. The physical ID table can be populated in a sparse manner using the valid bit to indicate assigned IDs. The index of the last valid entry is stored in the VMCB AVIC_PHYSICAL_MAX_INDEX field.

A pointer to this table is maintained in the VMCB. Because there is a single Physical APIC ID Table per virtual machine, the value of this pointer is the same for every virtual processor within the virtual machine.

Each entry in the table has the following format:

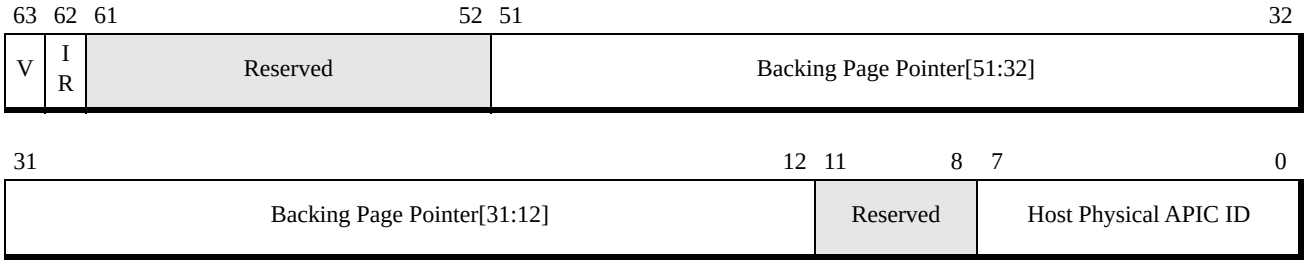

Figure 15-17. Physical APIC ID Table Entry

Table 15-25. Physical APIC ID Table Entry Fields

Bit(s)	Field Name	Description
63	V	Valid bit. When set, indicates that this entry contains a valid vAPIC backing page pointer. If cleared, this table entry contains no information.
62	IR	IsRunning. This bit indicates that the corresponding guest virtual processor is currently scheduled by the VMM to run on a physical core.
61:52	—	Reserved, SBZ. Should always be set to zero.
51:12	Backing Page Pointer	4-Kbyte aligned HPA of the vAPIC backing page for this virtual processor.
11:8	—	Reserved/SBZ for legacy APIC; extension of Host Physical APIC ID when x2APIC is enabled.
7:0	Host Physical APIC ID	Physical APIC ID of the physical core allocated by the VMM to host the guest virtual processor. This field is not valid unless the IsRunning bit is set.

Note that the IR bit, when set, indicates that the VMM has assigned a physical core to host this virtual processor. The bit does not differentiate between a physical processor running in guest mode (actively executing guest software) or in hypervisor mode (having suspended the execution of guest software).

The Physical APIC ID Table occupies the lower half of a single 4-Kbyte memory page, formatted as follows:

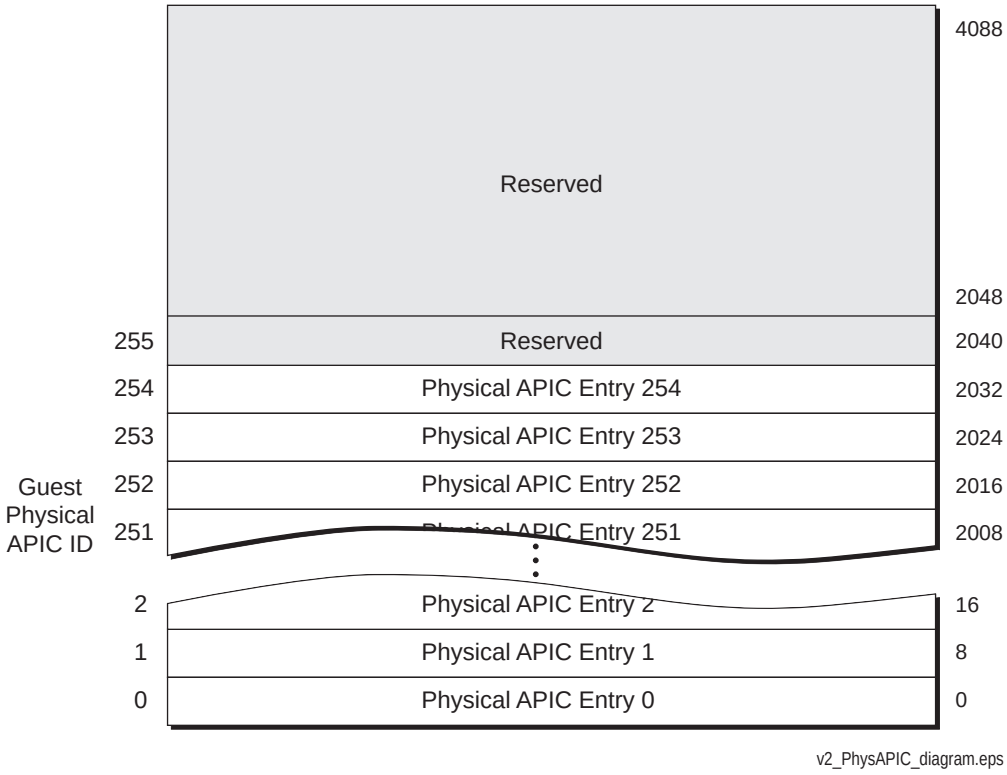

Figure 15-18. Physical APIC Table in Memory.

