src is rounded to single-precision using the rounding mode specified by RN.

The result is placed into bits 0:31 and bits 32:63 of doubleword element i of VSR[XT] in single-precision format.

If a trap-enabled exception occurs in any element of the vector, no results are written to VSR[XT].

#### Special Registers Altered

FX OX UX XX VXSNAN

#### Programming Note

Previous versions of the architecture allowed the contents of bits 32:63 of each doubleword in the result register to be undefined, however, all processors that support this instruction write the result into bits 32:63 of each doubleword in the result register as well as into bits 0:31, as is required by this version of the architecture.

#### Programming Note

Previous versions of the architecture allowed the contents of doubleword 1 of the result register to be undefined. However, all processors that support this instruction write 0s into doubleword 1 of the result register, as is required by this version of the architecture.

Let XT be the value 32×TX + T.  
Let XB be the value 32×BX + B.

For each integer value i from 0 to 1, do the following.  
Let src be the double-precision floating-point operand in doubleword element i of VSR[XB].

If src is a NaN, the result is the value 0x8000\_0000\_0000\_0000 and VXCVI is set to 1. If src is an SNaN, VXSNAN is also set to 1.

Otherwise, src is rounded to a floating-point integer using the rounding mode Round Toward Zero.

If the rounded value is greater than 2<sup>63</sup>-1, the result is 0x7FFF\_FFFF\_FFFF\_FFFF and VXCVI is set to 1.

Otherwise, if the rounded value is less than -2<sup>63</sup>, the result is 0x8000\_0000\_0000\_0000 and VXCVI is set to 1.

Otherwise, the result is the rounded value converted to 64-bit signed-integer format, and if the result is inexact (i.e., not equal to src), XX is set to 1.

The result is placed into doubleword element i of VSR[XT].

See Table 116.

If a trap-enabled exception occurs in any element of the vector, no results are written to VSR[XT].

**Special Registers Altered**

```

Let XT be the value  $32 \times TX + T$ .

Let XB be the value  $32 \times BX + B$ .

For each integer value  $i$  from 0 to 3, do the following.

Let *src* be the single-precision floating-point value in word element  $i$  of  $VSR[XB]$ .

If *src* is an SNaN, let *result* be the bfloat16 representation of that SNaN converted to a QNaN.

Otherwise, if *src* is a QNaN, let *result* be the bfloat16 representation of that QNaN.

Otherwise, if *src* is an Infinity, let *result* be the bfloat16 representation of Infinity with the same sign as *src*.

Otherwise, if *src* is a Zero, let *result* be the bfloat16 representation of Zero with the same sign as *src*.

Otherwise, let *result* be the bfloat16 representation of *src* rounded to bfloat16 precision using the rounding mode specified in RN.

*result* is placed into rightmost halfword of word element  $i$  of  $VSR[XT]$ .

The leftmost halfword of word element  $i$  of  $VSR[XT]$  is set to 0x0000.

If a trap-enabled exception occurs,  $VSR[XT]$  is not modified.

**Explanation:**

src1      The double-precision floating-point value in doubleword element  $i$  of  $\text{VSR}[\text{XA}]$  (where  $i = \{0, 1\}$ ).

src2      The double-precision floating-point value in doubleword element  $i$  of  $\text{VSR}[\text{XB}]$  (where  $i = \{0, 1\}$ ).

dQNaN     Default quiet NaN (0x7FF8\_0000\_0000\_0000).

NZF        Nonzero finite number.

Rezd       Exact-zero-difference result (addition of two finite numbers having same magnitude but different signs).

$\text{D}(x, y)$    Return the normalized quotient of floating-point value  $x$  divided by floating-point value  $y$ , having unbounded range and precision.

$\text{Q}(x)$       Return a QNaN with the payload of  $x$ .

$v$           The intermediate result having unbounded significand precision and unbounded exponent range.

Let XT be the value  $32 \times TX + T$ .

Let XA be the value  $32 \times AX + A$ .

Let XB be the value  $32 \times BX + B$ .

For each integer value  $i$  from 0 to 3, do the following.

Let  $src1$  be the single-precision floating-point operand in word element  $i$  of  $VSR[XA]$ .

Let  $src2$  be the single-precision floating-point operand in word element  $i$  of  $VSR[XB]$ .

$src1$  is divided<sup>[1]</sup> by  $src2$ , producing a quotient having unbounded range and precision.

The quotient is normalized<sup>[2]</sup>.

See Table 125.

The intermediate result is rounded to single-precision using the rounding mode specified by RN.

See Table 62, “Scalar Floating-Point Intermediate Result Handling,” on page 669.

The result is placed into word element  $i$  of  $VSR[XT]$  in single-precision format.

See Table 114, “Vector Floating-Point Final Result,” on page 832.

If a trap-enabled exception occurs in any element of the vector, no results are written to  $VSR[XT]$ .

**Explanation:**

src1      The single-precision floating-point value in word element  $i$  of  $\text{VSR}[\text{XA}]$  (where  $i = \{0, 1, 2, 3\}$ ).

src2      The single-precision floating-point value in word element  $i$  of  $\text{VSR}[\text{XB}]$  (where  $i = \{0, 1, 2, 3\}$ ).

dQNaN     Default quiet NaN (0x7FC0\_0000).

NZF        Nonzero finite number.

Rezd       Exact-zero-difference result (addition of two finite numbers having same magnitude but different signs).

$\text{D}(x, y)$    Return the normalized quotient of floating-point value  $x$  divided by floating-point value  $y$ , having unbounded range and precision.  
Note: If  $x = -y$ ,  $v$  is considered to be an exact-zero-difference result (Rezd).

$\text{Q}(x)$      Return a QNaN with the payload of  $x$ .

$v$           The intermediate result having unbounded significand precision and unbounded exponent range.

```

Let XA be the value of  $32 \times AX + A$ . If XA is in the range  $4 \times AT$  to  $4 \times AT + 3$ , the instruction form is invalid.  
 Let XB be the value of  $32 \times BX + B$ . If XB is in the range  $4 \times AT$  to  $4 \times AT + 3$ , the instruction form is invalid.

Let the contents of ACC[AT] be a  $4 \times 4$  matrix of single-precision floating-point values.

Let result be a  $4 \times 4$  matrix of word elements to be used as a temporary Accumulator.

For *xvf16ger2*, *xvf16ger2pp*, *xvf16ger2pn*, *xvf16ger2np*, or *xvf16ger2nn*, let PMSK=0b11, XMSK=0b1111, and YMSK=0b1111.

For each integer value *i* from 0 to 3, and each integer value *j* from 0 to 3, do the following.

If bit *i* of XMSK is equal to 1 and bit *j* of YMSK is equal to 1, do the following.

If bit 0 of PMSK is equal to 1, let src10 be the half-precision floating-point value in hword 0 of word element *i* of VSR[XA] and let src20 be the half-precision floating-point value in hword 0 of word element *j* of VSR[XB]. Otherwise, let src10 be the value 0.0 and let src20 be the value 0.0, causing the product of src10 and src20 to be 0.0.

If bit 1 of PMSK is equal to 1, let src11 be the half-precision floating-point value in hword 1 of word element *i* of VSR[XA] and let src21 be the half-precision floating-point value in hword 1 of word element *j* of VSR[XB]. Otherwise, let src11 be the value 0.0 and let src21 be the value 0.0, causing the product of src11 and src21 to be 0.0.

Let prod be the single-precision product of src10 and src20.

Let msum be the sum of prod added to the product of src11 and src21. msum is rounded to single-precision using the rounding mode specified in RN.

For **[pm]xvf16ger2**, the rounded msum is placed into word element *j* of ACC[AT][*i*] in single-precision floating-point format.

For **[pm]xvf16ger2pp**, the rounded msum is added to the single-precision floating-point value in word element *j* of ACC[AT][*i*], rounded to single-precision using the rounding mode specified in RN, and placed into word element *j* of ACC[AT][*i*] in single-precision floating-point format.

For **[pm]xvf16ger2pn**, the rounded msum is added to the negation of the single-precision floating-point value in word element *j* of ACC[AT][*i*], rounded to single-precision using the rounding mode specified in RN, and placed into word element *j* of ACC[AT][*i*] in single-precision floating-point format.

For **[pm]xvf16ger2np**, the negation of the rounded msum is added to the single-precision floating-point value in word element *j* of ACC[AT][*i*], rounded to single-precision using the rounding mode specified in RN, and placed into word element *j* of ACC[AT][*i*] in single-precision floating-point format.

For **[pm]xvf16ger2nn**, the negation of the rounded msum is added to the negation of the single-precision floating-point value in word element *j* of ACC[AT][*i*], rounded to single-precision using the rounding mode specified in RN, and placed into word element *j* of ACC[AT][*i*] in single-precision floating-point format.

Otherwise, the contents of ACC[AT][*i*][*j*] are set to 0x0000\_0000.

Unlike most other *VSX Vector Floating-Point* instructions, this instruction always updates the target register (here, ACC[AT]), even when a trap-enabled exception occurs. For every multiply-add operation that is performed as part of the execution of this instruction, the operation is performed as if all exception enable bits are zero, and the trap-disabled result is returned. If the operation causes underflow or produces an inexact result, whether the operation causes an Underflow or Inexact exception is based on the actual contents of the Underflow and Overflow Enable bits. Exception status is accumulated and the appropriate exception status bits in the FPSCR are updated at the completion of execution of the instruction. Otherwise, behavior is the same as any vector floating-point instruction that can cause an exception. Taking a Program interrupt on a trap-enabled exception when interrupts are enabled by MSR.FE0 and MSR.FE1 is still supported, albeit with ACC[AT] updated based on a trap-disabled result.

#### Special Registers Altered:

FX VXSAN VXIMZ OX UX XX (if **[pm]xvf16ger2**)  
 FX VXSAN VXIMZ VXISI OX UX XX(if **[pm]xvf16ger2pp**)  
 FX VXSAN VXIMZ VXISI OX UX XX(if **[pm]xvf16ger2pn**)  
 FX VXSAN VXIMZ VXISI OX UX XX(if **[pm]xvf16ger2np**)  
 FX VXSAN VXIMZ VXISI OX UX XX(if **[pm]xvf16ger2nn**)

**Programming Note**

Let X be the 4×2 matrix of half-precision floating-point values contained in VSR[XA] in row-major format.  
 Let Y be the 4×2 matrix of half-precision floating-point values contained in VSR[XB] in row-major format.  
 Let ACC[AT] be the Accumulator containing a 4×4 matrix of single-precision floating-point values.

Note that floating-point arithmetic is not associative. That is, (X+Y)+T can return a different result than X+(Y+T). The ordering specified by the instruction description for any result element *i, j* is the order the operations will be performed in hardware. The floating-point operations to implement each result element for *xvf16ger2[pp|pn|np|nn]* are shown below.

*[pm]xvf16ger2* performs the following form of accumulation of two outer products (rank 2 update).

for *i=0 to 3, j=0 to 3*:  
 $ACC[AT][i][j] = fmadds(X[i][1], Y[j][1], fmul s(X[i][0], Y[j][0]))$

*[pm]xvf16ger2pp* performs the following form of accumulation of two outer products (rank 2 update).

for *i=0 to 3, j=0 to 3*:  
 $ACC[AT][i][j] = fadds(fmadds(X[i][1], Y[j][1], fmul s(X[i][0], Y[j][0])), ACC[AT][i][j])$

*[pm]xvf16ger2pn* performs the following form of accumulation of two outer products (rank 2 update).

for *i=0 to 3, j=0 to 3*:  
 $ACC[AT][i][j] = fsubs(fmadds(X[i][1], Y[j][1], fmul s(X[i][0], Y[j][0])), ACC[AT][i][j])$

*[pm]xvf16ger2np* performs the following form of accumulation of two outer products (rank 2 update).

for *i=0 to 3, j=0 to 3*:  
 $ACC[AT][i][j] = fadds(fnmadds(X[i][1], Y[j][1], fmul s(X[i][0], Y[j][0])), ACC[AT][i][j])$

*[pm]xvf16ger2nn* performs the following form of accumulation of two outer products (rank 2 update).

for *i=0 to 3, j=0 to 3*:  
 $ACC[AT][i][j] = fsubs(fnmadds(X[i][1], Y[j][1], fmul s(X[i][0], Y[j][0])), ACC[AT][i][j])$

```

Let XA be the value of  $32 \times AX + A$ . If XA is in the range  $4 \times AT$  to  $4 \times AT + 3$ , the instruction form is invalid.

Let XB be the value of  $32 \times BX + B$ . If XB is in the range  $4 \times AT$  to  $4 \times AT + 3$ , the instruction form is invalid.

Let the contents of ACC[AT] be a  $4 \times 4$  matrix of single-precision floating-point values.

For *xvf32ger*, *xvf32gerpp*, *xvf32gerpn*, *xvf32gernp*, or *xvf32gernn*, let XMSK=0b1111 and YMSK=0b1111.

For each integer value *i* from 0 to 3, and each integer value *j* from 0 to 3, do the following.

If bit *i* of XMSK is equal to 1 and bit *j* of YMSK is equal to 1, do the following.

Let prod be the product of the single-precision floating-point value in word element *i* of VSR[XA] and the single-precision floating-point value in word element *j* of VSR[XB], having unbounded range and precision.

For **[pm]xvf32ger**, prod is rounded to single-precision using the rounding mode specified in RN. The rounded result is placed into word element *j* of ACC[AT][*i*] in single-precision floating-point format.

For **[pm]xvf32gerpp**, the single-precision floating-point value in word element *j* of ACC[AT][*i*] is added to prod. The intermediate result is rounded to single-precision using the rounding mode specified in RN. The rounded result is placed into word element *j* of ACC[AT][*i*] in single-precision floating-point format.

For **[pm]xvf32gerpn**, the single-precision floating-point value in word element *j* of ACC[AT][*i*] is subtracted from prod. The intermediate result is rounded to single-precision using the rounding mode specified in RN. The rounded result is placed into word element *j* of ACC[AT][*i*] in single-precision floating-point format.

For **[pm]xvf32gernp**, the single-precision floating-point value in word element *j* of ACC[AT][*i*] is subtracted from prod. The intermediate result is rounded to single-precision using the rounding mode specified in RN. The rounded result is negated and placed into word element *j* of ACC[AT][*i*] in single-precision floating-point format.

For **[pm]xvf32gernn**, the single-precision floating-point value in word element  $j$  of  $\text{ACC}[\text{AT}][i]$  is added to  $\text{prod}$ . The intermediate result is rounded to single-precision using the rounding mode specified in  $\text{RN}$ . The rounded result is negated and placed into word element  $j$  of  $\text{ACC}[\text{AT}][i]$  in single-precision floating-point format.

Otherwise, the contents of word element  $j$  of  $\text{ACC}[\text{AT}][i]$  are set to  $0x0000\_0000$ .

Unlike other vector floating-point instructions,  $\text{ACC}[\text{AT}]$  is always updated by the execution of the instruction, even when a trap-enabled exception occurs. For every multiply-add operation that is performed as part of the execution of this instruction, if an exception occurs as the result of that particular multiply-add operation, the trap-disabled exception result is returned, even if that exception type is trap-enabled. Exception detection is based on the trap-disable definition. Exception status is and the appropriate exception status bits in the FPSCR are updated at the completion of execution of the instruction. Otherwise, behavior is the same as any vector floating-point instruction that can cause an exception. Taking a Program interrupt on a trap-enabled exception when interrupts are enabled by MSR. FE0 and MSR. FE1 is still supported, albeit with the  $\text{ACC}[\text{AT}]$  updated based on a trap-disabled result.

Let  $XAp$  be the value of  $32 \times AX + Ap$ . If  $XAp$  is odd, or is in the range  $4 \times AT$  to  $4 \times AT + 3$ , the instruction form is invalid.

Let  $XB$  be the value of  $32 \times BX + B$ . If  $XB$  is in the range  $4 \times AT$  to  $4 \times AT + 3$ , the instruction form is invalid.

Let the contents of  $ACC[AT]$  be a  $4 \times 2$  matrix of double-precision floating-point values.

Let  $vsrcX$  be the concatenation of the contents of  $VSR[XAp]$  and  $VSR[XAp+1]$ .

Let  $vsrcY$  be the contents of  $VSR[XB]$ .

For *xvf64ger*, *xvf64gerpp*, *xvf64gerpn*, *xvf64gerpnp*, and *xvf64gerpnn*, let  $XMSK=0b1111$  and  $YMSK=0b11$ .

For each integer value  $i$  from 0 to 3, and each integer value  $j$  from 0 to 1, do the following.

If bit  $i$  of  $XMSK$  is equal to 1 and bit  $j$  of  $YMSK$  is equal to 1, do the following.

Let  $prod$  be the product of the double-precision floating-point value in doubleword element  $i$  of  $vsrcX$  and the double-precision floating-point value in doubleword element  $j$  of  $vsrcY$ , having unbounded range and precision.

For **[pm]xvf64ger**,  $prod$  is rounded to double-precision using the rounding mode specified in  $RN$ . The rounded result is placed into doubleword element  $j$  of  $ACC[AT][i]$  in double-precision floating-point format.

For **[pm]xvf64gerpp**,  $prod$  is added to the double-precision floating-point value in doubleword element  $j$  of  $ACC[AT][i]$ . The intermediate result is rounded to double-precision using the rounding mode specified in  $RN$ . The rounded result is placed into doubleword element  $j$  of  $ACC[AT][i]$  in double-precision floating-point format.

For **[pm]xvf64gerpn**, prod is added to the negation of the double-precision floating-point value in doubleword element *j* of ACC[AT][*i*]. The intermediate result is rounded to double-precision using the rounding mode specified in RN. The rounded result is placed into doubleword element *j* of ACC[AT][*i*] in double-precision floating-point format.

For **[pm]xvf64gernn**, prod is added to the double-precision floating-point value in doubleword element *j* of ACC[AT][*i*]. The intermediate result is rounded to double-precision using the rounding mode specified in RN. The rounded result is negated and placed into doubleword element *j* of ACC[AT][*i*] in double-precision floating-point format.

For **[pm]xvf64gernp**, prod is added to the negation of the double-precision floating-point value in doubleword element *j* of ACC[AT][*i*]. The intermediate result is rounded to double-precision using the rounding mode specified in RN. The rounded result is negated and placed into doubleword element *j* of ACC[AT][*i*] in double-precision floating-point format.

Otherwise, the contents of doubleword element *j* of ACC[AT][*i*] are set to 0x0000\_0000\_0000\_0000.

Unlike most other *VSX Vector Floating-Point* instructions, this instruction always updates the target register (here, ACC[AT]), even when a trap-enabled exception occurs. For every multiply-add operation that is performed as part of the execution of this instruction, the operation is performed as if all exception enable bits are zero, and the trap-disabled result is returned. If the operation causes underflow or produces an inexact result, whether the operation causes an Underflow or Inexact exception is based on the actual contents of the Underflow and Overflow Enable bits. Exception status is accumulated and the appropriate exception status bits in the FPSCR are updated at the completion of execution of the instruction. Otherwise, behavior is the same as any vector floating-point instruction that can cause an exception. Taking a Program interrupt on a trap-enabled exception when interrupts are enabled by MSR. FE0 and MSR. FE1 is still supported, albeit with ACC[AT] updated based on a trap-disabled result.

Let  $XB$  be the value of  $32 \times BX + B$ . If  $XB$  is in the range  $4 \times AT$  to  $4 \times AT + 3$ , the instruction form is invalid.

Let the contents of  $ACC[AT]$  be a  $4 \times 4$  matrix of 32-bit signed integer values.

For *xvi4ger8* or *xvi4ger8pp*, let  $PMSK = 0b11111111$ ,  $XMSK = 0b11111$ , and  $YMSK = 0b11111$ .

For each integer value  $i$  from 0 to 3, and each integer value  $j$  from 0 to 3, do the following.

If bit  $i$  of  $XMSK$  is equal to 1 and bit  $j$  of  $YMSK$  is equal to 1, do the following.

If bit 0 of  $PMSK$  is equal to 1, let  $prod0$  be the product of the 4-bit signed integer value in nibble 0 of word element  $i$  of  $VSR[XA]$  ( $X[i][0]$ ) and the 4-bit signed integer value in byte 0 of word element  $j$  of  $VSR[XB]$  ( $Y[j][0]$ ), sign-extended to 32 bits. Otherwise, let  $prod0$  be the value 0.

If bit 1 of  $PMSK$  is equal to 1, let  $prod1$  be the product of the 4-bit signed integer value in nibble 1 of word element  $i$  of  $VSR[XA]$  ( $X[i][1]$ ) and the 4-bit signed integer value in nibble 1 of word element  $j$  of  $VSR[XB]$  ( $Y[j][1]$ ), sign-extended to 32 bits. Otherwise, let  $prod1$  be the value 0.

If bit 2 of  $PMSK$  is equal to 1, let  $prod2$  be the product of the 4-bit signed integer value in nibble 2 of word element  $i$  of  $VSR[XA]$  ( $X[i][2]$ ) and the 4-bit signed integer value in nibble 2 of word element  $j$  of  $VSR[XB]$  ( $Y[j][2]$ ), sign-extended to 32 bits. Otherwise, let  $prod2$  be the value 0.

If bit 3 of  $PMSK$  is equal to 1, let  $prod3$  be the product of the 4-bit signed integer value in nibble 3 of word element  $i$  of  $VSR[XA]$  ( $X[i][3]$ ) and the 4-bit signed integer value in nibble 3 of word element  $j$  of  $VSR[XB]$  ( $Y[j][3]$ ), sign-extended to 32 bits. Otherwise, let  $prod3$  be the value 0.

If bit 4 of  $PMSK$  is equal to 1, let  $prod4$  be the product of the 4-bit signed integer value in nibble 4 of word element  $i$  of  $VSR[XA]$  ( $X[i][4]$ ) and the 4-bit signed integer value in nibble 4 of word element  $j$  of  $VSR[XB]$  ( $Y[j][4]$ ), sign-extended to 32 bits. Otherwise, let  $prod4$  be the value 0.

If bit 5 of  $PMSK$  is equal to 1, let  $prod5$  be the product of the 4-bit signed integer value in nibble 5 of word element  $i$  of  $VSR[XA]$  ( $X[i][5]$ ) and the 4-bit signed integer value in nibble 5 of word element  $j$  of  $VSR[XB]$  ( $Y[j][5]$ ), sign-extended to 32 bits. Otherwise, let  $prod5$  be the value 0.

If bit 6 of  $PMSK$  is equal to 1, let  $prod6$  be the product of the 4-bit signed integer value in nibble 6 of word element  $i$  of  $VSR[XA]$  ( $X[i][6]$ ) and the 4-bit signed integer value in nibble 6 of word element  $j$  of  $VSR[XB]$  ( $Y[j][6]$ ), sign-extended to 32 bits. Otherwise, let  $prod6$  be the value 0.

If bit 7 of  $PMSK$  is equal to 1, let  $prod7$  be the product of the 4-bit signed integer value in nibble 7 of word element  $i$  of  $VSR[XA]$  ( $X[i][7]$ ) and the 4-bit signed integer value in nibble 7 of word element  $j$  of  $VSR[XB]$  ( $Y[j][7]$ ), sign-extended to 32 bits. Otherwise, let  $prod7$  be the value 0.

Let  $psum$  be the sum of  $prod0$ ,  $prod1$ ,  $prod2$ ,  $prod3$ ,  $prod4$ ,  $prod5$ ,  $prod6$ , and  $prod7$ .

For *[pm]xvi4ger8*,  $psum$  is placed into word element  $j$  of  $ACC[AT][i]$  in 32-bit signed integer format.

For *[pm]xvi4ger8pp*,  $psum$  is added to the 32-bit signed integer value in word element  $j$  of  $ACC[AT][i]$ , and the result is placed into word element  $j$  of  $ACC[AT][i]$  in 32-bit signed integer format.

Otherwise, let  $ACC[AT][i][j]$  is set to  $0x0000_0000$ .

Let XA be the value of  $32 \times AX + A$ . If XA is in the range  $4 \times AT$  to  $4 \times AT + 3$ , the instruction form is invalid.

Let XB be the value of  $32 \times BX + B$ . If XB is in the range  $4 \times AT$  to  $4 \times AT + 3$ , the instruction form is invalid.

Let the contents of ACC[AT] be a  $4 \times 4$  matrix of 32-bit signed integer values.

For *xvi8ger4spp*, let PMSK=0b1111, XMSK=0b1111, and YMSK=0b1111.

For each integer value *i* from 0 to 3, and each integer value *j* from 0 to 3, do the following.

If bit *i* of XMSK is equal to 1 and bit *j* of YMSK is equal to 1, do the following.

If bit 0 of PMSK is equal to 1, let prod0 be the product of the 8-bit signed integer value in byte 0 of word element *i* of VSR[XA] ( $X[i][0]$ ) and the 8-bit unsigned integer value in byte 0 of word element *j* of VSR[XB] ( $Y[j][0]$ ), sign-extended to 32 bits. Otherwise, let prod0 be the value 0.

If bit 1 of PMSK is equal to 1, let prod1 be the product of the 8-bit signed integer value in byte 1 of word element *i* of VSR[XA] ( $X[i][1]$ ) and the 8-bit unsigned integer value in byte 1 of word element *j* of VSR[XB] ( $Y[j][1]$ ), sign-extended to 32 bits. Otherwise, let prod1 be the value 0.

If bit 2 of PMSK is equal to 1, let prod2 be the product of the 8-bit signed integer value in byte 2 of word element  $i$  of VSR[XA] ( $X[i][2]$ ) and the 8-bit unsigned integer value in byte 2 of word element  $j$  of VSR[XB] ( $Y[j][2]$ ), sign-extended to 32 bits. Otherwise, let prod2 be the value 0.

If bit 3 of PMSK is equal to 1, let prod3 be the product of the 8-bit signed integer value in byte 3 of word element  $i$  of VSR[XA] ( $X[i][3]$ ) and the 8-bit unsigned integer value in byte 3 of word element  $j$  of VSR[XB] ( $Y[j][3]$ ), sign-extended to 32 bits. Otherwise, let prod3 be the value 0.

Let psum be the sum of prod0, prod1, prod2, and prod3.

psum is added to the 32-bit signed integer value in word element  $j$  of ACC[AT][ $i$ ] and the result is placed into word element  $j$  of ACC[AT][ $i$ ] in 32-bit signed integer format.

If the result is less than  $-2^{31}$ , the result saturates to  $-2^{31}$  and SAT is set to 1.

If the result is greater than  $2^{31}-1$ , the result saturates to  $2^{31}-1$  and SAT is set to 1.

Otherwise, let word element  $j$  of ACC[AT][ $i$ ] is set to 0x0000\_0000.

### Programming Note

Let  $X$  be the  $4 \times 4$  matrix of 8-bit signed integer values contained in VSR[XA] in row-major format.  
 Let  $Y$  be the  $4 \times 4$  matrix of 8-bit unsigned integer values contained in VSR[XB] in row-major format.  
 Let ACC[AT] be the Accumulator containing a  $4 \times 4$  matrix of 32-bit signed integer values.

[pm]xvi8ger4 performs the following form of accumulation of four outer products (rank 4 update).

$$\text{ACC}[i][j] = \text{si\_32\_CHOP}(\text{EXTS}(X[i][0]) * \text{EXTZ}(Y[j][0]) + \\ \text{EXTS}(X[i][1]) * \text{EXTZ}(Y[j][1]) + \\ \text{EXTS}(X[i][2]) * \text{EXTZ}(Y[j][2]) + \\ \text{EXTS}(X[i][3]) * \text{EXTZ}(Y[j][3]))$$

Note that a saturating form of the above accumulation is not needed nor provided since the sum of four 16-bit signed integer products cannot overflow the 32-bit signed integer format.

[pm]xvi8ger4spp performs the following form of accumulation of four outer products (rank 4 update).

$$\text{ACC}[i][j] = \text{si\_32\_CLAMP}(\text{EXTS}(X[i][0]) * \text{EXTZ}(Y[j][0]) + \\ \text{EXTS}(X[i][1]) * \text{EXTZ}(Y[j][1]) + \\ \text{EXTS}(X[i][2]) * \text{EXTZ}(Y[j][2]) + \\ \text{EXTS}(X[i][3]) * \text{EXTZ}(Y[j][3]) + \\ \text{EXTS}(\text{ACC}[i][j]))$$

Let  $XA$  be the value of  $32 \times AX + A$ . If  $XA$  is in the range  $4 \times AT$  to  $4 \times AT + 3$ , the instruction form is invalid.  
Let  $XB$  be the value of  $32 \times BX + B$ . If  $XB$  is in the range  $4 \times AT$  to  $4 \times AT + 3$ , the instruction form is invalid.

Let the contents of  $ACC[AT]$  be a  $4 \times 4$  matrix of 32-bit signed integer values.

For *xvi16ger2* or *xvi16ger2pp*, let  $PMSK=0b11$ ,  $XMSK=0b1111$ , and  $YMSK=0b1111$ .

For each integer value  $i$  from 0 to 3 and each integer value  $j$  from 0 to 3, do the following.

If bit  $i$  of  $XMSK$  is equal to 1 and bit  $j$  of  $YMSK$  is equal to 1, do the following.

If bit 0 of  $PMSK$  is equal to 1, let  $prod0$  be the product of the 16-bit signed integer value in halfword 0 of word element  $i$  of  $VSR[XA]$  and the 16-bit signed integer value in halfword 0 of word element  $j$  of  $VSR[XB]$ .  
Otherwise, let  $prod0$  be the value 0.

If bit 1 of  $PMSK$  is equal to 1, let  $prod1$  be the product of the 16-bit signed integer value in halfword 1 of word element  $i$  of  $VSR[XA]$  and the 16-bit signed integer value in halfword 1 of word element  $j$  of  $VSR[XB]$ .  
Otherwise, let  $prod1$  be the value 0.

Let  $psum$  be the sum of  $prod0$  and  $prod1$ .

For *[pm]xvi16ger2*,  $psum$  is placed into word element  $j$  of  $ACC[AT][i]$  in 32-bit signed integer format.

For *[pm]xvi16ger2pp*,  $psum$  is added to the 32-bit signed integer value in word element  $j$  of  $ACC[AT][i]$ , and the result is placed into word element  $j$  of  $ACC[AT][i]$  in 32-bit signed integer format.

Otherwise, let  $ACC[AT][i][j]$  is set to  $0x0000_0000$ .

- Let src3 be the double-precision floating-point operand in doubleword element  $i$  of VSR[XB].

For **xvmaddmdp**, do the following.

- Let src1 be the double-precision floating-point operand in doubleword element  $i$  of VSR[XA].
- Let src2 be the double-precision floating-point operand in doubleword element  $i$  of VSR[XB].
- Let src3 be the double-precision floating-point operand in doubleword element  $i$  of VSR[XT].

src1 is multiplied<sup>[1]</sup> by src3, producing a product having unbounded range and precision.

See part 1 of Table 126.

src2 is added<sup>[2]</sup> to the product, producing a sum having unbounded range and precision.

The sum is normalized<sup>[3]</sup>.

See part 2 of Table 126.

The intermediate result is rounded to double-precision using the rounding mode specified by RN.

See Table 62, “Scalar Floating-Point Intermediate Result Handling,” on page 669.

The result is placed into doubleword element  $i$  of VSR[XT] in double-precision format.

See Table 114, “Vector Floating-Point Final Result,” on page 832.

If a trap-enabled exception occurs in any element of the vector, no results are written to VSR[XT].

### Special Registers Altered

FX OX UX XX VXSNAN VXISI VXIMZ

1. Floating-point multiplication is based on exponent addition and multiplication of the significands.
2. Floating-point addition is based on exponent comparison and addition of the two significands. The exponents of the two operands are compared, and the significand accompanying the smaller exponent is shifted right, with its exponent increased by one for each bit shifted, until the two exponents are equal. The two significands are then added or subtracted as appropriate, depending on the signs of the operands, to form an intermediate sum. All 53 bits of the significand as well as all three guard bits (G, R, and X) enter into the computation.
3. Floating-point normalization is based on shifting the significand left until the most-significant bit is 1 and decrementing the exponent by the number of bits the significand was shifted.

**Explanation:**

src1 The double-precision floating-point value in doubleword element *i* of VSR[XA] (where  $i = \{0, 1\}$ ).

src2 For *xvmaddadp*, the double-precision floating-point value in doubleword element *i* of VSR[XT] (where  $i = \{0, 1\}$ ). For *xvmaddmdp*, the double-precision floating-point value in doubleword element *i* of VSR[XB] (where  $i = \{0, 1\}$ ).

src3 For *xvmaddadp*, the double-precision floating-point value in doubleword element *i* of VSR[XB] (where  $i = \{0, 1\}$ ). For *xvmaddmdp*, the double-precision floating-point value in doubleword element *i* of VSR[XT] (where  $i = \{0, 1\}$ ).

dQNaN Default quiet NaN (0x7FF8\_0000\_0000\_0000).

NZF Nonzero finite number.

Rezd Exact-zero-difference result (addition of two finite numbers having same magnitude but different signs). Can also occur with two nonzero finite number source operands.

Q(x) Return a QNaN with the payload of *x*.

A(x, y) Return the normalized sum of floating-point value *x* and floating-point value *y*, having unbounded range and precision.  
Note: If  $x = -y$ , *v* is considered to be an exact-zero-difference result (Rezd).

M(x, y) Return the normalized product of floating-point value *x* and floating-point value *y*, having unbounded range and precision.

p The intermediate product having unbounded range and precision.

v The intermediate result having unbounded range and precision.

```

Let XT be the value  $32 \times TX + T$ .

Let XA be the value  $32 \times AX + A$ .

Let XB be the value  $32 \times BX + B$ .

For each integer value  $i$  from 0 to 3, do the following.

For **xvmaddasp**, do the following.

- Let src1 be the single-precision floating-point operand in word element  $i$  of VSR[XA].
- Let src2 be the single-precision floating-point operand in word element  $i$  of VSR[XT].
- Let src3 be the single-precision floating-point operand in word element  $i$  of VSR[XB].

For **xvmaddmsp**, do the following.

- Let src1 be the single-precision floating-point operand in word element  $i$  of VSR[XA].
- Let src2 be the single-precision floating-point operand in word element  $i$  of VSR[XB].
- Let src3 be the single-precision floating-point operand in word element  $i$  of VSR[XT].

src1 is multiplied<sup>[1]</sup> by src3, producing a product having unbounded range and precision.

See part 1 of Table 127.

src2 is added<sup>[2]</sup> to the product, producing a sum having unbounded range and precision.

The sum is normalized<sup>[3]</sup>.

See part 2 of Table 127.

The intermediate result is rounded to single-precision using the rounding mode specified by RN.

See Table 62, “Scalar Floating-Point Intermediate Result Handling,” on page 669.

The result is placed into word element  $i$  of VSR[XT] in single-precision format.

See Table 114, “Vector Floating-Point Final Result,” on page 832.

If a trap-enabled exception occurs in any element of the vector, no results are written to VSR[XT].

For each integer value  $i$  from 0 to 1, do the following.

Let  $src1$  be the double-precision floating-point operand in doubleword element  $i$  of  $VSR[XA]$ .

Let  $src2$  be the double-precision floating-point operand in doubleword element  $i$  of  $VSR[XB]$ .

If  $src1$  is greater than  $src2$ ,  $src1$  is placed into doubleword element  $i$  of  $VSR[XT]$  in double-precision format. Otherwise,  $src2$  is placed into doubleword element  $i$  of  $VSR[XT]$  in double-precision format.

The maximum of +0 and -0 is +0. The maximum of a QNaN and any value is that value. The maximum of any value and an SNaN when  $VE=0$  is that SNaN converted to a QNaN.