Since a destination of FFh is used to specify a broadcast, physical APIC ID FFh is reserved. The upper 2048 bytes of the table are reserved and should be set to zero.

15.29.5.3 Logical APIC ID Table

In addition to the Physical APIC ID Table, each guest VM is assigned a Logical APIC ID Table. This table is used to lookup the guest physical APIC ID for logically addressed interrupt requests. Each entry of this table provides the guest physical APIC ID corresponding to a single logically addressed APIC. Note that this implies that the logical ID of each vAPIC must be unique. The entries of this table are selected using the logical ID and interpreted differently depending upon logical APIC addressing mode of the guest. logical destination modes are supported: flat clustered.

If the guest attempts to change the logical ID of its APIC, the VMM must reflect this change in the Logical APIC ID Table. AVIC hardware supports the fixed interrupt message type targeting one or more logical destinations. The hardware also supports self and broadcast delivery modes specified via the Destination Shorthand (DSH) field of the ICRL. Any other message types must be supported through emulation by the VMM.

A pointer to this table is maintained in the VMCB. Because there is a single Logical APIC ID Table per virtual machine, the value of this pointer is the same for every virtual processor within the virtual machine.

For all logical destination modes, the table entries have the following format:

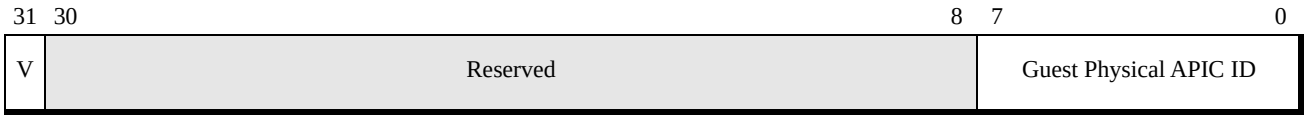

Figure 15-19. Logical APIC ID Table Entry

Table 15-26. Logical APIC ID Table Entry Fields

Bit(s)	Field Name	Description
31	V	Valid Bit. When set, indicates that this table entry contains a valid physical APIC ID. If cleared, this table entry contains no information.
30:8	—	Reserved, SBZ. Should always be set to zero.
7:0	Guest Physical APIC ID	Guest physical APIC ID corresponding to the local APIC selected when logically addressed.

Logical APIC ID Table Format for Flat Mode. When running in flat mode, AVIC expects the logical APIC ID table to be formatted as shown in Figure 15-20 below. This mode uses only the first 8 entries of the table. Although the logical APIC ID is an eight bit value, supported encodings must be of the form 2^i, where i = 0 to 7. In the figure the value i is used and represents the index into the table. The actual byte offset into the table for a given logical APIC ID *l_apic_id* is 4 * $\log_2$(l_apic_id).

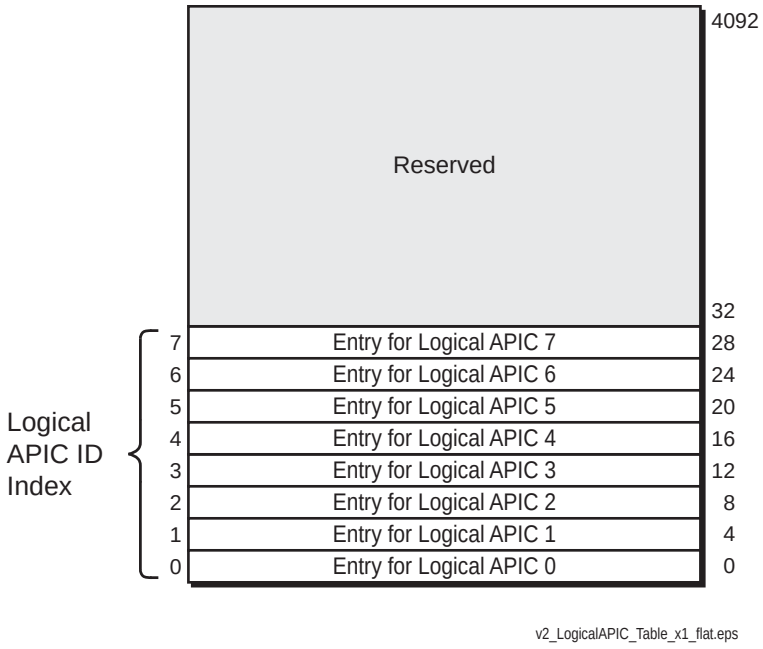

Figure 15-20. Logical APIC ID Table Format, Flat Mode.

Logical APIC ID Table Format for Cluster Mode. In cluster mode, bits [7:4] of the logical APIC ID represent the cluster number and bits [3:0] represent the APIC index (bit encoded). The cluster number Fh (15) is reserved. Since the APIC index field is four bits, four encodings are supported for the APIC index value.

The actual byte offset into the table for a given cluster *c* and an APIC index *apic_ix* is (16 * c) + 4 * $\log_2$(apic_ix)

When running in cluster mode, AVIC expects the logical APIC ID table to be formatted as shown in Figure 15-21 below.