See Table 128.

If a trap-enabled exception occurs in any element of the vector, no results are written to  $VSR[XT]$ .

Let XT be the value  $32 \times TX + T$ .

Let XA be the value  $32 \times AX + A$ .

Let XB be the value  $32 \times BX + B$ .

For each integer value i from 0 to 1, do the following.

For **xvmsubadp**, do the following.

- Let src1 be the double-precision floating-point operand in doubleword element i of VSR[XA].
- Let src2 be the double-precision floating-point operand in doubleword element i of VSR[XT].
- Let src3 be the double-precision floating-point operand in doubleword element i of VSR[XB].

For **xvmsubmdp**, do the following.

- Let src1 be the double-precision floating-point operand in doubleword element i of VSR[XA].
- Let src2 be the double-precision floating-point operand in doubleword element i of VSR[XB].
- Let src3 be the double-precision floating-point operand in doubleword element i of VSR[XT].

src1 is multiplied<sup>[1]</sup> by src3, producing a product having unbounded range and precision.

See part 1 of Table 132.

src2 is negated and added<sup>[2]</sup> to the product, producing a sum having unbounded range and precision.

The sum is normalized<sup>[3]</sup>.

See part 2 of Table 132.

The intermediate result is rounded to double-precision using the rounding mode specified by RN.

See Table 62, "Scalar Floating-Point Intermediate Result Handling," on page 669.

The result is placed into doubleword element i of VSR[XT] in double-precision format.

See Table 114, "Vector Floating-Point Final Result," on page 832.

If a trap-enabled exception occurs in any element of the vector, no results are written to VSR[XT].

#### Special Registers Altered

FX OX UX XX VXSNAN VXISI VXIMZ

1. Floating-point multiplication is based on exponent addition and multiplication of the significands.
2. Floating-point addition is based on exponent comparison and addition of the two significands. The exponents of the two operands are compared, and the significand accompanying the smaller exponent is shifted right, with its exponent increased by one for each bit shifted, until the two exponents are equal. The two significands are then added or subtracted as appropriate, depending on the signs of the operands, to form an intermediate sum. All 53 bits of the significand as well as all three guard bits (G, R, and X) enter into the computation.
3. Floating-point normalization is based on shifting the significand left until the most-significant bit is 1 and decrementing the exponent by the number of bits the significand was shifted.

**Explanation:**

src1	The double-precision floating-point value in doubleword element $i$ of VSR[XA] (where $i = \{0, 1\}$ ).
src2	For <i>xvmsubadp</i> , the double-precision floating-point value in doubleword element $i$ of VSR[XT] (where $i = \{0, 1\}$ ). For <i>xvmsubmdp</i> , the double-precision floating-point value in doubleword element $i$ of VSR[XB] (where $i = \{0, 1\}$ ).
src3	For <i>xvmsubadp</i> , the double-precision floating-point value in doubleword element $i$ of VSR[XB] (where $i = \{0, 1\}$ ). For <i>xvmsubmdp</i> , the double-precision floating-point value in doubleword element $i$ of VSR[XT] (where $i = \{0, 1\}$ ).
dQNaN	Default quiet NaN (0x7FF8_0000_0000_0000).
NZF	Nonzero finite number.
Rezd	Exact-zero-difference result (addition of two finite numbers having same magnitude but different signs). Can also occur with two nonzero finite number source operands.
Q(x)	Return a QNaN with the payload of $x$ .
S(x, y)	Return the normalized sum of floating-point value $x$ and negated floating-point value $y$ , having unbounded range and precision. Note: If $x = y$ , $v$ is considered to be an exact-zero-difference result (Rezd).
M(x, y)	Return the normalized product of floating-point value $x$ and floating-point value $y$ , having unbounded range and precision.
p	The intermediate product having unbounded range and precision.
v	The intermediate result having unbounded range and precision.

end

if ex_flag=0 then VSR[32×TX+T] ← result

```

Let XT be the value  $32 \times TX + T$ .

Let XA be the value  $32 \times AX + A$ .

Let XB be the value  $32 \times BX + B$ .

For each integer value  $i$  from 0 to 3, do the following.

For **xvmsubasp**, do the following.

- Let src1 be the single-precision floating-point operand in word element  $i$  of VSR[XA].
- Let src2 be the single-precision floating-point operand in word element  $i$  of VSR[XT].
- Let src3 be the single-precision floating-point operand in word element  $i$  of VSR[XB].

For **xvmsubmsp**, do the following.

- Let src1 be the single-precision floating-point operand in word element  $i$  of VSR[XA].
- Let src2 be the single-precision floating-point operand in word element  $i$  of VSR[XB].
- Let src3 be the single-precision floating-point operand in word element  $i$  of VSR[XT].

src1 is multiplied<sup>[1]</sup> by src3, producing a product having unbounded range and precision.

See part 1 of Table 133.

src2 is negated and added<sup>[2]</sup> to the product, producing a sum having unbounded range and precision.

The sum is normalized<sup>[3]</sup>.

See part 2 of Table 133.

The intermediate result is rounded to single-precision using the rounding mode specified by RN.

See Table 62, “Scalar Floating-Point Intermediate Result Handling,” on page 669.

The result is placed into word element  $i$  of VSR[XT] in single-precision format.

See Table 114, “Vector Floating-Point Final Result,” on page 832.

If a trap-enabled exception occurs in any element of the vector, no results are written to VSR[XT].

### Special Registers Altered

FX OX UX XX VXSAN VXISI VXIMZ

1. Floating-point multiplication is based on exponent addition and multiplication of the significands.
2. Floating-point addition is based on exponent comparison and addition of the two significands. The exponents of the two operands are compared, and the significand accompanying the smaller exponent is shifted right, with its exponent increased by one for each bit shifted, until the two exponents are equal. The two significands are then added or subtracted as appropriate, depending on the signs of the operands, to form an intermediate sum. All 53 bits of the significand as well as all three guard bits (G, R, and X) enter into the computation.
3. Floating-point normalization is based on shifting the significand left until the most-significant bit is 1 and decrementing the exponent by the number of bits the significand was shifted.

**Explanation:**

src1	The double-precision floating-point value in doubleword element $i$ of $\text{VSR}[XA]$ (where $i = \{0, 1\}$ ).
src2	The double-precision floating-point value in doubleword element $i$ of $\text{VSR}[XB]$ (where $i = \{0, 1\}$ ).
dQNaN	Default quiet NaN (0x7FF8_0000_0000_0000).
NZF	Nonzero finite number.
$M(x, y)$	Return the normalized product of floating-point value $x$ and floating-point value $y$ , having unbounded range and precision.
$Q(x)$	Return a QNaN with the payload of $x$ .
$v$	The intermediate result having unbounded significand precision and unbounded exponent range.

Let XT be the value  $32 \times TX + T$ .

Let XA be the value  $32 \times AX + A$ .

Let XB be the value  $32 \times BX + B$ .

For each integer value  $i$  from 0 to 3, do the following.

Let src1 be the single-precision floating-point operand in word element  $i$  of VSR[XA].

Let src2 be the single-precision floating-point operand in word element  $i$  of VSR[XB].

src1 is multiplied<sup>[1]</sup> by src2, producing a product having unbounded range and precision.

The product is normalized<sup>[2]</sup>.

See Table 135.

The intermediate result is rounded to single-precision using the rounding mode specified by RN.

See Table 62, “Scalar Floating-Point Intermediate Result Handling,” on page 669.

The result is placed into word element  $i$  of VSR[XT] in single-precision format.

See Table 114, “Vector Floating-Point Final Result,” on page 832.

If a trap-enabled exception occurs in any element of the vector, no results are written to VSR[XT].

Let XT be the value  $32 \times TX + T$ .

Let XA be the value  $32 \times AX + A$ .

Let XB be the value  $32 \times BX + B$ .

For each integer value  $i$  from 0 to 1, do the following.

For **xvnmaddadp**, do the following.

- Let src1 be the double-precision floating-point operand in doubleword element  $i$  of VSR[XA].
- Let src2 be the double-precision floating-point operand in doubleword element  $i$  of VSR[XT].
- Let src3 be the double-precision floating-point operand in doubleword element  $i$  of VSR[XB].

For **xvnmaddmdp**, do the following.

- Let src1 be the double-precision floating-point operand in doubleword element  $i$  of VSR[XA].
- Let src2 be the double-precision floating-point operand in doubleword element  $i$  of VSR[XB].
- Let src3 be the double-precision floating-point operand in doubleword element  $i$  of VSR[XT].

src1 is multiplied<sup>[1]</sup> by src3, producing a product having unbounded range and precision.

See part 1 of Table 136.

src2 is added<sup>[2]</sup> to the product, producing a sum having unbounded range and precision.

The sum is normalized<sup>[3]</sup>.

See part 2 of Table 136.

The intermediate result is rounded to double-precision using the rounding mode specified by RN.

See Table 62, “Scalar Floating-Point Intermediate Result Handling,” on page 669.

The result is negated and placed into doubleword element  $i$  of VSR[XT] in double-precision format.

See Table 137, “Vector Floating-Point Final Result with Negation,” on page 935.

If a trap-enabled exception occurs in any element of the vector, no results are written to VSR[XT].

**Special Registers Altered**

FX OX UX XX VXSNAN VXISI VXIMZ

1. Floating-point multiplication is based on exponent addition and multiplication of the significands.
2. Floating-point addition is based on exponent comparison and addition of the two significands. The exponents of the two operands are compared, and the significand accompanying the smaller exponent is shifted right, with its exponent increased by one for each bit shifted, until the two exponents are equal. The two significands are then added or subtracted as appropriate, depending on the signs of the operands, to form an intermediate sum. All 53 bits of the significand as well as all three guard bits (G, R, and X) enter into the computation.
3. Floating-point normalization is based on shifting the significand left until the most-significant bit is 1 and decrementing the exponent by the number of bits the significand was shifted.

**Explanation:**

src1 The double-precision floating-point value in doubleword element *i* of VSR[XA] (where  $i = \{0, 1\}$ ).

src2 For *xvnmaddadp*, the double-precision floating-point value in doubleword element *i* of VSR[XT] (where  $i = \{0, 1\}$ ). For *xvnmaddmdp*, the double-precision floating-point value in doubleword element *i* of VSR[XB] (where  $i = \{0, 1\}$ ).

src3 For *xvnmaddadp*, the double-precision floating-point value in doubleword element *i* of VSR[XB] (where  $i = \{0, 1\}$ ). For *xvnmaddmdp*, the double-precision floating-point value in doubleword element *i* of VSR[XT] (where  $i = \{0, 1\}$ ).

dQNaN Default quiet NaN (0x7FF8\_0000\_0000\_0000).

NZF Nonzero finite number.

Rezd Exact-zero-difference result (addition of two finite numbers having same magnitude but different signs). Can also occur with two nonzero finite number source operands.

Q(x) Return a QNaN with the payload of *x*.

A(x, y) Return the normalized sum of floating-point value *x* and floating-point value *y*, having unbounded range and precision.  
Note: If  $x = -y$ , *v* is considered to be an exact-zero-difference result (Rezd).

M(x, y) Return the product of floating-point value *x* and floating-point value *y*, having unbounded range and precision.

p The intermediate product having unbounded range and precision.

v The intermediate result having unbounded range and precision.

	-	-	1	-	-	-	-	-	yes	-	yes	yes	fx(UX), fx(XX), error()

**Explanation:**

- The results do not depend on this condition.
- error() The system error handler is invoked for the trap-enabled exception if MSR.FE0 and MSR.FE1 are set to any mode other than the ignore-exception mode. Update of the target VSR is suppressed for all vector elements.
- fx(x) FPSCR.FX is set to 1 if FPSCR.x=0. FPSCR.x is set to 1.
- q The value defined in Table 62, "Scalar Floating-Point Intermediate Result Handling," on page 669, significand rounded to the target precision, unbounded exponent range.
- r The value defined in Table 62, "Scalar Floating-Point Intermediate Result Handling," on page 669, significand rounded to the target precision, bounded exponent range.
- v The precise intermediate result defined in the instruction having unbounded significand precision, unbounded exponent range.
- N(x) The value x is negated by complementing the sign bit of x.
- T(x) The value x is placed in element i of VSR[XT] in the target precision format (where i={0, 1} for results with 64-bit elements, and i={0, 1, 3, 4} for results with 32-bit elements).

end

if ex\_flag=0 then VSR[32×TX+T] ← vresult

Let XT be the value  $32 \times TX + T$ .

Let XA be the value  $32 \times AX + A$ .

Let XB be the value  $32 \times BX + B$ .

For each integer value i from 0 to 3, do the following.

For **xvnmaddasp**, do the following.

- Let src1 be the single-precision floating-point operand in word element i of VSR[XA].
- Let src2 be the single-precision floating-point operand in word element i of VSR[XT].
- Let src3 be the single-precision floating-point operand in word element i of VSR[XB].

For **xvnmaddmsp**, do the following.

- Let src1 be the single-precision floating-point operand in word element i of VSR[XA].
- Let src2 be the single-precision floating-point operand in word element i of VSR[XB].
- Let src3 be the single-precision floating-point operand in word element i of VSR[XT].

src1 is multiplied<sup>[1]</sup> by src3, producing a product having unbounded range and precision.

See part 1 of Table 138.

src2 is added<sup>[2]</sup> to the product, producing a sum having unbounded range and precision.

The sum is normalized<sup>[3]</sup>.

See part 2 of Table 138.

The intermediate result is rounded to single-precision using the rounding mode specified by RN.

See Table 62, “Scalar Floating-Point Intermediate Result Handling,” on page 669.

The result is negated and placed into word element i of VSR[XT] in single-precision format.

See Table 137, “Vector Floating-Point Final Result with Negation,” on page 935.

If a trap-enabled exception occurs in any element of the vector, no results are written to VSR[XT].

#### Special Registers Altered

FX OX UX XX VXSNAN VXISI VXIMZ

1. Floating-point multiplication is based on exponent addition and multiplication of the significands.
2. Floating-point addition is based on exponent comparison and addition of the two significands. The exponents of the two operands are compared, and the significand accompanying the smaller exponent is shifted right, with its exponent increased by one for each bit shifted, until the two exponents are equal. The two significands are then added or subtracted as appropriate, depending on the signs of the operands, to form an intermediate sum. All 53 bits of the significand as well as all three guard bits (G, R, and X) enter into the computation.
3. Floating-point normalization is based on shifting the significand left until the most-significant bit is 1 and decrementing the exponent by the number of bits the significand was shifted.

end
```

```
if ex_flg=0 then VSR[32×TX+T] ← vresult
```

Let XT be the value  $32 \times TX + T$ .

Let XA be the value  $32 \times AX + A$ .

Let XB be the value  $32 \times BX + B$ .

For each integer value  $i$  from 0 to 1, do the following.

For **xvnmsubadp**, do the following.

- Let src1 be the double-precision floating-point operand in doubleword element  $i$  of VSR[XA].
- Let src2 be the double-precision floating-point operand in doubleword element  $i$  of VSR[XT].
- Let src3 be the double-precision floating-point operand in doubleword element  $i$  of VSR[XB].

For **xvnmsubmdp**, do the following.

- Let src1 be the double-precision floating-point operand in doubleword element  $i$  of VSR[XA].
- Let src2 be the double-precision floating-point operand in doubleword element  $i$  of VSR[XB].
- Let src3 be the double-precision floating-point operand in doubleword element  $i$  of VSR[XT].

src1 is multiplied<sup>[1]</sup> by src3, producing a product having unbounded range and precision.

See part 1 of Table 139.

src2 is negated and added<sup>[2]</sup> to the product, producing a sum having unbounded range and precision.

The sum is normalized<sup>[3]</sup>.

See part 2 of Table 139.

The intermediate result is rounded to double-precision using the rounding mode specified by RN.

See Table 62, “Scalar Floating-Point Intermediate Result Handling,” on page 669.

The result is negated and placed into doubleword element  $i$  of VSR[XT] in double-precision format.

See Table 137, “Vector Floating-Point Final Result with Negation,” on page 935.

If a trap-enabled exception occurs in any element of the vector, no results are written to VSR[XT].

**Special Registers Altered**

FX OX UX XX VXSNAN VXISI VXIMZ

1. Floating-point multiplication is based on exponent addition and multiplication of the significands.
2. Floating-point addition is based on exponent comparison and addition of the two significands. The exponents of the two operands are compared, and the significand accompanying the smaller exponent is shifted right, with its exponent increased by one for each bit shifted, until the two exponents are equal. The two significands are then added or subtracted as appropriate, depending on the signs of the operands, to form an intermediate sum. All 53 bits of the significand as well as all three guard bits (G, R, and X) enter into the computation.
3. Floating-point normalization is based on shifting the significand left until the most-significant bit is 1 and decrementing the exponent by the number of bits the significand was shifted.

**Explanation:**

src1	The double-precision floating-point value in doubleword element $i$ of VSR[XA] (where $i=\{0,1\}$ ).
src2	For <i>xvnmsubadp</i> , the double-precision floating-point value in doubleword element $i$ of VSR[XT] (where $i=\{0,1\}$ ). For <i>xvnmsubmdp</i> , the double-precision floating-point value in doubleword element $i$ of VSR[XB] (where $i=\{0,1\}$ ).
src3	For <i>xvnmsubadp</i> , the double-precision floating-point value in doubleword element $i$ of VSR[XB] (where $i=\{0,1\}$ ). For <i>xvnmsubmdp</i> , the double-precision floating-point value in doubleword element $i$ of VSR[XT] (where $i=\{0,1\}$ ).
dQNaN	Default quiet NaN (0x7FF8_0000_0000_0000).
NZF	Nonzero finite number.
Rezd	Exact-zero-difference result (addition of two finite numbers having same magnitude but different signs). Can also occur with two nonzero finite number source operands.
Q(x)	Return a QNaN with the payload of $x$ .
S(x,y)	Return the normalized sum of floating-point value $x$ and negated floating-point value $y$ , having unbounded range and precision. Note: If $x = -y$ , $v$ is considered to be an exact-zero-difference result (Rezd).
M(x,y)	Return the normalized product of floating-point value $x$ and floating-point value $y$ , having unbounded range and precision.
p	The intermediate product having unbounded range and precision.
v	The intermediate result having unbounded range and precision.