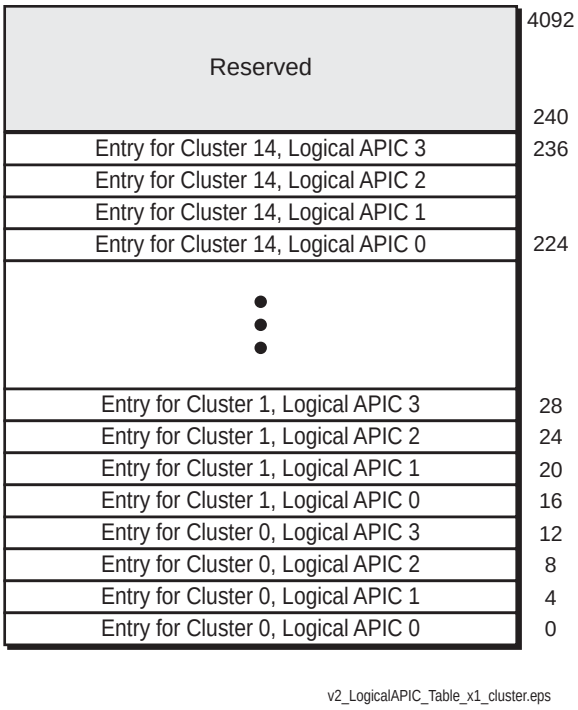

Figure 15-21. Logical APIC ID Table Format, Cluster Mode.

15.29.6 Interrupt Delivery

There are two fundamental types of virtual interrupts—interprocessor interrupts (IPIs) and I/O device interrupts (device interrupts). An IPI is initiated when guest system software writes the ICRL register. A device interrupt is initiated by a I/O device that has been programmed by guest system software (usually a device driver) to send a message signaling an event to a specific guest physical processor. This message usually includes an interrupt vector number indicating the nature of the event.

The following sections discuss the actions taken by AVIC hardware when a virtual processor signals an IPI and the actions taken by I/O virtualization hardware when a device signals a virtual interrupt.

15.29.6.1 Interprocessor Interrupts

To process an IPI, AVIC hardware executes the following steps:

1. If the destination-shorthand coded in the command is 01b (i.e. self), update the IRR in the backing page, signal doorbell to self and skip remaining steps.
2. If destination-shorthand is non-zero, or if the destination field is FFh (i.e. broadcast), jump to step 4.
3. If the destination(s) is (are) logically addressed, lookup the guest physical APIC IDs for each logical ID using the Logical APIC ID table.

   If the entry is not valid (V bit is cleared), cause a #VMEXIT.

If the entry is valid, but contains an invalid backing page pointer, cause a #VMEXIT.

4. Lookup the vAPIC backing page address in the Physical APIC table using the guest physical APIC ID as an index into the table.

   For directed interrupts, if the selected table entry is not valid, cause a #VMEXIT. For broadcast IPIs, invalid entries are ignored.

5. For every valid destination:
   - Atomically set the appropriate IRR bit in each of the destinations' vAPIC backing page.
   - Check the IsRunning status of each destination.
   - If the destination IsRunning bit is set, send a doorbell message using the host physical core number from the Physical APIC ID table.

6. If any destinations are identified as not currently scheduled on a physical core (i.e., the IsRunning bit for that virtual processor is not set), cause a #VMEXIT.

Refer to Section 15.29.9.1, "AVIC IPI Delivery Not Completed," on page 563 for new exitcodes associated with the #VMEXIT exceptions listed above.

15.29.6.2 Device Interrupts

The delivery of a I/O device interrupt to a virtual processor is handled by an IOMMU with virtual interrupt capability. To deliver a virtual interrupt, I/O virtualization hardware executes the following steps:

1. An interrupt message arrives from the I/O device identifying the source device and interrupt vector number.
2. I/O virtualization hardware uses the device ID to determine the guest physical APIC ID of the core that is the target of the device interrupt.
3. I/O virtualization hardware uses the guest physical APID ID to index into the Physical APIC ID Table to find the SPA of the vAPIC backing page. If the I/O virtualization hardware accesses an entry in the Physical APIC ID Table that is not valid (V bit is cleared), the I/O virtualization hardware aborts the virtual interrupt delivery and logs an error.
4. I/O virtualization hardware performs any required vector number translation.
5. I/O virtualization hardware atomically sets the bit in the IRR in the vAPIC backing page that corresponds to the vector.
6. If the virtual processor that is the target of the interrupt is not currently running on its assigned physical core, the virtual interrupt will be presented when the virtual processor is made active again. I/O virtualization hardware may provide additional information to the VMM about the device interrupt to aid in virtual processor scheduling decisions.

   If the virtual processor that is the target of the interrupt is scheduled on a physical processor (indicated by the IsRunning bit of the Physical APIC ID table entry being set), I/O virtualization hardware uses the host physical APIC ID in the table entry to send a doorbell signal to the corresponding processor core to signal that an interrupt needs to be processed.

15.29.7 CPUID Feature Bits for AVIC

A CPUID feature bit is used indicate support for AVIC on a specific hardware implementation. CPUID Fn8000_000A_EDX[AVIC] is designated for this purpose and is returned in bit 13 of EDX. If EDX[13] is set, the AVIC architecture is supported on that hardware.

See Section 3.3, “Processor Feature Identification,” on page 71 for more information on using the CPUID instruction.

15.29.8 New Processor Mechanisms

In order to support the direct injection of interrupts into the guest and to accelerate critical vAPIC functions, new hardware mechanisms are implemented in the processor.

15.29.8.1 Special Trap/Fault Handling for vAPIC Accesses

To virtualize the local APIC utilized by the guest to generate and process interrupts, all read and write accesses by the guest virtual processor to its local APIC registers are redirected to the vAPIC backing page. Most reads and many writes to this guest physical address range read or write the contents of memory locations within the vAPIC backing page at the corresponding offset.

To support proper handling and emulation of the guest local APIC, the processor provides permissions filtering hardware (Refer to Figure 15-15.) that detects and intercepts accesses to specific offsets (representing APIC registers) within the vAPIC backing page. This hardware either allows the access, blocks the access and causes a #VMEXIT (fault behavior), or allows the access and then causes a #VMEXIT (trap behavior).

Hardware directly handles the side effects of guest writes to the TPR and EOI registers. Writes to the ICRL register with simple functional side effects such as the generation of a directed IPI or a self-IPI request are handled directly. Values written to the ICRL defined to initiate more complex behavior cause a #VMEXIT to allow the VMM to emulate the function. A guest write to the ICRH register has no immediate hardware side effect and is allowed.

Most other write access attempts within the vAPIC register bank address range cause a #VMEXIT with trap or fault behavior allowing the VMM to emulate the function of that register. See Table 15-22 for more detail.

Reads and writes to locations within the vAPIC backing page, but outside the offset range of defined vAPIC registers are allowed to complete.

15.29.8.2 Doorbell Mechanism

Each core provides a doorbell mechanism that is used by other cores (for IPIs) and the IOMMU (for device interrupts) to signal to the VMM of the target physical core that a virtual interrupt requires processing. The exact mechanism is implementation-specific, but must be protected from access from non-privileged software running on other cores and from direct access by an external device.

When the doorbell is received in guest mode, hardware on the receiving core evaluates the vAPIC state in the vAPIC backing page for the currently running virtual processor and injects the interrupt into the guest as appropriate.

Doorbell Register. The system programming interface to the doorbell mechanism is provided via an MSR. Sending a doorbell signal to a another core is initiated by writing the physical APIC ID corresponding to that core to the Doorbell Register (MSR C001_011Bh). The format of this register is shown in Figure 15-22 below.

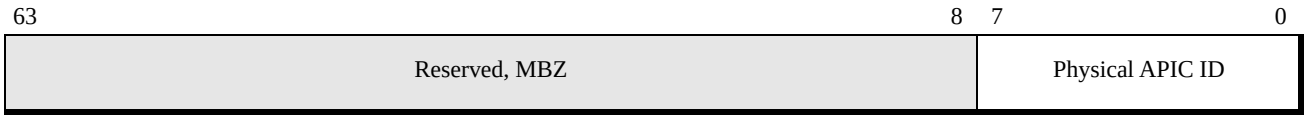

Figure 15-22. Doorbell Register, MSR C001_011Bh

Writing to this register causes a doorbell signal to be sent to the specified physical core. The serializing semantics of WRMSR are relaxed when writing to the Doorbell Register. Any attempt to read from this register results in a #GP.

Processing of Doorbell Signals. A doorbell signal delivered to a running guest is recognized by the hardware regardless of whether it can be immediately injected into the guest as a virtual interrupt. On the next VMRUN, the virtual interrupt delivery mechanism evaluates the state of the IRR register of the guest's vAPIC backing page to find the highest priority pending interrupt and injects it if interrupt masking and priority allow.

15.29.8.3 Additional VMRUN Handling

In addition to the normal VMRUN operations, the core re-evaluates the APIC state in the vAPIC backing page upon entry into the guest and processes pending interrupts as necessary. Specifically:

- On VMRUN the interrupt state is evaluated and the highest priority pending interrupt indicated in the IRR is delivered if interrupt masking and priority allow
- Any doorbell signals received during VMRUN processing are recognized immediately after entering the guest
- When AVIC mode is enabled for a virtual processor, the V_IRQ, V_INTR_PRIO, V_INTR_VECTOR, and V_IGN_TPR fields in the VMCB are ignored.

15.29.9 New Exit Codes for AVIC

The AVIC architecture defines two new AVIC-related #VMEXIT events. These cases are described in the following sections. Assigned EXITCODE values are given in Table C-1 on page 693.

15.29.9.1 AVIC IPI Delivery Not Completed

An IPI could not be delivered to all targeted guest virtual processors because at least one guest virtual processor was not allocated to a physical core at the time. This results in a #VMEXIT with an exit code

of AVIC_INCOMPLETE_IPI. Additional data associated with this #VMEXIT event is returned in the EXITINFO1 and EXITINFO2 fields.

EXITINFO1. This field contains the values written to the vAPIC ICRH and ICRL registers.

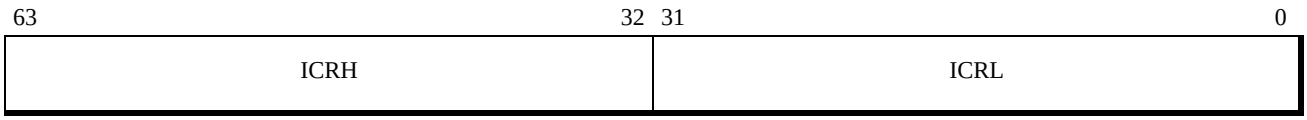

Figure 15-23. EXITINFO1

Table 15-27. EXTINFO1 Fields

Bit(s)	Field Name	Description
63:32	ICRH	Value written to the vAPIC ICRH register.
31:0	ICRL	Value written to the vAPIC ICRL register.