Let XT be the value  $32 \times TX + T$ .

Let XA be the value  $32 \times AX + A$ .

Let XB be the value  $32 \times BX + B$ .

For each integer value  $i$  from 0 to 3, do the following.

For **xvnmsubasp**, do the following.

- Let src1 be the single-precision floating-point operand in word element  $i$  of VSR[XA].
- Let src2 be the single-precision floating-point operand in word element  $i$  of VSR[XT].
- Let src3 be the single-precision floating-point operand in word element  $i$  of VSR[XB].

For **xvnmsubmsp**, do the following.

- Let src1 be the single-precision floating-point operand in word element  $i$  of VSR[XA].
- Let src2 be the single-precision floating-point operand in word element  $i$  of VSR[XB].
- Let src3 be the single-precision floating-point operand in word element  $i$  of VSR[XT].

src1 is multiplied<sup>[1]</sup> by src3, producing a product having unbounded range and precision.

See part 1 of Table 140.

src2 is negated and added<sup>[2]</sup> to the product, producing a sum having unbounded range and precision.

The sum is normalized<sup>[3]</sup>.

See part 2 of Table 140.

The intermediate result is rounded to single-precision using the rounding mode specified by RN.

See Table 62, “Scalar Floating-Point Intermediate Result Handling,” on page 669.

The result is negated and placed into word element  $i$  of VSR[XT] in single-precision format.

See Table 137, “Vector Floating-Point Final Result with Negation,” on page 935.

If a trap-enabled exception occurs in any element of the vector, no results are written to VSR[XT].

Let XT be the value 32×TX + T.

Let XB be the value 32×BX + B.

For each integer value i from 0 to 3, do the following.  
Let src be the single-precision floating-point operand in word element i of VSR[XB].

A single-precision floating-point estimate of the reciprocal square root of src is placed into word element i of VSR[XT] in single-precision format.

Unless the reciprocal of the square root of src would be a zero, an infinity, or a QNaN, the estimate has a relative error in precision no greater than one part in 16384 of the reciprocal of the square root of src. That is,

$$\left| \frac{\text{estimate} - \frac{1}{\sqrt{\text{src}}}}{\frac{1}{\sqrt{\text{src}}}} \right| \leq \frac{1}{16384}$$

Operation with various special values of the operand is summarized below.

Source Value	Result	Exception
−Infinity	QNaN <sup>1</sup>	VXSQRT
+Infinity	+Zero	None
−Finite	QNaN <sup>1</sup>	VXSQRT
−Zero	−Infinity <sup>2</sup>	ZX
+Zero	+Infinity <sup>2</sup>	ZX
SNaN	QNaN <sup>1</sup>	VXSNAN
QNaN	QNaN	None

1. No result if VE=1.
2. No result if ZE=1.

If a trap-enabled exception occurs in any element of the vector, no results are written to VSR[XT].

The results of executing this instruction is permitted to vary between implementations, and between different executions on the same implementation.

- Floating-point addition is based on exponent comparison and addition of the two significands. The exponents of the two operands are compared, and the significand accompanying the smaller exponent is shifted right, with its exponent increased by one for each bit shifted, until the two exponents are equal. The two significands are then added or subtracted as appropriate, depending on the signs of the operands, to form an intermediate sum. All 53 bits of the significand as well as all three guard bits (G, R, and X) enter into the computation.
- Floating-point normalization is based on shifting the significand left until the most-significant bit is 1 and decrementing the exponent by the number of bits the significand was shifted.

**Programming Note**

The following is an example of how a *Load VSX Vector and Expand Byte*, when using Big-Endian byte-ordering, can be emulated using *VSX Vector Generate PCV from Mask Byte*.

```

xxgenpcvbm vPCV, vMASK, 0b00000 // generates the required permute control vector for Big-Endian expansion
vcntmbb   vN, vMASK, 0b1 // calculates N, number of true byte-mask elements
lxvl      vLD, EA, rN // loads N bytes

// Option 1: expand & merge
xxperm    vT, vLD, vT, vPCV // perform the expansion,
// specifying vT as 2nd source operand causes expanded load data to be
// merged into VSR[vT]

// Option 2: expand & zero
xxperm    vT, vLD, vZERO, vPCV // perform the expansion,
// specifying vZERO (vector of 0s) as 2nd source operand causes expanded
// load data to be placed into VSR[vT] with other elements set to 0

```

The following is an example of how a *Load VSX Vector Expand Byte*, when using Little-Endian byte-ordering, can be emulated using *VSX Vector Generate PCV from Mask Byte*.

```

xxgenpcvbm vPCV, vMASK, 0b00010 // generates the required permute control vector for Big-Endian expansion
vcntmbb   vN, vMASK, 0b1 // calculates N, number of true byte-mask elements
lxvl      vLD, EA, rN // loads N bytes

// Option 1: expand & merge
xxpermr   vT, vLD, vT, vPCV // perform the expansion,
// specifying vT as 2nd source operand causes expanded load data to be
// merged into VSR[vT]

// Option 2: expand & zero
xxpermr   vT, vLD, vZERO, vPCV // perform the expansion,
// specifying vZERO (vector of 0s) as 2nd source operand causes expanded
// load data to be placed into VSR[vT] with other elements set to 0

```

The following is an example of how a *VSX Vector Compress Byte and Store*, when using Big-Endian byte-ordering, can be emulated using *VSX Vector Generate PCV from Mask Byte*.

```

xxgenpcvbm vPCV, vMASK, 0b00001 // generates the required permute control vector for Big-Endian compression
vcntmbb   vN, vMASK, 0b1 // calculates N, number of true byte-mask elements
xxperm    vSD, vS, vS, vPCV // perform the compression
stxvl     vSD, rEA, rN // store N bytes

```

The following is an example of how a *VSX Vector Byte Compress and Store*, when using Little-Endian byte-ordering, can be emulated using *VSX Vector Generate PCV from Mask*.

```

xxgenpcvbm vPCV, vMASK, 0b00011 // generates the required permute control vector for Big-Endian compression
vcntmbb   vN, vMASK, 0b1 // calculates N, number of true byte-mask elements
xxpermr   vSD, vS, vS, vPCV // perform the compression
stxvl     vSD, rEA, rN // store N bytes

```

**Programming Note**

The following is an example of how a *Load VSX Vector Expand Doubleword*, when using Big-Endian byte-ordering, can be emulated using *VSX Vector Generate PCV from Mask Doubleword*.

```

xxgenpcvdm vPCV, vMASK, 0b00000 // generates the required permute control vector for Big-Endian expansion
vcntmbd   rN, vMASK, 0b1 // calculates N, number of true doubleword-mask elements, adjusted to # of bytes
lxvl      vLD, EA, rN // loads 8xN bytes

// Option 1: expand & merge
xxperm    vT, vLD, vT, vPCV // perform the expansion,
                             // specifying vT as 2nd source operand causes expanded load data to be
                             // merged into VSR[vT]

// Option 2: expand & zero
xxperm    vT, vLD, vZERO, vPCV // perform the expansion,
                                // specifying vZERO (vector of 0s) as 2nd source operand causes expanded
                                // load data to be placed into VSR[vT] with other elements set to 0

```

The following is an example of how a *Load VSX Vector Expand Doubleword*, when using Little-Endian byte-ordering, can be emulated using *VSX Vector Generate PCV from Mask Doubleword*.

```

xxgenpcvdm vPCV, vMASK, 0b00010 // generates the required permute control vector for Little-Endian expansion
vcntmbd   rN, vMASK, 0b1 // calculates N, number of true doubleword-mask elements, adjusted to # of bytes
lxvl      vLD, EA, rN // loads 8xN bytes

// Option 1: expand & merge
xxpermr   vT, vLD, vT, vPCV // perform the expansion,
                             // specifying vT as 2nd source operand causes expanded load data to be
                             // merged into VSR[vT]

// Option 2: expand & zero
xxpermr   vT, vLD, vZERO, vPCV // perform the expansion,
                                // specifying vZERO (vector of 0s) as 2nd source operand causes expanded
                                // load data to be placed into VSR[vT] with other elements set to 0

```

The following is an example of how a *Store VSX Vector Compress Doubleword*, when using Big-Endian byte-ordering, can be emulated using *VSX Vector Generate PCV from Mask Doubleword*.

```

xxgenpcvdm vPCV, vMASK, 0b00001 // generates the required permute control vector for Big-Endian compression
vcntmbd   rN, vMASK, 0b1 // calculates N, number of true doubleword-mask elements, adjusted to # of bytes
xxperm    vSD, vS, vS, vPCV // perform the compression
stxvl     vSD, rEA, rN // store 8xN bytes

```

The following is an example of how a *Store VSX Vector Compress Doubleword*, when using Little-Endian byte-ordering, can be emulated using *VSX Vector Generate PCV from Mask Doubleword*.

```

xxgenpcvdm vPCV, vMASK, 0b00011 // generates the required permute control vector for Little-Endian compression
vcntmbd   rN, vMASK, 0b1 // calculates N, number of true doubleword-mask elements, adjusted to # of bytes
xxpermr   vSD, vS, vS, vPCV // perform the compression
stxvl     vSD, rEA, rN // store 8xN bytes

```

For each integer value *i* from 0 to 3, the contents of row *i* of ACC[AS] are placed into VSR[4×AS+*i*].

**Special Registers Altered:**

None

**Programming Note**

During extended periods of the execution of an application when there isn't any active use of the Accumulators and VSX Vector GER instructions, hardware may deactivate these facilities for power savings. Once deactivated, while any attempted execution of any *xxmfacc*, *xxmtacc*, *xxsetaccz*, or VSX Vector GER instruction will cause these facilities to become reactivated, this reactivation causes significant delay beyond the normal execution of these instructions. This delay can be avoided by periodically issuing an *xxmfacc* with AS=0 instruction during extended times that the facilities are not being used to keep the facilities activated. Since the contents of ACC[0] will be undefined after the first execution, performance on subsequent executions of *xxmfacc* 0 can be expected to be degraded compared to performance when the contents of ACC[0] are defined. As such, to keep the facilities activated, *xxmfacc* 0 should be used with attention to performance implications.

**Programming Note**

The following is an example of emulating 256-bit *xxperm*, where a 256-bit vector is contained in a pair of VSRs. The instruction is capable of emulating up to a 2048-bit *xxperm*.

```

vT0a = xxpermx(vA0, vA1, vC0, 0);
vT0b = xxpermx(vB0, vB1, vC0, 1);
vT1a = xxpermx(vA0, vA1, vC1, 0);
vT1b = xxpermx(vB0, vB1, vC1, 1);
vT0 = xxi or(vT0a, vT0b);
vT1 = xxi or(vT1a, vT1b);

```

**Programming Note**

The following is an example of a parallel table lookup. In this case, a 16-way SIMD 256-entry byte table lookup.

```

vT0 = xxpermx(vS0, vS1, vI NDEX, 0);
vT1 = xxpermx(vS2, vS3, vI NDEX, 1);
vT2 = xxpermx(vS4, vS5, vI NDEX, 2);
vT3 = xxpermx(vS6, vS7, vI NDEX, 3);
vT4 = xxpermx(vS8, vS9, vI NDEX, 4);
vT5 = xxpermx(vSA, vSB, vI NDEX, 5);
vT6 = xxpermx(vSC, vSD, vI NDEX, 6);
vT7 = xxpermx(vSE, vSF, vI NDEX, 7);

```

```

vT0 = xxi or(vT0, vT1);
vT1 = xxi or(vT2, vT3);
vT2 = xxi or(vT4, vT5);
vT3 = xxi or(vT6, vT7);

```

```

vT0 = xxi or(vT0, vT1);
vT1 = xxi or(vT2, vT3);

```

## Appendix B. Densely Packed Decimal

The trailing significand field of the decimal floating-point data format is encoded using Densely Packed Decimal (DPD). DPD encoding is a compression technique which supports the representation of decimal integers of arbitrary length. Translation operates on three Binary Coded Decimal (BCD) digits at a time compressing the 12 bits into 10 bits with an algorithm that

can be applied or reversed using simple Boolean operations. In the following examples, a 3-digit BCD number is represented as (abcd)(efgh)(ijklm), a 10-bit DPD number is represented as (pqr)(stu)(v)(wxy), and the Boolean operations, & (AND), | (OR), and ¬ (NOT) are used.

### B.1 BCD-to-DPD Translation

The translation from a 3-digit BCD number to a 10-bit DPD can be performed through the following Boolean operations.

$$\begin{aligned} p &= (f \& a \& i \& \neg e) \mid (j \& a \& \neg i) \mid (b \& \neg a) \\ q &= (g \& a \& i \& \neg e) \mid (k \& a \& \neg i) \mid (c \& \neg a) \\ r &= d \end{aligned}$$

$$\begin{aligned} s &= (j \& \neg a \& e \& \neg i) \mid (f \& \neg i \& \neg e) \mid \\ &\quad (f \& \neg a \& \neg e) \mid (e \& i) \\ t &= (k \& \neg a \& e \& \neg i) \mid (g \& \neg i \& \neg e) \mid \\ &\quad (g \& \neg a \& \neg e) \mid (a \& i) \\ u &= h \end{aligned}$$

$$v = a \mid e \mid i$$

$$\begin{aligned} w &= (\neg e \& j \& \neg i) \mid (e \& i) \mid a \\ x &= (\neg a \& k \& \neg i) \mid (a \& i) \mid e \\ y &= m \end{aligned}$$

Alternatively, the following table can be used to perform the translation. The most significant bit of the three BCD digits (left column) is used to select a specific 10-bit encoding (right column) of the DPD.

aei	pqr stu v wxy
000	bcd fgh 0 jkm
001	bcd fgh 1 00m
010	bcd jkh 1 01m
011	bcd 10h 1 11m
100	jdk fgh 1 10m
101	fgd 01h 1 11m
110	jdk 00h 1 11m
111	00d 11h 1 11m

The full translation of a 3-digit BCD number (000 - 999) to a 10-bit DPD is shown in Table 146 on page 1019,

with the DPD entries shown in hexadecimal format. The BCD number is produced by replacing ‘\_’ in the leftmost column with the corresponding digit along the top row. The table is split into two halves, with the right half being a continuation of the left half.

### B.2 DPD-to-BCD Translation

The translation from a 10-bit DPD to a 3-digit BCD number can be performed through the following Boolean operations.

$$\begin{aligned} a &= (\neg s \& v \& w) \mid (t \& v \& w \& s) \mid (v \& w \& \neg x) \\ b &= (p \& s \& x \& \neg t) \mid (p \& \neg w) \mid (p \& \neg v) \\ c &= (q \& s \& x \& \neg t) \mid (q \& \neg w) \mid (q \& \neg v) \\ d &= r \end{aligned}$$

$$\begin{aligned} e &= (v \& \neg w \& x) \mid (s \& v \& w \& x) \mid \\ &\quad (\neg t \& v \& x \& w) \\ f &= (p \& t \& v \& w \& x \& \neg s) \mid (s \& \neg x \& v) \mid \\ &\quad (s \& \neg v) \\ g &= (q \& t \& w \& v \& x \& \neg s) \mid (t \& \neg x \& v) \mid \\ &\quad (t \& \neg v) \\ h &= u \end{aligned}$$

$$\begin{aligned} i &= (t \& v \& w \& x) \mid (s \& v \& w \& x) \mid \\ &\quad (v \& \neg w \& \neg x) \\ j &= (p \& \neg s \& \neg t \& w \& v) \mid (s \& v \& \neg w \& x) \mid \\ &\quad (p \& w \& \neg x \& v) \mid (w \& \neg v) \\ k &= (q \& \neg s \& \neg t \& v \& w) \mid (t \& v \& \neg w \& x) \mid \\ &\quad (q \& v \& w \& \neg x) \mid (x \& \neg v) \\ m &= y \end{aligned}$$

Alternatively, the following table can be used to perform the translation. A combination of five bits in the DPD encoding (leftmost column) are used to specify a translation to the 3-digit BCD encoding. Dashes (-) in the table are don't cares, and can be either one or zero.

vwxst	abcd	efgh	ijklm
0----	0pqr	0stu	0wxy
100--	0pqr	0stu	100y
101--	0pqr	100u	0sty
110--	100r	0stu	0pqy
11100	100r	100u	0pqy
11101	100r	0pqu	100y
11110	0pqr	100u	100y
11111	100r	100u	100y

The full translation of the 10-bit DPD to a 3-digit BCD number is shown in Table 147 on page 1020. The 10-bit DPD index is produced by concatenating the 6-bit value shown in the left column with the 4-bit index along the top row, both represented in hexadecimal. The values in parentheses are non-preferred translations and are explained further in the following section.

### B.3 Preferred DPD encoding

Translating from a 3-digit BCD number (1000 numbers) to a 10-bit DPD encoding (1024 combinations) leaves 24 redundant translations. The 24 redundant combinations are evenly assigned to eight BCD numbers and are shown in the following table, with the non-preferred encoding in parentheses. The preferred encoding is produced by translating a 3-digit BCD number with the translation table or Boolean operations shown in Section B.1. The redundant DPD encodings are all valid and will be correctly translated to their respective BCD value through the mechanisms provided in Section B.2. For decimal floating-point operations all DPD encodings are recognized as source operands.

DPD Code	BCD Value	DPD Code	BCD Value

## Appendix C. Assembler Extended Mnemonics

In order to make assembler language programs simpler to write and easier to understand, a set of extended mnemonics and symbols is provided that defines simple shorthand for the most frequently used forms of *Branch Conditional*, *Compare*, *Trap*, *Rotate and Shift*, and certain other instructions.

Assemblers should provide the extended mnemonics and symbols listed here, and may provide others.