EXITINFO2. This field contains information describing the specific reason for the IPI delivery failure.

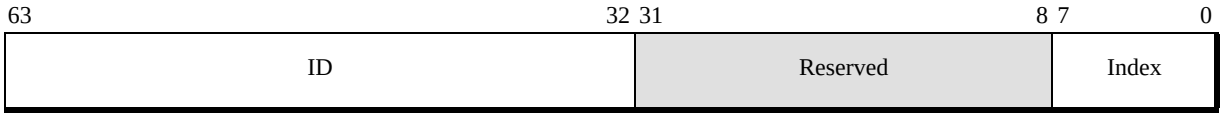

Figure 15-24. EXITINFO2

Table 15-28. EXTINFO2 Fields

Bit(s)	Field Name	Description
63:32	ID	Specific reason for the delivery failure. See Table 15-29 for defined values.
31:8	—	Reserved
7:0	Index	For ID = 1 – 3, this field provides the index of a logical or physical table entry. Reserved for all other ID values.

The ID field identifies the reason for the IPI delivery failure:

Table 15-29. ID Field—IPI Delivery Failure Cause

ID	Cause	Description	Index
0	Invalid Interrupt type	The trigger mode for the specified IPI was set to level or the destination type is unsupported.	Reserved.
1	IPI Target Not Running	IsRunning bit of the target for a Singlecast/Broadcast/Multicast IPI is not set in the physical APIC ID table.	Index of the physical or logical APIC ID table entry for the target virtual processor that was not scheduled on a physical core.
2	Invalid Target in IPI	Target ID invalid. This is due to one the following reasons: • In logical mode: cluster > max_cluster (64) • In physical mode: target > max_physical (512) • address is not present in the physical or logical ID tables	Index of the physical or logical table entry for the invalid target.
3	Invalid Backing Page Pointer	The vAPIC Backing Page Pointer field of the Physical APIC ID Table contained an invalid physical address.	For shorthand or broadcast delivery modes, index of the physical APIC ID Table containing the invalid address. For directed IPIs, index of the logical or physical APIC ID table depending on the destination mode.
> 3	Reserved	—	Reserved

15.29.9.2 AVIC Access to un-accelerated vAPIC register

A guest access to an APIC register that is not accelerated by AVIC results in a #VMEXIT with the exit code of AVIC_NOACCEL. This fault is also generated if an EOI is attempted when the highest priority in-service interrupt is set for level-triggered mode. Additional data associated with this #VMEXIT event is returned in the EXITINFO1 and EXITINFO2 fields.

EXITINFO1. This field contains the offset of the un-accelerated virtual APIC register and a bit indicating whether a read or write operation was attempted.

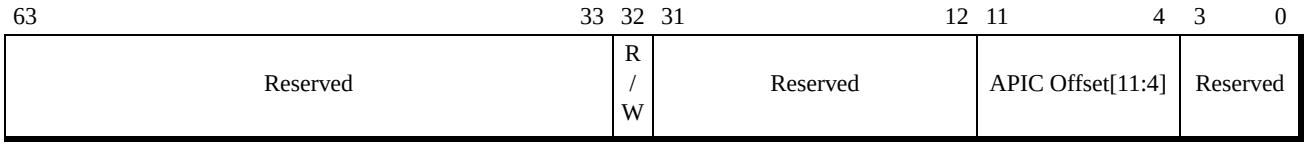

Table 15-30. EXTINFO1 Fields

Bit(s)	Field Name	Description
63:33	—	Reserved.
32	R/W	If set, write was attempted. If clear, read was attempted.

Table 15-30. EXTINFO1 Fields (continued)

Bit(s)	Field Name	Description
31:12	—	Reserved.
11:4	APIC_Offset[11:4]	Offset within virtual vAPIC backing page at which read or write was attempted. APIC_Offset[3:0] = 0, since all registers are aligned on 16-byte boundaries.
3:0	—	Reserved.

EXITINFO2. This field contains extra information for the un-accelerated operation. If the EXITINFO1 fields indicate a write to the vAPIC EOI register (offset = B0h), bits 7:0 of this value contain the number of the highest in-service vector found in the virtual APIC ISR.

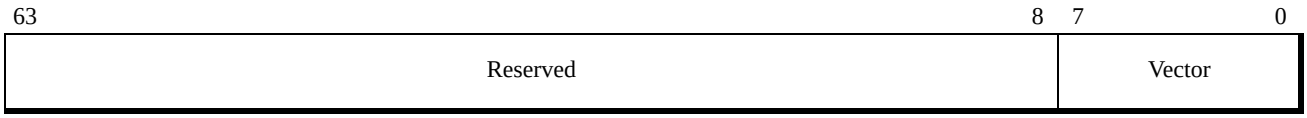

Table 15-31. EXTINFO2 Fields

Bit(s)	Field Name	Description
63:8	—	Reserved.
31:0	Vector	Vector for attempted EOI; otherwise undefined.

15.30 SVM Related MSRs

SVM uses the following MSRs for various control purposes. These MSRs are available regardless of whether SVM is enabled in EFER.SVME. For details on implementation-specific features, see the *BIOS and Kernel Developer's Guide (BKDG)* or *Processor Programming Reference Manual* applicable to your product.

15.30.1 VM_CR MSR (C001_0114h)

The VM_CR MSR controls certain global aspects of SVM. The layout of the MSR is shown in Figure 15-25.

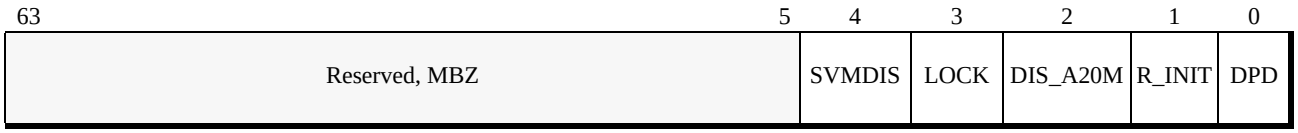

Figure 15-25. Layout of VM_CR MSR (C001_0114h)

The individual fields are as follows:

- DPD—Bit 0. If set, disables the external hardware debug port and certain internal debug features.
- R_INIT—Bit 1. If set, non-intercepted INIT signals are converted into an #SX exception.

- DIS_A20M—Bit 2. If set, disables A20 masking.
- LOCK—Bit 3. When this bit is set, writes to LOCK and SVMDIS are silently ignored. When this bit is clear, VM_CR bits 3 and 4 can be written. Once set, LOCK can only be cleared using the SVM_KEY MSR (See Section 15.31.) This bit is not affected by INIT or SKINIT.
- SVMDIS—Bit 4. When this bit is set, writes to EFER treat the SVME bit as MBZ. When this bit is clear, EFER.SVME can be written normally. This bit does not prevent CPUID from reporting that SVM is available. Setting SVMDIS while EFER.SVME is 1 generates a #GP fault, regardless of the current state of VM_CR.LOCK. This bit is not affected by SKINIT. It is cleared by INIT when LOCK is cleared to 0; otherwise, it is not affected.

15.30.2 IGNNE MSR (C001_0115h)

The read/write IGNNE MSR is used to set the state of the processor-internal IGNNE signal directly. This is only useful if IGNNE emulation has been enabled in the HW_CR MSR (and thus the external signal is being ignored). Bit 0 specifies the current value of IGNNE; all other bits are MBZ.

15.30.3 SMM_CTL MSR (C001_0116h)

The write-only SMM_CTL MSR provides software control over SMM signals. SMM_CTL MSR is not supported when CPUID Fn8000_0021[NoSmmCtlMSR] is set.

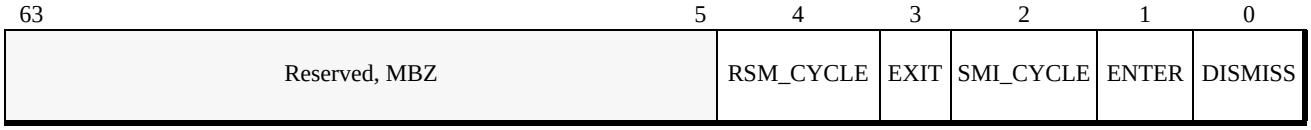

Figure 15-26. Layout of SMM_CTL MSR (C001_0116h)

Writing individual bits causes the following actions:

- DISMISS—Bit 0. Clear the processor-internal “SMI pending” flag.
- ENTER—Bit 1. Enter SMM: map the SMRAM memory areas, record whether NMI was currently blocked and block further NMI and SMI interrupts.
- SMI_CYCLE—Bit 2. Send SMI special cycle.
- EXIT—Bit 3. Exit SMM: unmap the SMRAM memory areas, restore the previous masking status of NMI and unconditionally reenable SMI.
- RSM_CYCLE—Bit 4. Send RSM special cycle.

Writes to the SMM_CTL MSR cause a #GP if platform firmware has locked the SMM control registers by setting HWCR[SMMLOCK].

Conceptually, the bits are processed in the order of ENTER, SMI_CYCLE, DISMISS, RSM_CYCLE, EXIT, though only the following bit combinations may be set together in a single write (for all other combinations of more than one bit, behavior is undefined):

- ENTER + SMI_CYCLE

- DISMISS + ENTER
- DISMISS + ENTER + SMI_CYCLE
- EXIT + RSM_CYCLE

The VMM must ensure that ENTER and EXIT operations are properly matched, and *not* nested, otherwise processor behavior is undefined. Also undefined are ENTER when the processor is already in SMM, and EXIT when the processor is not in SMM.

15.30.4 VM_HSAVE_PA MSR (C001_0117h)

The 64-bit read/write VM_HSAVE_PA MSR holds the physical address of a 4KB block of memory where VMRUN saves host state, and from which #VMEXIT reloads host state. The VMM software is expected to set up this register before issuing the first VMRUN instruction. Software must not attempt to read or write the host save-state area directly.

Writing this MSR causes a #GP if:

- any of the low 12 bits of the address written are nonzero, or
- the address written is greater than or equal to the maximum supported physical address for this implementation.

15.30.5 TSC Ratio MSR (C000_0104h)

Writing to the TSC Ratio MSR allows the hypervisor to control the guest's view of the Time Stamp Counter. The contents of TSC Ratio MSR sets the value of the TSCRatio. This constant scales the timestamp value returned when the TSC is read by a guest via the RDTSC or RDTSCP instructions or when the TSC, MPERF, or MPerfReadOnly MSRs are read via the RDMSR instruction by a guest running under virtualization.