### C.1 Symbols

The following symbols are defined for use in instructions (basic or extended mnemonics) that specify a Condition Register field or a Condition Register bit. The first five (lt, ..., un) identify a bit number within a CR field. The remainder (cr0, ..., cr7) identify a CR field. An expression in which a CR field symbol is multiplied by 4 and then added to a bit-number-within-CR-field symbol and 32 can be used to identify a CR bit.

Symbol	Value	Meaning
lt	0	Less than
gt	1	Greater than
eq	2	Equal
so	3	Summary overflow
un	3	Unordered (after floating-point comparison)
cr0	0	CR Field 0
cr1	1	CR Field 1
cr2	2	CR Field 2
cr3	3	CR Field 3
cr4	4	CR Field 4
cr5	5	CR Field 5
cr6	6	CR Field 6
cr7	7	CR Field 7

The extended mnemonics in Sections C.2.2 and C.3 require identification of a CR bit: if one of the CR field symbols is used, it must be multiplied by 4 and added to a bit-number-within-CR-field (value in the range 0-3, explicit or symbolic) and 32. The extended mnemonics in Sections C.2.3 and C.5 require identification of a CR field: if one of the CR field symbols is used, it must *not* be multiplied by 4 or added to 32. (For the extended mnemonics in Section C.2.3, the bit number within the CR field is part of the extended mnemonic. The programmer identifies the CR field, and the Assembler does the multiplication and addition required to produce a CR bit number for the BI field of the underlying basic mnemonic.)

## C.2 Branch Mnemonics

The mnemonics discussed in this section are variations of the *Branch Conditional* instructions.

**Note:** *bclr*, *bclrl*, *bcctr*, and *bcctrl* each serve as both a basic and an extended mnemonic. The Assembler will recognize a *bclr*, *bclrl*, *bcctr*, or *bcctrl* mnemonic with three operands as the basic form, and a *bclr*, *bclrl*, *bcctr*, or *bcctrl* mnemonic with two operands as the extended form. In the extended form the BH operand is omitted and assumed to be 0b00. Similarly, for all the extended mnemonics described in Sections C.2.2 - C.2.4 that devolve to any of these four basic mnemonics the BH operand can either be coded or omitted. If it is omitted it is assumed to be 0b00.

### C.2.1 BO and BI Fields

The 5-bit BO and BI fields control whether the branch is taken. Providing an extended mnemonic for every possible combination of these fields would be neither useful nor practical. The mnemonics described in Sections C.2.2 - C.2.4 include the most useful cases. Other cases can be coded using a basic *Branch Conditional* mnemonic (*bc[l][a]*, *bclrl*, *bcctrl*) with the appropriate operands.

### C.2.2 Simple Branch Mnemonics

Instructions using one of the mnemonics in Table 148 that tests a Condition Register bit specify the corresponding bit as the first operand. The symbols defined in Section C.1 can be used in this operand.

Notice that there are no extended mnemonics for relative and absolute unconditional branches. For these the basic mnemonics *b*, *ba*, *bl*, and *bla* should be used.

Branch Semantics	LR not Set				LR Set			
	<i>bc</i> Relative	<i>bca</i> Absolute	<i>bclr</i> To LR	<i>bcctr</i> To CTR	<i>bcl</i> Relative	<i>bcla</i> Absolute	<i>bclrl</i> To LR	<i>bcctrl</i> To CTR
Branch unconditionally	-	-	blr	bctr	-	-	blrl	bctrl
Branch if CR <sub>BI</sub> =1	bt	bta	btlr	btctr	btl	btla	btlrl	btctrl
Branch if CR <sub>BI</sub> =0	bf	bfa	bflr	bfctr	bfl	bfla	bflrl	bfctrl
Decrement CTR, branch if CTR nonzero	bdnz	bdnza	bdnzlr	-	bdnzl	bdnzla	bdnzlrl	-
Decrement CTR, branch if CTR nonzero and CR <sub>BI</sub> =1	bdnzt	bdnzta	bdnztlr	-	bdnztl	bdnztla	bdnztlrl	-
Decrement CTR, branch if CTR nonzero and CR <sub>BI</sub> =0	bdnzf	bdnzfa	bdnzflr	-	bdnzfl	bdnzfla	bdnzflrl	-
Decrement CTR, branch if CTR zero	bdz	bdza	bdzlr	-	bdzl	bdzla	bdzlrl	-
Decrement CTR, branch if CTR zero and CR <sub>BI</sub> =1	bdzt	bdzta	bdztlr	-	bdztl	bdztle	bdztlrl	-
Decrement CTR, branch if CTR zero and CR <sub>BI</sub> =0	bdzf	bdzfa	bdzflr	-	bdzfl	bdzfla	bdzflrl	-

### Examples

- Decrement CTR and branch if it is still nonzero (closure of a loop controlled by a count loaded into CTR).

```
bdnz target          (equivalent to: bc 16,0,target)
```

- Same as (1) but branch only if CTR is nonzero and condition in CR0 is "equal".

```
bdnzt eq,target      (equivalent to: bc 8,2,target)
```

- Same as (2), but "equal" condition is in CR5.

```
bdnzt 4×cr5+eq,target (equivalent to: bc 8,22,target)
```

4. Branch if bit 59 of CR is 0.

`bf 27,target` (equivalent to: `bc 4,27,target`)

5. Same as (4), but set the Link Register. This is a form of conditional “call”.

`bfl 27,target` (equivalent to: `bcl 4,27,target`)

## C.2.3 Branch Mnemonics Incorporating Conditions

In the mnemonics defined in Table 149, the test of a bit in a Condition Register field is encoded in the mnemonic.

Instructions using the mnemonics in Table 149 specify the CR field as an optional first operand. One of the CR field symbols defined in Section C.1 can be used for this operand. If the CR field being tested is CR Field 0, this operand need not be specified unless the resulting basic mnemonic is *bclr[l]* or *bcctr[l]* and the BH operand is specified.

A standard set of codes has been adopted for the most common combinations of branch conditions.

Code	Meaning
lt	Less than
le	Less than or equal
eq	Equal
ge	Greater than or equal
gt	Greater than
nl	Not less than
ne	Not equal
ng	Not greater than
so	Summary overflow
ns	Not summary overflow
un	Unordered (after floating-point comparison)
nu	Not unordered (after floating-point comparison)

These codes are reflected in the mnemonics shown in Table 149.

Branch Semantics	LR not Set				LR Set			
	<i>bc</i> Relative	<i>bca</i> Absolute	<i>bclr</i> To LR	<i>bcctr</i> To CTR	<i>bcl</i> Relative	<i>bcla</i> Absolute	<i>bclr</i> To LR	<i>bcctr</i> To CTR
Branch if less than	<i>blt</i>	<i>blta</i>	<i>bltlr</i>	<i>bltctr</i>	<i>bltl</i>	<i>bltla</i>	<i>bltlrl</i>	<i>bltctrl</i>
Branch if less than or equal	<i>ble</i>	<i>blea</i>	<i>blelr</i>	<i>blectr</i>	<i>blel</i>	<i>blela</i>	<i>blelrl</i>	<i>blectrl</i>
Branch if equal	<i>beq</i>	<i>beqa</i>	<i>beqlr</i>	<i>beqctr</i>	<i>beql</i>	<i>beqla</i>	<i>beqlrl</i>	<i>beqctrl</i>
Branch if greater than or equal	<i>bge</i>	<i>bgea</i>	<i>bgehr</i>	<i>bgectr</i>	<i>bgel</i>	<i>bgela</i>	<i>bgelrl</i>	<i>bgectrl</i>
Branch if greater than	<i>bgt</i>	<i>bgta</i>	<i>bgtr</i>	<i>bgctr</i>	<i>bgtl</i>	<i>bgta</i>	<i>bgtrrl</i>	<i>bgctrl</i>
Branch if not less than	<i>bnl</i>	<i>bnla</i>	<i>bnlhr</i>	<i>bnlctr</i>	<i>bnll</i>	<i>bnlla</i>	<i>bnlrl</i>	<i>bnlctrl</i>
Branch if not equal	<i>bne</i>	<i>bnea</i>	<i>bnelr</i>	<i>bnecr</i>	<i>bnel</i>	<i>bnela</i>	<i>bnelrl</i>	<i>bnecr</i>
Branch if not greater than	<i>bng</i>	<i>bnga</i>	<i>bnglr</i>	<i>bngctr</i>	<i>bngl</i>	<i>bngla</i>	<i>bnglrl</i>	<i>bngctrl</i>
Branch if summary overflow	<i>bso</i>	<i>bsoa</i>	<i>bsolr</i>	<i>bsocr</i>	<i>bsol</i>	<i>bsola</i>	<i>bsolrl</i>	<i>bsocr</i>
Branch if not summary overflow	<i>bns</i>	<i>bnsa</i>	<i>bnslr</i>	<i>bnsctr</i>	<i>bns</i>	<i>bnsa</i>	<i>bnsrl</i>	<i>bnsctr</i>
Branch if unordered	<i>bun</i>	<i>buna</i>	<i>bunlr</i>	<i>bunctr</i>	<i>bunl</i>	<i>bunla</i>	<i>bunlrl</i>	<i>bunctrl</i>
Branch if not unordered	<i>bnu</i>	<i>bnua</i>	<i>bnulr</i>	<i>bnuctr</i>	<i>bnul</i>	<i>bnula</i>	<i>bnulrl</i>	<i>bnuctrl</i>

## Examples

1. Branch if CR0 reflects condition “not equal”.

`bne target` (equivalent to: `bc 4,2,target`)

2. Same as (1), but condition is in CR3.

bne cr3,target (equivalent to: bc 4,14,target)

3. Branch to an absolute target if CR4 specifies “greater than”, setting the Link Register. This is a form of conditional “call”.

bgtla cr4,target (equivalent to: bcla 12,17,target)

4. Same as (3), but target address is in the Count Register.

bgtctrl cr4 (equivalent to: bcctrl 12,17,0)

## C.2.4 Branch Prediction

Software can use the “at” bits of *Branch Conditional* instructions to provide a hint to the processor about the behavior of the branch. If, for a given such instruction, the branch is almost always taken or almost always not taken, a suffix can be added to the mnemonic indicating the value to be used for the “at” bits.

- + Predict branch to be taken (at=0b11)
- Predict branch not to be taken (at=0b10)

Such a suffix can be added to any *Branch Conditional* mnemonic, either basic or extended, that tests either the Count Register or a CR bit (but not both). Assemblers should use 0b00 as the default value for the “at” bits, indicating that software has offered no prediction.

### Examples

1. Branch if CR0 reflects condition “less than”, specifying that the branch should be predicted to be taken.

blt+ target

2. Same as (1), but target address is in the Link Register and the branch should be predicted not to be taken.

bltlr-

## C.3 Condition Register Logical Mnemonics

The *Condition Register Logical* instructions can be used to set (to 1), clear (to 0), copy, or invert a given Condition Register bit. Extended mnemonics are provided that allow these operations to be coded easily.

Operation	Extended Mnemonic	Equivalent to
Condition Register set	crset bx	creqv bx,bx,bx
Condition Register clear	crclr bx	crxor bx,bx,bx
Condition Register move	crmove bx,by	cror bx,by,by
Condition Register not	crnot bx,by	crnor bx,by,by

The symbols defined in Section C.1 can be used to identify the Condition Register bits.

### Examples

1. Set CR bit 57.

```
crset 25          (equivalent to:  creqv 25,25,25)
```

2. Clear the SO bit of CR0.

```
crclr so         (equivalent to:  crxor 3,3,3)
```

3. Same as (2), but SO bit to be cleared is in CR3.

```
crclr 4xcr3+so  (equivalent to:  crxor 15,15,15)
```

4. Invert the EQ bit.

```
crnot eq,eq     (equivalent to:  crnor 2,2,2)
```

5. Same as (4), but EQ bit to be inverted is in CR4, and the result is to be placed into the EQ bit of CR5.

```
crnot 4xcr5+eq,4xcr4+eq  (equivalent to:  crnor 22,18,18)
```

## C.4 Subtract Mnemonics

### C.4.1 Subtract Immediate

Although there is no “Subtract Immediate” instruction, its effect can be achieved by using an Add Immediate instruction with the immediate operand negated. Extended mnemonics are provided that include this negation, making the intent of the computation clearer.

```
subi  Rx,Ry,value  (equivalent to:  addi  Rx,Ry,-value)
subis Rx,Ry,value  (equivalent to:  addis Rx,Ry,-value)
subic Rx,Ry,value  (equivalent to:  addic  Rx,Ry,-value)
subic. Rx,Ry,value (equivalent to:  addic. Rx,Ry,-value)
```

### C.4.2 Subtract

The *Subtract From* instructions subtract the second operand (RA) from the third (RB). Extended mnemonics are provided that use the more “normal” order, in which the third operand is subtracted from the second. Both these mnemonics can be coded with a final “o” and/or “.” to cause the OE and/or R<sub>c</sub> bit to be set in the underlying instruction.

```
sub  Rx,Ry,Rz      (equivalent to:  subf  Rx,Rz,Ry)
subc Rx,Ry,Rz      (equivalent to:  subfc Rx,Rz,Ry)
```

## C.5 Compare Mnemonics

The L field in the fixed-point *Compare* instructions controls whether the operands are treated as 64-bit quantities or as 32-bit quantities. Extended mnemonics are provided that represent the L value in the mnemonic rather than requiring it to be coded as a numeric operand.

The BF field can be omitted if the result of the comparison is to be placed into CR Field 0. Otherwise the target CR field must be specified as the first operand. One of the CR field symbols defined in Section C.1 can be used for this operand.

**Note:** The Assembler will recognize a basic *Compare* mnemonic with three operands, and will generate the instruction with L=0. Thus the Assembler must require that the BF field, which normally can be omitted when CR Field 0 is the target, be specified explicitly if L is.

### C.5.1 Doubleword Comparisons

Operation	Extended Mnemonic	Equivalent to
Compare doubleword immediate	cmpdi bf,ra,si	cmpi bf,1,ra,si
Compare doubleword	cmpd bf,ra,rb	cmp bf,1,ra,rb
Compare logical doubleword immediate	cmpldi bf,ra,ui	cmpli bf,1,ra,ui
Compare logical doubleword	cmpld bf,ra,rb	cmpl bf,1,ra,rb

#### Examples

1. Compare register Rx and immediate value 100 as unsigned 64-bit integers and place result into CR0.

```
cmpldi Rx,100          (equivalent to:  cmpli  0,1,Rx,100)
```

2. Same as (1), but place result into CR4.

```
cmpldi cr4,Rx,100     (equivalent to:  cmpli  4,1,Rx,100)
```

3. Compare registers Rx and Ry as signed 64-bit integers and place result into CR0.

```
cmpd Rx,Ry           (equivalent to:  cmp   0,1,Rx,Ry)
```

### C.5.2 Word Comparisons

Operation	Extended Mnemonic	Equivalent to
Compare word immediate	cmpwi bf,ra,si	cmpi bf,0,ra,si
Compare word	cmpw bf,ra,rb	cmp bf,0,ra,rb
Compare logical word immediate	cmplwi bf,ra,ui	cmpli bf,0,ra,ui
Compare logical word	cmplw bf,ra,rb	cmpl bf,0,ra,rb

#### Examples

1. Compare bits 32:63 of register Rx and immediate value 100 as signed 32-bit integers and place result into CR0.

```
cmpwi Rx,100          (equivalent to:  cmpi  0,0,Rx,100)
```

2. Same as (1), but place result into CR4.

```
cmpwi cr4,Rx,100     (equivalent to:  cmpi  4,0,Rx,100)
```

3. Compare bits 32:63 of registers Rx and Ry as unsigned 32-bit integers and place result into CR0.

```
cmplw Rx,Ry          (equivalent to:  cmpl  0,0,Rx,Ry)
```

## C.6 Trap Mnemonics

The mnemonics defined in Table 153 are variations of the *Trap* instructions, with the most useful values of TO represented in the mnemonic rather than specified as a numeric operand.

A standard set of codes has been adopted for the most common combinations of trap conditions.

Code	Meaning	TO encoding	<	>	=	< <sup>u</sup>	> <sup>u</sup>
lt	Less than	16	1	0	0	0	0
le	Less than or equal	20	1	0	1	0	0
eq	Equal	4	0	0	1	0	0
ge	Greater than or equal	12	0	1	1	0	0
gt	Greater than	8	0	1	0	0	0
nl	Not less than	12	0	1	1	0	0
ne	Not equal	24	1	1	0	0	0
ng	Not greater than	20	1	0	1	0	0
llt	Logically less than	2	0	0	0	1	0
lle	Logically less than or equal	6	0	0	1	1	0
lge	Logically greater than or equal	5	0	0	1	0	1
lgt	Logically greater than	1	0	0	0	0	1
lnl	Logically not less than	5	0	0	1	0	1
lng	Logically not greater than	6	0	0	1	1	0
u	Unconditionally with parameters	31	1	1	1	1	1
(none)	Unconditional	31	1	1	1	1	1

These codes are reflected in the mnemonics shown in Table 153.

Trap Semantics	64-bit Comparison		32-bit Comparison	
	<i>tdi</i> Immediate	<i>td</i> Register	<i>twi</i> Immediate	<i>tw</i> Register
Trap unconditionally	-	-	-	trap
Trap unconditionally with parameters	tdui	tdu	twui	twu
Trap if less than	tdlti	tdlt	twlti	twlt
Trap if less than or equal	tdlei	tdle	twlei	twle
Trap if equal	tdeqi	tdeq	tweqi	tweq
Trap if greater than or equal	tdgei	tdge	twgei	twge
Trap if greater than	tdgti	tdgt	twgti	twgt
Trap if not less than	tdnli	tdnl	twnli	twnl
Trap if not equal	tdnei	tdne	twnei	twne
Trap if not greater than	tdngi	tdng	twngi	twng
Trap if logically less than	tdllti	tdllt	twllti	twllt
Trap if logically less than or equal	tdllei	tdlle	twllei	twlle
Trap if logically greater than or equal	tdlgei	tdlge	twlgei	twlge
Trap if logically greater than	tdlgti	tdlgt	twlgti	twlgt
Trap if logically not less than	tdlnli	tdlnl	twlnli	twlnl
Trap if logically not greater than	tdlngi	tdlng	twlngi	twlng

## Examples

1. Trap if register Rx is not 0.

`tdnei Rx,0` (equivalent to: `tdi 24,Rx,0`)

2. Same as (1), but comparison is to register Ry.

`tdne Rx,Ry` (equivalent to: `td 24,Rx,Ry`)

3. Trap if bits 32:63 of register Rx, considered as a 32-bit quantity, are logically greater than 0x7FF.

`twlgti Rx,0x7FF` (equivalent to: `twi 1,Rx,0x7FF`)

4. Trap unconditionally.

`trap` (equivalent to: `tw 31,0,0`)

5. Trap unconditionally with immediate parameters Rx and Ry

`tdu Rx,Ry` (equivalent to: `td 31,Rx,Ry`)

## C.7 Integer Select Mnemonics

The mnemonics defined in Table 154, “Integer Select mnemonics,” on page 1028 are variations of the *Integer Select* instructions, with the most useful values of BC represented in the mnemonic rather than specified as a numeric operand..

Code	Meaning
lt	Less than
eq	Equal
gt	Greater than

These codes are reflected in the mnemonics shown in Table 154.

Select semantics	<i>isel</i> extended mnemonic
Integer Select if less than	isel <sub>lt</sub>
Integer Select if equal	iseleq
Integer Select if greater than	isel <sub>gt</sub>

## Examples

1. Set register Rx to Ry if the LT bit is set in CR0, and to Rz otherwise.

`isellt Rx,Ry,Rz` (equivalent to: `isel Rx,Ry,Rz,0`)

2. Set register Rx to Ry if the GT bit is set in CR0, and to Rz otherwise.

`iselgt Rx,Ry,Rz` (equivalent to: `isel Rx,Ry,Rz,1`)

3. Set register Rx to Ry if the EQ bit is set in CR0, and to Rz otherwise.

`iseleq Rx,Ry,Rz` (equivalent to: `isel Rx,Ry,Rz,2`)

## C.8 Rotate and Shift Mnemonics

The *Rotate and Shift* instructions provide powerful and general ways to manipulate register contents, but can be difficult to understand. Extended mnemonics are provided that allow some of the simpler operations to be coded easily.

Mnemonics are provided for the following types of operation.

**Extract** Select a field of  $n$  bits starting at bit position  $b$  in the source register; left or right justify this field in the target register; clear all other bits of the target register to 0.

**Insert** Select a left-justified or right-justified field of  $n$  bits in the source register; insert this field starting at bit position  $b$  of the target register; leave other bits of the target register unchanged. (No extended mnemonic is provided for insertion of a left-justified field when operating on doublewords, because such an insertion requires more than one instruction.)

**Rotate** Rotate the contents of a register right or left  $n$  bits without masking.

**Shift** Shift the contents of a register right or left  $n$  bits, clearing vacated bits to 0 (logical shift).

**Clear** Clear the leftmost or rightmost  $n$  bits of a register to 0.

**Clear left and shift left**

Clear the leftmost  $b$  bits of a register, then shift the register left by  $n$  bits. This operation can be used to scale  $a$  (known nonnegative) array index by the width of an element.

### C.8.1 Operations on Doublewords

All these mnemonics can be coded with a final “.” to cause the Rc bit to be set in the underlying instruction.

Operation	Extended Mnemonic	Equivalent to
Extract and left justify immediate	extldi ra,rs,n,b ( $n > 0$ )	rldicr ra,rs,b,n-1
Extract and right justify immediate	extrdi ra,rs,n,b ( $n > 0$ )	rldicl ra,rs,b+n,64-n
Insert from right immediate	insrdi ra,rs,n,b ( $n > 0$ )	rldimi ra,rs,64-(b+n),b
Rotate left immediate	rotldi ra,rs,n	rldicl ra,rs,n,0
Rotate right immediate	rotrdi ra,rs,n	rldicl ra,rs,64-n,0
Rotate left	rotld ra,rs,rb	rldcl ra,rs,rb,0
Shift left immediate	sldi ra,rs,n ( $n < 64$ )	rldicr ra,rs,n,63-n
Shift right immediate	srdi ra,rs,n ( $n < 64$ )	rldicl ra,rs,64-n,n
Clear left immediate	clrldi ra,rs,n ( $n < 64$ )	rldicl ra,rs,0,n
Clear right immediate	clrrdi ra,rs,n ( $n < 64$ )	rldicr ra,rs,0,63-n
Clear left and shift left immediate	clrldi ra,rs,b,n ( $n \leq b < 64$ )	rldicr ra,rs,n,b-n

### Examples

1. Extract the sign bit (bit 0) of register Ry and place the result right-justified into register Rx.

extrdi Rx,Ry,1,0 (equivalent to: rldicl Rx,Ry,1,63)

2. Insert the bit extracted in (1) into the sign bit (bit 0) of register Rz.

insrdi Rz,Rx,1,0 (equivalent to: rldimi Rz,Rx,63,0)

3. Shift the contents of register Rx left 8 bits.

sldi Rx,Rx,8 (equivalent to: rldicr Rx,Rx,8,55)

4. Clear the high-order 32 bits of register Ry and place the result into register Rx.

clrldi Rx,Ry,32 (equivalent to: rldicl Rx,Ry,0,32)

## C.8.2 Operations on Words

All these mnemonics can be coded with a final “.” to cause the Rc bit to be set in the underlying instruction. The operations as described above apply to the low-order 32 bits of the registers, as if the registers were 32-bit registers. The Insert operations either preserve the high-order 32 bits of the target register or place rotated data there; the other operations clear these bits.

Operation	Extended Mnemonic	Equivalent to
Extract and left justify immediate	extlwi ra,rs,n,b (n > 0)	rlwinm ra,rs,b,0,n-1
Extract and right justify immediate	extrwi ra,rs,n,b (n > 0)	rlwinm ra,rs,b+n,32-n,31
Insert from left immediate	inslwi ra,rs,n,b (n > 0)	rlwimi ra,rs,32-b,b,(b+n)-1
Insert from right immediate	insrwi ra,rs,n,b (n > 0)	rlwimi ra,rs,32-(b+n),b,(b+n)-1
Rotate left immediate	rotlwi ra,rs,n	rlwinm ra,rs,n,0,31
Rotate right immediate	rotrwi ra,rs,n	rlwinm ra,rs,32-n,0,31
Rotate left	rotlw ra,rs,rb	rlwnm ra,rs,rb,0,31
Shift left immediate	slwi ra,rs,n (n < 32)	rlwinm ra,rs,n,0,31-n
Shift right immediate	srwi ra,rs,n (n < 32)	rlwinm ra,rs,32-n,n,31
Clear left immediate	clrlwi ra,rs,n (n < 32)	rlwinm ra,rs,0,n,31
Clear right immediate	clrrwi ra,rs,n (n < 32)	rlwinm ra,rs,0,0,31-n
Clear left and shift left immediate	clrlslwi ra,rs,b,n (n ≤ b < 32)	rlwinm ra,rs,n,b-n,31-n

### Examples

- Extract the sign bit (bit 32) of register Ry and place the result right-justified into register Rx.  

```
extrwi Rx,Ry,1,0      (equivalent to:  rlwinm Rx,Ry,1,31,31)
```
- Insert the bit extracted in (1) into the sign bit (bit 32) of register Rz.  

```
insrwi Rz,Rx,1,0      (equivalent to:  rlwimi Rz,Rx,31,0,0)
```
- Shift the contents of register Rx left 8 bits, clearing the high-order 32 bits.  

```
slwi Rx,Rx,8          (equivalent to:  rlwinm Rx,Rx,8,0,23)
```
- Clear the high-order 16 bits of the low-order 32 bits of register Ry and place the result into register Rx, clearing the high-order 32 bits of register Rx.  

```
clrlwi Rx,Ry,16       (equivalent to:  rlwinm Rx,Ry,0,16,31)
```

## C.9 Move To/From Special Purpose Register Mnemonics

The *mtspr* and *mfspir* instructions specify a Special Purpose Register (SPR) as a numeric operand. Extended mnemonics are provided that represent the SPR in the mnemonic rather than requiring it to be coded as an operand.

Special Purpose Register	Move To SPR		Move From SPR	
	Extended	Equivalent to	Extended	Equivalent to
XER	mtxer Rx	mtspr 1,Rx	mfixer Rx	mfspir Rx,1
DSCR	mtudscr Rx	mtspr 3,Rx	mfudscr Rx	mfspir Rx,3
LR	mtlr Rx	mtspr 8,Rx	mflr Rx	mfspir Rx,8
CTR	mtctr Rx	mtspr 9,Rx	mfctr Rx	mfspir Rx,9
AMR	mtuamr Rx	mtspr 13,Rx	mfuamr Rx	mfspir Rx,13
CTRL	-	-	mfctrl Rx	mfspir Rx,136
VRSAVE	mtvrsave Rx	mtspr 256,Rx	mfvrsave Rx	mfspir Rx,256
SPRG3	-	-	mfusprg3 Rx	mfspir Rx,259
TB	-	-	mftb Rx	mftb Rx,268 mfspir Rx,268
TBU	-	-	mftbu Rx	mftb Rx,269 mfspir Rx,269
SIER	-	-	mfusier Rx	mfspir Rx,768
MMCR2	mtummcr2 Rx	mtspr 769,Rx	mfummcr2 Rx	mfspir Rx,769
MMCR0	mtummcr0 Rx	mtspr 770,Rx	mfummcr0 Rx	mfspir Rx,770
PMC1	mtupmc1 Rx	mtspr 771,Rx	mfupmc1 Rx	mfspir Rx,771
PMC2	mtupmc2 Rx	mtspr 772,Rx	mfupmc2 Rx	mfspir Rx,772
PMC3	mtupmc3 Rx	mtspr 773,Rx	mfupmc3 Rx	mfspir Rx,773
PMC4	mtupmc4 Rx	mtspr 774,Rx	mfupmc4 Rx	mfspir Rx,774
PMC5	mtupmc5 Rx	mtspr 775,Rx	mfupmc5 Rx	mfspir Rx,775
PMC6	mtupmc6 Rx	mtspr 776,Rx	mfupmc6 Rx	mfspir Rx,776
MMCR0	mtummcr0 Rx	mtspr 779,Rx	mfummcr0 Rx	mfspir Rx,779
SIAR	-	-	mfusiar Rx	mfspir Rx,780
SDAR	-	-	mfusdar Rx	mfspir Rx,781
MMCR1	-	-	mfummcr1 Rx	mfspir Rx,782
BESCRS	mtbescrs Rx	mtspr 800,Rx	mfbescrs Rx	mfspir Rx,800
BESCRU	mtbescru Rx	mtspr 801,Rx	mfbescru Rx	mfspir Rx,801
BESCRR	mtbescrr Rx	mtspr 802,Rx	mfbescrr Rx	mfspir Rx,802
BESCRRU	mtbescrru Rx	mtspr 803,Rx	mfbescrru Rx	mfspir Rx,803
EBBHR	mtebbhr Rx	mtspr 804,Rx	mfebbhr Rx	mfspir Rx,804
EBBRR	mtebbrr Rx	mtspr 805,Rx	mfebbrr Rx	mfspir Rx,805
BESCR	mtbescr Rx	mtspr 806,Rx	mfbescr Rx	mfspir Rx,806
TAR	mttar Rx	mtspr 815,Rx	mftar Rx	mfspir Rx,815
PPR	mtppr Rx	mtspr 896,Rx	mfppr Rx	mfspir Rx,896
PPR32	mtppr32 Rx	mtspr 898,Rx	mfppr32 Rx	mfspir Rx,898

### Examples

- Copy the contents of register Rx to the XER.

mtxer Rx (equivalent to: mtspr 1,Rx)

2. Copy the contents of the LR to register Rx.

mf<sub>lr</sub> Rx (equivalent to: mf<sub>spr</sub> Rx,8)

3. Copy the contents of register Rx to the CTR.

mt<sub>ctr</sub> Rx (equivalent to: mt<sub>spr</sub> 9,Rx)

## C.10 Miscellaneous Mnemonics

### No-op

Many Power ISA instructions can be coded in a way such that, effectively, no operation is performed. An extended mnemonic is provided for the preferred form of no-op. If an implementation performs any type of run-time optimization related to no-ops, the preferred form is the no-op that will trigger this.

nop (equivalent to: ori 0,0,0)

For some uses of a no-op instruction, optimizations related to no-ops, such as removal from the execution stream, are not desirable. An extended mnemonic is provided for the executed form of no-op. This form of no-op will still consume execution resources.

xnop (equivalent to: xori 0,0,0)

To avoid certain security vulnerabilities, it is sometimes desirable to constrain the order in which instructions are executed at certain points in a program. An extended mnemonic is provided for a form of the *Or Immediate* instruction that serves this purpose. See Section 9.2.1 of Book III.

exser (equivalent to: ori 31,31,0)

### Load Immediate

The ***addi*** and ***addis*** instructions can be used to load an immediate value into a register. Extended mnemonics are provided to convey the idea that no addition is being performed but merely data movement (from the immediate field of the instruction to a register).

Load a 16-bit signed immediate value into register Rx.

li Rx,value (equivalent to: addi Rx,0,value)

Load a 16-bit signed immediate value, shifted left by 16 bits, into register Rx.

lis Rx,value (equivalent to: addis Rx,0,value)

### Load Next Instruction Address

The ***addpcis*** instruction can be used to load the next instruction address into a register. An extended mnemonic is provided to perform this operation.

lnia Rx (equivalent to: addpcis Rx,0)

## Load Address

This mnemonic permits computing the value of a base-displacement operand, using the ***addi*** instruction which normally requires separate register and immediate operands.

```
la    Rx,D(Ry)      (equivalent to:  addi    Rx,Ry,D)
```

The ***la*** mnemonic is useful for obtaining the address of a variable specified by name, allowing the Assembler to supply the base register number and compute the displacement. If the variable *v* is located at offset *Dv* bytes from the address in register *Rv*, and the Assembler has been told to use register *Rv* as a base for references to the data structure containing *v*, then the following line causes the address of *v* to be loaded into register *Rx*.

```
la    Rx,v          (equivalent to:  addi    Rx,Rv,Dv)
```

## Move Register

Several Power ISA instructions can be coded in a way such that they simply copy the contents of one register to another. An extended mnemonic is provided to convey the idea that no computation is being performed but merely data movement (from one register to another).

The following instruction copies the contents of register *Ry* to register *Rx*. This mnemonic can be coded with a final “.” to cause the *Rc* bit to be set in the underlying instruction.

```
mr    Rx,Ry        (equivalent to:  or     Rx,Ry,Ry)
```

## Complement Register

Several Power ISA instructions can be coded in a way such that they complement the contents of one register and place the result into another register. An extended mnemonic is provided that allows this operation to be coded easily.

The following instruction complements the contents of register *Ry* and places the result into register *Rx*. This mnemonic can be coded with a final “.” to cause the *Rc* bit to be set in the underlying instruction.

```
not   Rx,Ry        (equivalent to:  nor    Rx,Ry,Ry)
```

## Move To/From Condition Register

This mnemonic permits copying the contents of the low-order 32 bits of a GPR to the Condition Register, using the same style as the ***mfcrr*** instruction.

```
mtr   Rx           (equivalent to:  mtrcf  0xFF,Rx)
```

The following instructions may generate either the (old) ***mtrcf*** or ***mfcrr*** instructions or the (new) ***mtocrf*** or ***mfoocrf*** instruction, respectively, depending on the target machine type assembler parameter.

```
mtrcf FXM,Rx
mfcrr  Rx
```

All three extended mnemonics in this subsection are being phased out. In future assemblers the form “*mtr Rx*” may not exist, and the ***mtrcf*** and ***mfcrr*** mnemonics may generate the old form instructions (with bit 11 = 0) regardless of the target machine type assembler parameter, or may cease to exist.

## **Book II:**

# **Power ISA Virtual Environment Architecture**

# Chapter 1. Storage Model

## 1.1 Definitions

The following definitions, in addition to those specified in Book I, are used in this Book. In these definitions, “*Load* instruction” includes the *Cache Management* and other instructions that are stated in the instruction descriptions to be “treated as a *Load*”, and similarly for “*Store* instruction”.

- **system**

A combination of processors, storage, and associated mechanisms that is capable of executing programs. Sometimes the reference to system includes services provided by the privileged software.

- **main storage**

The level of storage hierarchy in which all storage state is visible to all processors and mechanisms in the system.

- **normal memory**

Coherently-accessed, well-behaved regions of main storage that hold supervisor software and data and general purpose applications and data. This is in contrast with regions of main storage associated with I/O interfaces or devices such as accelerators or attached to other systems. Normal memory is assumed to have the following storage control attributes (see Section 1.6): not Write Through Required, not Caching Inhibited, Memory Coherence Required, and not Guarded.

- **control memory**

Regions of main storage that are associated with individual devices or groups of similar devices and used to deliver control information, such as commands, to the respective devices. Control memory can be accessed only as the target of a data transfer (see Section 1.7.1.1).

- **persistent storage**

Storage that retains its contents when power is removed, and is “behind” certain regions of main storage, that is not Caching Inhibited, in the sense that a store (to a location in such a region of main

storage) will get to main storage before it gets to persistent storage.

- **primary cache**

The level of cache closest to the processor.

- **secondary cache**

After the primary cache, the next closest level of cache to the processor.

- **instruction storage**

The view of storage as seen by the mechanism that fetches instructions.

- **data storage**

The view of storage as seen by a *Load* or *Store* instruction.

- **program order**

The execution of instructions in the order required by the sequential execution model. (See Section 2.2 of Book I.) A *dcbz* instruction that modifies storage which contains instructions has the same effect with respect to the sequential execution model as a *Store* instruction as described there.)