This facility allows the hypervisor to provide a consistent TSC, MPERF, and MPerfReadOnly rate for a guest process when moving that process between cores that have a differing P0 rate. The TSCRatio does not affect the value read from the TSC, MPERF, and MPerfReadOnly MSRs when in host mode or when virtualization is disabled. System Management Mode (SMM) code sees unscaled TSC, MPERF and MPerfReadOnly values unless the SMM code is executed within a guest container. The TSCRatio value does not affect the rate of the underlying TSC, MPERF, and MPerfReadOnly counters, nor the value that gets written to the TSC, MPERF, and MPerfReadOnly MSRs counters on a write by either the host or the guest.

The TSC Ratio MSR specifies the TSCRatio value as a fixed-point binary number in 8.32 format, which is composed of 8 bits of integer and 32 bits of fraction. This number is the ratio of the desired P0 frequency to be presented to the guest relative to the P0 frequency of the core (See Section 17.1, “P-State Control,” on page 639). The reset value of the TSCRatio is 1.0, which sets the guest P0 frequency to match the core P0 frequency.

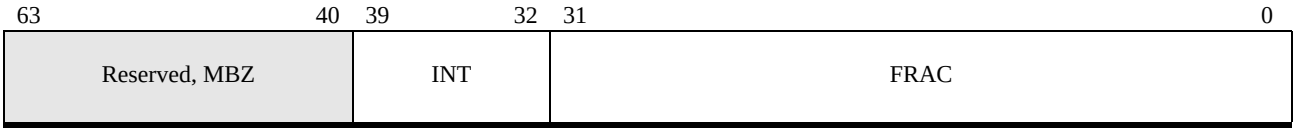
Note that:

TSCFreq = Core P0 frequency * TSCRatio, so TSCRatio = (Desired TSCFreq) / Core P0 frequency.

The TSC value read by the guest is computed using the TSC Ratio MSR along with the TSC_OFFSET field from the VMCB so that the actual value returned is:

TSC Value (in guest) = (P0 frequency * TSCRatio * t) + VMCB.TSC_OFFSET + (Last Value Written to TSC) * TSCRatio
Where **t** is time since the TSC was last written via the TSC MSR (or since reset if not written)

The layout of the TSC Ratio MSR is illustrated in figure below.



Bits	Mnemonic	Description	Access Type
63:40	—	Reserved	Reserved, MBZ
39:32	INT	Integer Part	R/W
31:0	FRAC	Fractional Part	R/W

Figure 15-27. TSC Ratio MSR (C000_0104h)

INT. Integer Part. Bits 39:32. Integer part of TSCRatio.

FRAC. Fractional Part. Bits 39:32. Fractional part of TSCRatio.

$TSCRatio = INT + FRAC \times 2^{-32}$

CPUID Fn8000_000A_EDX[TscRateMsr] =1 indicates support for the TSC Ratio MSR. See Section 3.3, “Processor Feature Identification,” on page 71 for more information on using the CPUID instruction.

15.31 SVM-Lock

The SVM-Lock feature allows software to prevent EFER.SVME from being set, either unconditionally or with a 64-bit key to re-enable SVM functionality.

Support for SVM-Lock is indicated by CPUID Fn8000_000A_EDX[SVML] = 1. On processors that support the SVM-Lock feature, SKINIT and STGI can be executed even if EFER.SVME=0. See descriptions of LOCK and SVMDIS bits in Section 15.30.1. When the SVM-Lock feature is not available, hypervisors can use the read-only VM_CR.SVMDIS bit to detect SVM (see Section 15.4).

15.31.1 SVM_KEY MSR (C001_0118h)

The write-only SVM_KEY MSR is used to create a password-protected mechanism to clear VM_CR.LOCK.

When VM_CR.LOCK is zero, writes to SVM_KEY MSR set the 64-bit SVM Key value.

When VM_CR.LOCK is one, writes to SVM_KEY MSR compare the written value to the SVM Key value; if the values match and are non-zero, the VM_CR.LOCK bit is cleared. If the values mismatch or the SVM Key value is zero, the write to SVM_KEY is ignored, and VM_CR.LOCK is unmodified. Software should read VM_CR.LOCK after writing SVM_KEY to determine whether the unlock succeeded.

If SVM Key is zero when VM_CR.LOCK is one, VM_CR.LOCK can only be cleared by a processor reset.

To preserve the security of the SVM key, reading the SVM_KEY MSR always returns zero.

15.32 SMM-Lock

The SMM-Lock feature allows platform firmware to prevent System Management Interrupts (SMI) from being intercepted in SVM. The SmmLock bit is located in the HWCR MSR register.

15.32.1 SmmLock Bit — HWCR[0]

The SmmLock bit (bit 0) is located in the HWCR MSR (C001_0015h). When SmmLock is clear, it can be set to one. Once set, the bit cannot be cleared by software and writes to it are ignored. SmmLock can only be cleared using the SMM_KEY MSR (see Section 15.32.2), or by a processor reset. This bit is not affected by INIT or SKINIT. When SmmLock is set, other SMM configuration registers cannot be written. For complete information on the HWCR register, see the *BIOS and Kernel Developer's Guide (BKDG)* or *Processor Programming Reference Manual* applicable to your product.

15.32.2 SMM_KEY MSR (C001_0119h)

The write-only SMM_KEY MSR is used to create a password-protected mechanism to clear SmmLock.

When SmmLock is zero, writes to SMM_KEY MSR set the 64-bit SMM Key value.

When SmmLock is one, writes to SMM_KEY MSR compare the written value to the SMM Key value; if the values match and are non-zero, the SmmLock bit is cleared. If the values mismatch or the SMM Key value is zero, the write to SMM_KEY is ignored, and SmmLock is unmodified. Software should read SmmLock after writing SMM_KEY to determine whether the unlock succeeded.

If SMM_Key MSR is equal to zero when SmmLock is one, SmmLock can only be cleared by a processor reset.

To preserve the security of the SMM key, reading SMM_KEY MSR always returns zero.

15.33 Nested Virtualization

Hardware support for improved performance of nested virtualization, which is the act of running a hypervisor as a guest under a higher-level hypervisor, is provided through the features described here.

These relieve the top-level hypervisor from performing certain common, high-overhead operations that can occur with nested virtualization.

15.33.1 VMSAVE and VMLOAD Virtualization

This feature allows the VMSAVE and VMLOAD instructions to execute in guest mode without causing a #VMEXIT. The VMCB address in RAX is treated as a guest physical address and is translated to a host physical address. Any page fault in attempting that translation will result in a normal #VMEXIT with a nested page fault exit code. If the translation is successful, the register state transfer to or from the VMCB will then be performed.

Support for virtualized VMSAVE and VMLOAD is indicated by CPUID Fn8000_000A_EDX[15]=1. When this feature is available, it must be explicitly enabled by setting bit 1 of VMCB offset 0B8h to 1. This enable bit is only recognized when the hypervisor is in 64 bit mode, nested paging is enabled and Secure Encrypted Virtualization is disabled, otherwise attempted execution of a VMLOAD or VMSAVE in the guest will result in a #VMEXIT with a VMSAVE/VMLOAD exit code.

15.33.2 Virtual GIF (VGIF)

This feature allows STGI and CLGI to execute in guest mode and control virtual interrupts in guest mode while still allowing physical interrupts to be intercepted by the hypervisor. The presence of the VGIF feature is indicated by CPUID Fn8000_000A_EDX[16]=1.

In order to provide this ability, two new bits are added to the VMCB field at offset 60h:

Offset	Bit	Description
60h	9	VGIF value (0 – Virtual interrupts are masked, 1 – Virtual Interrupts are unmasked)
60h	25	Virtual GIF enable for this guest (0 - Disabled, 1 - Enabled)

When a VMRUN is executed and VGIF is enabled, the processor uses bit 9 as the starting value of the virtual GIF. It then provides masking capability for when virtual interrupts are taken. STGI executed in the guest sets bit 9 of VMCB offset 60h and allows a virtual interrupt to be taken. CLGI executed in the guest clears bit 9 of VMCB offset 60h and causes the virtual interrupt to be masked. Bit 9 in the VMCB is also writeable by the hypervisor, and loaded on VMRUN and is saved on #VMEXIT.

The hypervisor can still use the STGI and CLGI intercept controls in the VMCB to intercept execution of these in the guest regardless of VGIF enablement.

15.34 Secure Encrypted Virtualization

Secure Encrypted Virtualization (SEV) is available when the CPU is running in guest mode utilizing AMD-V virtualization features. SEV enables running encrypted virtual machines (VMs) in which the code and data of the virtual machine are secured so that the decrypted version is available only within the VM itself. Each virtual machine may be associated with a unique encryption key so if data is

accessed by a different entity using a different key, the SEV encrypted VM's data will be decrypted with an incorrect key, leading to unintelligible data.

It is important to note that SEV mode therefore *represents a departure from the standard x86 virtualization security model*, as the hypervisor is no longer able to inspect or alter all guest code or data. The guest page tables, managed by the guest, may mark data memory pages as either private or shared, thus allowing selected pages to be shared outside the guest. Private memory is encrypted using a guest-specific key, while shared memory is accessible to the hypervisor.

15.34.1 Determining Support for SEV

Support for memory encryption features is reported in CPUID 8000_001F[EAX] as described in Section 7.10.1, “Determining Support for Secure Memory Encryption,” on page 228. Bit 1 indicates support for Secure Encrypted Virtualization.

When memory encryption features are present, CPUID 8000_001F[EBX] and 8000_001F[ECX] supply additional information regarding the use of memory encryption, such as the number of keys supported simultaneously and which page table bit is used to mark pages as encrypted. Additionally, in some implementations, the physical address size of the processor may be reduced when memory encryption features are enabled, for example from 48 to 43 bits. In this example, physical address bits 47:43 would be treated as reserved except where otherwise indicated. When memory encryption is supported in an implementation, CPUID 8000_001F[EBX] reports any physical address size reduction present. Bits reserved in this mode are treated the same as other page table reserved bits, and will generate a page fault if found to be non-zero when used for address translation.

Full CPUID details for memory encryption features may be found in Volume 3, section E.4.17.

15.34.2 Key Management

Under the memory encryption extensions defined here, each SEV-enabled guest virtual machine is associated with a memory encryption key, and the SME mode (if used, see Section 7.10 on page 228) is associated with a separate key. Key management for the SEV feature is not handled by the CPU but rather by a separate processor known as the AMD Secure Processor (AMD-SP) which is present on AMD SOCs. A detailed discussion of AMD-SP operation is beyond the scope of this manual.