For the instructions and facilities defined in this Book, there are two additional exceptions to the sequential execution model that the processor obeys beyond those described in Section 2.2 of Book I.

- an event-based branch occurs (see Chapter 6)
- the BHRB is read (see Section 7.2)

- **event-based exception**

An unusual condition, or external signal, that sets a status bit in the BESCR and may or may not cause an event-based branch, depending upon whether event-based branches are enabled.

- **storage location**

A contiguous sequence of one or more bytes in storage. When used in association with a specific instruction or the instruction fetching mechanism, the length of the sequence of one or more bytes is typically implied by the operation. In other uses, it

may refer more abstractly to a group of bytes which share common storage attributes.

#### ■ **storage access**

An access to a storage location. There are three (mutually exclusive) kinds of storage access.

##### – **data access**

An access to the storage location specified by a *Load* or *Store* instruction, or, if the access is performed “out-of-order” (see Section 6.5 of Book III), an access to a storage location as if it were the storage location specified by a *Load* or *Store* instruction.

##### – **instruction fetch**

An access for the purpose of fetching an instruction.

##### – **implicit access**

An access by the processor for the purpose of finding the address translation tables, translating an address, or recording reference and change information (see Book III).

#### ■ **caused by, associated with**

##### – **caused by**

A storage access is said to be caused by an instruction if the instruction is a *Load* or *Store* and the access (data access) is to the storage location specified by the instruction.

##### – **associated with**

A storage access is said to be associated with an instruction if the access is for the purpose of fetching the instruction (instruction fetch), or is a data access caused by the instruction, or is an implicit access that occurs as a side effect of fetching or executing the instruction.

#### ■ **metadata**

Companion data associated with a storage location. In addition to the data that is loaded into a target register or stored from a source register, a storage location may be associated with additional control information. The granularity, meaning, and treatment of the control information may vary based on the type of storage access involved and on the state of the process making the access. Unless otherwise stated or obvious from context, loads ignore the metadata and stores zero the metadata.

Note that not all storage locations have associated metadata. The absence of associated metadata does not necessarily prevent successful completion of an instruction that specifies the treatment of metadata. Unless otherwise stated or obvious from context, metadata associated with a store is

lost, and a load will have its metadata set to zero if the storage location has no associated metadata.

#### ■ **prefetched instructions**

Instructions for which a copy of the instruction has been fetched from instruction storage, but the instruction has not yet been executed.

#### ■ **uniprocessor**

A system that contains one processor.

#### ■ **multiprocessor**

A system that contains two or more processors.

#### ■ **shared storage multiprocessor**

A multiprocessor that contains some common storage, which all the processors in the system can access.

#### ■ **performed**

A load or instruction fetch by a processor or mechanism (P1) is performed with respect to any processor or mechanism (P2) when the value to be returned by the load or instruction fetch can no longer be changed by a store by P2. A store by P1 is performed with respect to P2 when a load by P2 from the location accessed by the store will return the value stored (or a value stored subsequently). An instruction cache block invalidation by P1 is performed with respect to P2 when the instruction that requested the invalidation has caused the specified block, if present, to be made invalid in P2’s instruction cache, and similarly for a data cache block invalidation.

The preceding definitions apply regardless of whether P1 and P2 are the same entity.

#### ■ **page (virtual page)**

$2^n$  contiguous bytes of storage aligned such that the effective address of the first byte in the page is an integral multiple of the page size for which protection and control attributes are independently specifiable and for which reference and change status are independently recorded.

#### ■ **block**

The aligned unit of storage operated on by the *Cache Management* instructions. The size of an instruction cache block may differ from the size of a data cache block, and both sizes may vary between implementations. The maximum block size is equal to the minimum page size.

## 1.2 Introduction

The Power ISA User Instruction Set Architecture, discussed in Book I, defines storage as a linear array of bytes indexed from 0 to a maximum of  $2^{64}-1$ . Each byte is identified by its index, called its address, and each

byte contains a value. This information is sufficient to allow the programming of applications that require no special features of any particular system environment. The Power ISA Virtual Environment Architecture, described herein, expands this simple storage model to include caches, virtual storage, and shared storage multiprocessors. The Power ISA Virtual Environment Architecture, in conjunction with services based on the Power ISA Operating Environment Architecture (see Book III) and provided by the operating system, permits explicit control of this expanded storage model. A simple model for sequential execution allows at most one storage access to be performed at a time and requires that all storage accesses appear to be performed in program order. In contrast to this simple model, the Power ISA specifies a relaxed model of storage consistency. In a multiprocessor system that allows multiple copies of a storage location, aggressive implementations of the architecture can permit intervals of time during which different copies of a storage location have different values. This chapter describes features of the Power ISA that enable programmers to write correct programs for this storage model.

### 1.3 Virtual Storage

The Power ISA system implements a virtual storage model for applications. This means that a combination of hardware and software can present a storage model that allows applications to exist within a “virtual” address space larger than either the effective address space or the real address space.

Each program can access  $2^{64}$  bytes of “effective address” (EA) space, subject to limitations imposed by the operating system. In a typical Power ISA system, each program's EA space is a subset of a larger “virtual address” (VA) space managed by the operating system.

Each effective address is translated to a real address (i.e., to an address of a byte in real storage or on an I/O device) before being used to access storage. The hardware accomplishes this, using the address translation mechanism described in Book III. The operating system manages the real (physical) storage resources of the system, by setting up the tables and other information used by the hardware address translation mechanism.

In general, real storage may not be large enough to map all the virtual pages used by the currently active applications. With support provided by hardware, the operating system can attempt to use the available real pages to map a sufficient set of virtual pages of the applications. If a sufficient set is maintained, “paging” activity is minimized. If not, performance degradation is likely.

The operating system can support restricted access to virtual pages (including read/write, read only, and no access; see Book III), based on system standards (e.g., program code might be read only) and application requests.

### 1.4 Single-Copy Atomicity

An access is *single-copy atomic*, or simply *atomic*, if it is always performed in its entirety with no visible fragmentation. Atomic accesses are thus serialized: each happens in its entirety in some order, even when that order is not specified in the program or enforced between processors.

The access caused by an instruction other than a *Load/Store Multiple* or *Move Assist* instruction is guaranteed to be atomic if the storage operand is not larger than a doubleword and is aligned (see Section 1.10.1 of Book I). For *Load (Store) Multiple Word* instructions, this section applies as if the instruction were the corresponding sequence of *Load Word and Zero (Store Word)* instructions. Thus, for example, the access to each word specified by a *Load/Store Multiple Word* instruction is guaranteed to be atomic if the storage operand is aligned.

Quadword accesses with aligned storage operands are guaranteed to be atomic when caused by the following instructions.

- *lq*
- *stq*
- *lqarx*
- *stqcx*.

Quadword atomicity applies only to storage that is neither Write Through Required nor Caching Inhibited. The cases described above are the only cases in which the access to the storage operand is guaranteed to be atomic. For example, the access caused by the following instructions is not guaranteed to be atomic.

- any *Load* or *Store* instruction for which the storage operand is unaligned
- *lswi*, *lswx*, *stswi*, *stswx*
- *lfdp*, *lfdpx*, *stfdp*, *stfdpx*
- any *Cache Management* instruction

An access that is not atomic is performed as a set of smaller disjoint atomic accesses. If the non-atomic access is caused by an instruction other than a *Move Assist* instruction and one of the following conditions is satisfied, the non-atomic access is performed as described in the corresponding list item. The first list item matching a given situation applies.

- The storage operand is at least 16 bytes long, has length that is an integral multiple of eight, and is doubleword-aligned:  
the access is performed as a set of disjoint atomic accesses each of which consists of one or more aligned doublewords.

- The storage operand is at least eight bytes long, has length that is an integral multiple of four, and is word-aligned:  
the access is performed as a set of disjoint atomic accesses each of which consists of one or more aligned words.
- The storage operand is at least four bytes long, has length that is an integral multiple of two, and is halfword-aligned:  
the access is performed as a set of disjoint atomic accesses each of which consists of one or more aligned halfwords.

In all other cases the number, length, and alignment of the component disjoint atomic accesses are implementation-dependent. In all cases the relative order in which the component disjoint atomic accesses are performed is implementation-dependent.

The results for several combinations of loads and stores to the same or overlapping locations are described below.

1. When two processors perform atomic stores to locations that do not overlap, and no other stores are performed to those locations, the contents of those locations are the same as if the two stores were performed by a single processor.
2. When two processors perform atomic stores to the same storage location, and no other store is performed to that location, the contents of that location are the result stored by one of the processors.
3. When two processors perform stores that have the same target location and are not guaranteed to be atomic, and no other store is performed to that location, the result is some combination of the bytes stored by both processors.
4. When two processors perform stores to overlapping locations, and no other store is performed to those locations, the result is some combination of the bytes stored by the processors to the overlapping bytes. The portions of the locations that do not overlap contain the bytes stored by the processor storing to the location.
5. When a processor performs an atomic store to a location, a second processor performs an atomic load from that location, and no other store is performed to that location, the value returned by the load is the contents of the location before the store or the contents of the location after the store.
6. When a load and a store with the same target location can be performed simultaneously, and the accesses are not guaranteed to be atomic, and no other store is performed to that location, the value returned by the load is some combination of the contents of the location before the store and the contents of the location after the store.

## 1.5 Cache Model

A cache model in which there is one cache for instructions and another cache for data is called a “Harvard-style” cache. This is the model assumed by the Power ISA, e.g., in the descriptions of the *Cache Management* instructions in Section 4.3. Alternative cache models may be implemented (e.g., a “combined cache” model, in which a single cache is used for both instructions and data, or a model in which there are several levels of caches), but they support the programming model implied by a Harvard-style cache.

The processor is not required to maintain copies of storage locations in the instruction cache consistent with modifications to those storage locations (e.g., modifications caused by *Store* instructions).

A location in the data cache is considered to be modified in that cache if the location has been modified (e.g., by a *Store* instruction) and the modified data have not been written to main storage.

*Cache Management* instructions are provided so that programs can manage the caches when needed. For example, program management of the caches is needed when a program generates or modifies code that will be executed (i.e., when the program modifies data in storage and then attempts to execute the modified data as instructions). The *Cache Management* instructions are also useful in optimizing the use of memory bandwidth in such applications as graphics and numerically intensive computing. The functions performed by these instructions depend on the storage control attributes associated with the specified storage location (see Section 1.6, “Storage Control Attributes”).

The *Cache Management* instructions allow the program to do the following.

- invalidate the copy of storage in an instruction cache block (*icbi*)
- provide a hint that an instruction will probably soon be accessed from a specified instruction cache block (*icbt*)
- provide a hint that the program will probably soon access a specified data cache block (*dcbt*, *dcbtst*)
- set the contents of a data cache block to zeros (*dcbz*)
- copy the contents of a modified data cache block to main storage (*dcbst*)
- copy the contents of a modified data cache block to main storage and make the copy of the block in the data cache invalid (*dcbf* or *dcbfi*)

A write to main storage caused by a *dcbst* or *dcbf* instruction has updated main storage when a load by any given processor, that is satisfied from main storage from the location accessed by the write, will return the value written (or a value written or stored subsequently), and similarly for the store caused by a *Store* instruction.

## 1.6 Storage Control Attributes

Some operating systems may provide a means to allow programs to specify the storage control attributes described in this section. Because the support provided for these attributes by the operating system may vary between systems, the details of the specific system being used must be known before these attributes can be used.

Storage control attributes are associated with units of storage that are multiples of the page size. Each storage access is performed according to the storage control attributes of the specified storage location, as described below. The storage control attributes are the following.

- Write Through Required
- Caching Inhibited
- Memory Coherence Required
- Guarded
- 

These attributes have meaning only when an effective address is translated by the processor performing the storage access.

### Programming Note

The Write Through Required and Caching Inhibited attributes are mutually exclusive because, as described below, the Write Through Required attribute permits the storage location to be in the data cache while the Caching Inhibited attribute does not.

Storage that is Write Through Required or Caching Inhibited is not intended to be used for general-purpose programming. For example, the *lbarx*, *lharx*, *lwarx*, *ldarx*, *lqarx*, *stbcx.*, *sthcx.*, *stwcx.*, *stdcx.*, and *stqcx.* instructions may cause the system data storage error handler to be invoked if they specify a location in storage having either of these attributes. To obtain the best performance across the widest range of implementations, storage that is Write Through Required or Caching Inhibited should be used only when the use of such storage meets specific functional or semantic needs or enables a performance optimization.

In the remainder of this section, “*Load* instruction” includes the *Cache Management* and other instructions that are stated in the instruction descriptions to be “treated as a *Load*” unless they are explicitly excluded, and similarly for “*Store* instruction”.

### 1.6.1 Write Through Required

A store to a Write Through Required storage location is performed in main storage. A Store instruction that specifies a location in Write Through Required storage may cause additional locations in main storage to be

accessed. If a copy of the block containing the specified location is retained in the data cache, the store is also performed in the data cache. The store does not cause the block to be considered to be modified in the data cache.

In general, accesses caused by separate *Store* instructions that specify locations in Write Through Required storage may be combined into one access. Such combining does not occur if the *Store* instructions are separated by a *sync* or *eieio* instruction.

### 1.6.2 Caching Inhibited

An access to a Caching Inhibited storage location is performed in main storage. A *Load* instruction that specifies a location in Caching Inhibited storage may cause additional locations in main storage to be accessed unless the specified location is also Guarded. An instruction fetch from Caching Inhibited storage may cause additional words in main storage to be accessed. No copy of the accessed locations is placed into the caches.

In general, non-overlapping accesses caused by separate *Load* instructions that specify locations in Caching Inhibited storage may be combined into one access, as may non-overlapping accesses caused by separate *Store* instructions that specify locations in Caching Inhibited storage. Such combining does not occur if the *Load* or *Store* instructions are separated by a *sync* instruction. Combining may also occur among such accesses from multiple processors that share a common memory interface. No combining occurs if the storage is also Guarded.

### Programming Note

None of the memory barrier instructions prevent the combining of accesses from different processors. The Guarded storage attribute must be used in combination with Caching Inhibited to prevent such combining.

Prefixed instructions are not fetched from storage that is Caching Inhibited. If the instruction addressed by the current instruction address is a prefixed instruction and is in such storage, the system instruction storage error handler is invoked (see Section 7.5.5 of Book III).

### 1.6.3 Memory Coherence Required

An access to a Memory Coherence Required storage location is performed coherently, as follows.

Memory coherence refers to the ordering of stores to a single location. Atomic stores to a given location are *coherent* if they are serialized in some order, and no processor or mechanism is able to observe any subset of those stores as occurring in a conflicting order. This

serialization order is an abstract sequence of values; the physical storage location need not assume each of the values written to it. For example, a processor may update a location several times before the value is written to physical storage. The result of a store operation is not available to every processor or mechanism at the same instant, and it may be that a processor or mechanism observes only some of the values that are written to a location. However, when a location is accessed atomically and coherently by all processors and mechanisms, the sequence of values loaded from the location by any processor or mechanism during any interval of time forms a subsequence of the sequence of values that the location logically held during that interval. That is, a processor or mechanism can never load a “newer” value first and then, later, load an “older” value.

Memory coherence is managed in blocks called coherence *blocks*. Their size is implementation-dependent, but is larger than a word and is usually the size of a cache block.

For storage that is not Memory Coherence Required, software must explicitly manage memory coherence to the extent required by program correctness. The operations required to do this may be system-dependent.

Because the Memory Coherence Required attribute for a given storage location is of little use unless all processors that access the location do so coherently, in statements about Memory Coherence Required storage elsewhere in this document it is generally assumed that the storage has the Memory Coherence Required attribute for all processors that access it.

#### Programming Note

Operating systems that allow programs to request that storage not be Memory Coherence Required should provide services to assist in managing memory coherence for such storage, including all system-dependent aspects thereof.

In most systems the default is that all storage is Memory Coherence Required. For some applications in some systems, software management of coherence may yield better performance. In such cases, a program can request that a given unit of storage not be Memory Coherence Required, and can manage the coherence of that storage by using the **sync** instruction, the *Cache Management* instructions, and services provided by the operating system.

### 1.6.4 Guarded

A data access to a Guarded storage location is performed only if either (a) the access is caused by an instruction that is known to be required by the sequential execution model, or (b) the access is a load and the storage location is already in a cache. If the storage is also Caching Inhibited, only the storage location speci-

fied by the instruction is accessed; otherwise any storage location in the cache block containing the specified storage location may be accessed.

Except in ultravisor or hypervisor real addressing mode, instructions are not fetched from storage that is Guarded. Except in these addressing modes, if the instruction addressed by the current instruction address is in such storage, the system instruction storage error handler is invoked (see Section 7.5.5 of Book III).

#### Programming Note

In some implementations, instructions may be executed before they are known to be required by the sequential execution model. Because the results of instructions executed in this manner are discarded if it is later determined that those instructions would not have been executed in the sequential execution model, this behavior does not affect most programs.

This behavior does affect programs that access storage locations that are not “well-behaved” (e.g., a storage location that represents a control register on an I/O device that, when accessed, causes the device to perform an operation). To avoid unintended results, programs that access such storage locations should request that the storage be Guarded, and should prevent such storage locations from being in a cache (e.g., by requesting that the storage also be Caching Inhibited).

## 1.7 Shared Storage

This architecture supports the sharing of storage between programs, between different instances of the same program, and between processors and other mechanisms. It also supports access to a storage location by one or more programs using different effective addresses. All these cases are considered storage sharing. Storage is shared in blocks that are an integral number of pages.

When the same storage location has different effective addresses, the addresses are said to be *aliases*. Each application can be granted separate access privileges to aliased pages.

### 1.7.1 Storage Access Ordering

The storage model for the ordering of storage accesses is weakly consistent. This model provides an opportunity for improved performance over a model that has stronger consistency rules, but places the responsibility on the program to ensure that ordering or synchronization instructions are properly placed when storage is shared by two or more programs.

The order in which the processor performs storage accesses, the order in which those accesses are performed with respect to another processor or mechanism, and the order in which those accesses are performed in main storage may all be different. Several means of enforcing an ordering of storage accesses are provided to allow programs to share storage with other programs, or with mechanisms such as I/O devices. These means are listed below. The phrase “to the extent required by the associated Memory Coherence Required attributes” refers to the Memory Coherence Required attribute, if any, associated with each access.

- If two *Store* instructions or two *Load* instructions specify storage locations that are both Caching Inhibited and Guarded, the corresponding storage accesses are performed in program order with respect to any processor or mechanism.
- If a *Load* instruction depends on the value returned by a preceding *Load* instruction (because the value is used to compute the effective address specified by the second *Load*), the corresponding storage accesses are performed in program order with respect to any processor or mechanism to the extent required by the associated Memory Coherence Required attributes. This applies even if the dependency has no effect on program logic (e.g., the value returned by the first *Load* is ANDed with zero and then added to the effective address specified by the second *Load*).
- When a processor (P1) executes a *Synchronize or eieio* instruction a *memory barrier* is created, which orders applicable storage accesses pairwise, as follows. Let A be a set of storage accesses that includes all storage accesses associated with instructions preceding the barrier-creating instruction, and let B be a set of storage accesses that includes all storage accesses associated with instructions following the barrier-creating instruction. For each applicable pair  $a_i, b_j$  of storage accesses such that  $a_i$  is in A and  $b_j$  is in B, the memory barrier ensures that  $a_i$  will be performed with respect to any processor or mechanism, to the extent required by the associated Memory Coherence Required attributes, before  $b_j$  is performed with respect to that processor or mechanism.

The ordering done by a memory barrier is said to be “cumulative” if it also orders storage accesses that are performed by processors and mechanisms other than P1, as follows.

- A includes all applicable storage accesses by any such processor or mechanism that have been performed with respect to P1 before the memory barrier is created.
- B includes all applicable storage accesses by any such processor or mechanism that are

performed after a *Load* instruction executed by that processor or mechanism has returned the value stored by a store that is in B.

No ordering should be assumed among the storage accesses caused by a single instruction (i.e., by an instruction for which the access is not atomic), and no means are provided for controlling that order.

## Programming Note

Because stores cannot be performed “out-of-order” (see Book III), if a *Store* instruction depends on the value returned by a preceding *Load* instruction (because the value returned by the *Load* is used to compute either the effective address specified by the *Store* or the value to be stored), the corresponding storage accesses are performed in program order. The same applies if *whether* the *Store* instruction is executed depends on a conditional *Branch* instruction that in turn depends on the value returned by a preceding *Load* instruction.

Because an *isync* instruction prevents the execution of instructions following the *isync* until instructions preceding the *isync* have completed, if an *isync* follows a conditional *Branch* instruction that depends on the value returned by a preceding *Load* instruction, the load on which the *Branch* depends is performed before any loads caused by instructions following the *isync*. This applies even if the effects of the “dependency” are independent of the value loaded (e.g., the value is compared to itself and the *Branch* tests the EQ bit in the selected CR field), and even if the branch target is the sequentially next instruction.

With the exception of the cases described above and earlier in this section, data dependencies and control dependencies do not order storage accesses. Examples include the following.

- If a *Load* instruction specifies the same storage location as a preceding *Store* instruction and the location is in storage that is not Caching Inhibited, the load may be satisfied from a “store queue” (a buffer into which the processor places stored values before presenting them to the storage subsystem), and not be visible to other processors and mechanisms. A consequence is that if a subsequent *Store* depends on the value returned by the *Load*, the two stores need not be performed in program order with respect to other processors and mechanisms.
- Because a *Store Conditional* instruction may complete before its store has been performed, a conditional *Branch* instruction that depends on the CR0 value set by a *Store Conditional* instruction does

not order the *Store Conditional*s store with respect to storage accesses caused by instructions that follow the *Branch*.

- Because processors may predict branch target addresses and branch condition resolution, control dependencies (e.g., branches) do not order storage accesses except as described above. For example, when a subroutine returns to its caller the return address may be predicted, with the result that loads caused by instructions at or after the return address may be performed before the load that obtains the return address is performed.

Because processors may implement nonarchitected duplicates of architected resources (e.g., GPRs, CR fields, and the Link Register), resource dependencies (e.g., specification of the same target register for two *Load* instructions) do not order storage accesses.

Examples of correct uses of dependencies, *sync* and *lwsync* to order storage accesses can be found in Appendix B. “Programming Examples for Sharing Storage” on page 1117.

Because the storage model is weakly consistent, the sequential execution model as applied to instructions that cause storage accesses guarantees only that those accesses appear to be performed in program order with respect to the processor executing the instructions. For example, an instruction may complete, and subsequent instructions may be executed, before storage accesses caused by the first instruction have been performed. However, for a sequence of atomic accesses to the same storage location, if the location is in storage that is Memory Coherence Required the definition of coherence guarantees that the accesses are performed in program order with respect to any processor or mechanism that accesses the location coherently, and similarly if the location is in storage that is Caching Inhibited.

Because accesses to storage that is Caching Inhibited are performed in main storage, memory barriers and dependencies on *Load* instructions order such accesses with respect to any processor or mechanism even if the storage is not Memory Coherence Required.

**Programming Note**

The first example below illustrates cumulative ordering of storage accesses preceding a memory barrier, and the second illustrates cumulative ordering of storage accesses following a memory barrier. Assume that locations X, Y, and Z initially contain the value 0.

**Example 1:**

Processor A:  
stores the value 1 to location X

Processor B:  
loads from location X obtaining the value 1, executes a **sync** instruction, then stores the value 2 to location Y

Processor C:  
loads from location Y obtaining the value 2, executes a **sync** instruction, then loads from location X

**Example 2:**

Processor A:  
stores the value 1 to location X, executes a **sync** instruction, then stores the value 2 to location Y

Processor B:  
loops loading from location Y until the value 2 is obtained, then stores the value 3 to location Z

Processor C:  
loads from location Z obtaining the value 3, executes a **sync** instruction, then loads from location X

In both cases, cumulative ordering dictates that the value loaded from location X by processor C is 1.

### 1.7.1.1 Storage Ordering of Copy/Paste-Initiated Data Transfers

The Copy-Paste Facility (see Section 4.4) uses pairs of instructions to initiate 128-byte data transfers. They are referred to as “data transfers” to differentiate them from the “normal” storage accesses caused by or associated with loads, stores, and instructions that are treated as loads and stores. In the absence of barriers, the relative ordering among adjacent data transfers or data transfers and storage accesses is not defined, and the sequential execution model and coherence-required ordering relationships do not apply. To establish order between adjacent data transfers or between data transfers and storage accesses, **hwsync** must be used. See the description of the *Synchronize* instruction in Section 4.6.3 for more information.

**Programming Note**

It may be helpful to think of a **copy/paste** pair sending the real storage addresses of the 128-byte source and destination to an asynchronous data transfer engine completely separate from the processor that is executing the **copy** and **paste** instructions. The data transfers collect in the engine’s queue. The engine may perform the data transfers in any order, and with the only relative timing relationship to adjacent transfers and accesses being determined by **hwsync**.

### 1.7.1.2 Storage Ordering of Stores to Persistent Storage

A location in a region of main storage that is backed by persistent storage is considered to be modified relative to persistent storage if the location has been modified in main storage (e.g., by a *Store* instruction) and the modified data have not been written to persistent storage. A store has updated persistent storage when a load by any given processor, from the location accessed by the store, would return the value stored (or a value stored subsequently) if system power were lost temporarily between the time the store has updated persistent storage and the time the load is performed. A store may update persistent storage significantly later than it updates main storage. The **dcbstps** (data cache block store to persistent storage) and **dcbfps** (data cache block flush to persistent storage) instructions can be used to write modified locations in a block to persistent storage (and to perform the functions of *Data Cache Block Store* and *Data Cache Block Flush* respectively). The **phwsync** (persistent heavyweight sync) and **plwsync** (persistent lightweight sync) instructions can be used to establish order for these writes to persistent storage. A store may update persistent storage even in the absence of **dcbstps** and **dcbfps** instructions targeting the cache block(s) affected by the store. See Section 4.3.2 and Section 4.6.3 for more information.

Except in this section and in other material dealing with persistent storage, references to the storage subsystem in this document assume system power is not lost unless otherwise stated or obvious from context.

**Programming Note**

On the POWER9 processor, **dcbf** performs the functions required of **dcbfps** and **dcbstps**. The encodings chosen for **dcbfps** and **dcbstps** are decoded as **dcbf** on the POWER9 processor.

On the POWER9 processor, **lwsync** and **hwsync** perform the functions required of **plwsync** and **phwsync**, respectively. The encodings chosen for **plwsync** and **phwsync** are decoded as **lwsync** and **hwsync**, respectively, on the POWER9 processor.

The encodings for **dcbfps**, **dcbstps**, **plwsync**, and **phwsync** were chosen to enable software developed to control updates to persistent storage on processors that comply with Version 3.1 and subsequent versions of the architecture to run compatibly on the POWER9 processor.

**Programming Note**

The ordering of loads from persistent storage is not discussed because loads are satisfied from the nearest source (store buffer, nearest cache, or memory) of a consistent value for a datum.

### 1.7.1.3 Storage Ordering of I/O Accesses

A “coherence domain” consists of all processors and all interfaces to main storage. Memory reads and writes initiated by mechanisms outside the coherence domain are performed within the coherence domain in the order in which they enter the coherence domain and are performed as coherent accesses.

## 1.7.2 Atomic Update

The *Load And Reserve* and *Store Conditional* instructions together permit atomic update of a shared storage location. There are byte, halfword, word, doubleword, and quadword forms of each of these instructions. Described here is the operation of the word forms **lwarx** and **stwcx.**; operation of the byte, halfword, doubleword, and quadword forms **lbarx**, **stbcx.**, **lharx**, **sthcx.**, **ldarx**, **stdcx.**, **lqarx**, and **stqcx.** is the same except for obvious substitutions.

The **lwarx** instruction is a load from a word-aligned location that has two side effects. Both of these side effects occur at the same time that the load is performed.

1. A reservation for a subsequent **stwcx.** instruction is created.

2. The memory coherence mechanism is notified that a reservation exists for the storage location specified by the **lwarx**.

The **stwcx.** instruction is a store to a word-aligned location that is conditioned on the existence of the reservation created by the **lwarx** and on whether the same storage location is specified by both instructions. To emulate an atomic operation with these instructions, it is necessary that both the **lwarx** and the **stwcx.** specify the same storage location.

A **stwcx.** performs a store to the target storage location only if the reservation created by the **lwarx** still exists at the time the **stwcx.** is executed, and only if the storage locations specified by the two instructions are in the same aligned block of real storage whose size is the smallest real page size supported by the implementation. The remainder of this paragraph assumes that these two conditions are satisfied. If the storage locations specified by the two instructions differ, or if a *Store Conditional* instruction is used with a preceding *Load And Reserve* instruction that has a different storage operand length (e.g., **stwcx.** with **ldarx**), whether the store is performed is undefined. Otherwise the store is performed.

A **stwcx.** that performs its store is said to “succeed”.

Examples of the use of **lwarx** and **stwcx.** are given in Appendix B. “Programming Examples for Sharing Storage” on page 1117.

A successful **stwcx.** to a given location may complete before its store has been performed with respect to other processors and mechanisms. As a result, a subsequent load or **lwarx** from the given location by another processor may return a “stale” value. However, a subsequent **lwarx** from the given location by the other processor followed by a successful **stwcx.** by that processor is guaranteed to have returned the value stored by the first processor’s **stwcx.** (in the absence of other stores to the given location).

**Programming Note**

The store caused by a successful **stwcx.** is ordered, by a dependence on the reservation, with respect to the load caused by the **lwarx** that established the reservation, such that the two storage accesses are performed in program order with respect to any processor or mechanism.

### Programming Note

If a virtual address is reassigned to a different real page, a reservation established at the virtual address before the reassignment will not be cleared by a store to the new real page by some other processor or mechanism. (As described in Section 1.7.2.1, reservations are held on real addresses.) If *Store Conditional* instructions did not suppress the store when the storage location specified by the *Store Conditional* instruction is in a different real page from the storage location specified by the corresponding *Load And Reserve* instruction, such virtual address reassignment could permit a *Store Conditional* instruction that specifies the same virtual address as the corresponding *Load And Reserve* instruction, and logically should fail because the other processor or mechanism stored to the virtual address, to succeed.

This real address checking cannot detect that the virtual page in which the reservation was established has been moved to a new real page and back again to the original real page that was accessed by the *Load And Reserve* instruction. It also cannot detect that the real address of the storage location specified by a *Store Conditional* instruction is the same as the real address of the reservation, or is in the same real page as the reservation, *only* because the virtual page containing the storage location specified by the *Store Conditional* instruction has been moved to the real page that was accessed by the corresponding *Load And Reserve* instruction. Privileged software that moves a virtual page should clear the reservation on the processor it is running on in order to ensure that a *Store Conditional* instruction executed by that processor does not succeed in these cases. (If the software that moves the virtual page uses *Load And Reserve* and *Store Conditional* for its own purposes, the clearing of the original reservation will happen naturally. The stores that occur naturally as part of moving the virtual page will cause any reservations, held by other processors, in the target real page to be cleared.)

supported by the implementation. The reservation granule associated with effective address EA contains the real address to which EA maps. (“real\_addr(EA)” in the RTL for the *Load And Reserve* and *Store Conditional* instructions stands for “real address to which EA maps”.) The reservation also has an associated length, which is equal to the storage operand length, in bytes, of the *Load And Reserve* instruction that established the reservation.

A processor has at most one reservation at any time. A reservation is established by executing a *lbarx*, *lharx*, *lwarx*, *ldarx*, or *lqarx* instruction, as described in item 1 below, and is lost or may be lost, depending on the item, if any of the following occur. Items 1-8 apply only if the relevant access is performed. (For example, an access that would ordinarily be caused by an instruction might not be performed if the instruction causes the system error handler to be invoked.)

1. The processor holding the reservation executes another *lbarx*, *lharx*, *lwarx*, or *ldarx*: this clears the first reservation and establishes a new one.
2. The processor holding the reservation executes any *stbcx.*, *sthcx.*, *stwcx.*, *stdcx.*, or *stqcx.*, regardless of whether the specified address matches the address specified by the *lbarx*, *lharx*, *lwarx*, *ldarx*, or *lqarx* that established the reservation, and regardless of whether the storage operand lengths of the two instructions are the same.
3. The processor holding the reservation executes an AMO that updates the same reservation granule: whether the reservation is lost is undefined.
4. Some other processor executes a *Store* or *dcbz* that specifies a location in the same reservation granule.
5. Some other processor executes a *dcbtst*, or *dcbt* that specifies a location in the same reservation granule: whether the reservation is lost is undefined. (For a *dcbtst* instruction that specifies a data stream, “location” in the preceding sentence includes all locations in the data stream.)
6. Any processor modifies a Reference or Change bit in the same reservation granule: the reservation is lost if the modification is atomic; otherwise whether the reservation is lost is undefined. (See Section 6.7.12 of Book III)
7. Some mechanism other than a processor modifies a storage location in the same reservation granule.
8. An interrupt (see Book III) occurs on the processor holding the reservation: the interrupt itself does not clear the reservation, but system software invoked by the interrupt may clear the reservation.
9. Implementation-specific characteristics of the coherence mechanism cause the reservation to be lost.

### 1.7.2.1 Reservations

The ability to emulate an atomic operation using *lwarx* and *stwcx.* is based on the conditional behavior of *stwcx.*, the reservation created by *lwarx*, and the clearing of that reservation if the target storage location is modified by another processor or mechanism before the *stwcx.* performs its store.

A reservation is held on an aligned unit of real storage called a reservation granule. The size of the reservation granule is  $2^n$  bytes, where  $n$  is implementation-dependent but is always at least 4 (thus the minimum reservation granule size is a quadword), and where  $2^n$  is not larger than the smallest real page size

The reservation is also used by the *waitrsv* instruction (see Section 4.6.4).

#### Virtualized Implementation Note

A reservation may be lost if:

- Software executes a privileged instruction or utilizes a privileged facility
- Software accesses storage not intended for general-purpose programming

#### Programming Note

One use of *lwarx* and *stwcx.* is to emulate a “Compare and Swap” primitive like that provided by the IBM System/370 Compare and Swap instruction; see Section B.1, “Atomic Update Primitives” on page 1117. A System/370-style Compare and Swap checks only that the old and current values of the word being tested are equal, with the result that programs that use such a Compare and Swap to control a shared resource can err if the word has been modified and the old value subsequently restored. The combination of *lwarx* and *stwcx.* improves on such a Compare and Swap, because the reservation reliably binds the *lwarx* and *stwcx.* together. The reservation is always lost if the word is modified by another processor or mechanism between the *lwarx* and *stwcx.*, so the *stwcx.* never succeeds unless the word has not been stored into (by another processor or mechanism) since the *lwarx*.

#### Programming Note

In general, programming conventions must ensure that *lwarx* and *stwcx.* specify addresses that match; a *stwcx.* should be paired with a specific *lwarx* to the same storage location. Situations in which a *stwcx.* may erroneously be issued after some *lwarx* other than that with which it is intended to be paired must be scrupulously avoided. For example, there must not be a context switch in which the processor holds a reservation in behalf of the old context, and the new context resumes after a *lwarx* and before the paired *stwcx.*. The *stwcx.* in the new context might succeed, which is not what was intended by the programmer. Such a situation must be prevented by executing a *stbcx.*, *stbcx.*, *stwcx.*, *stdcx.*, or *stqcx.* that specifies a dummy writable aligned location as part of the context switch; see Section 7.4.3 of Book III.

#### Programming Note

Because the reservation is lost if another processor stores anywhere in the reservation granule, lock words (or bytes, halfwords, or doublewords) should be allocated such that few such stores occur, other than perhaps to the lock word itself. (Stores by other processors to the lock word result from contention for the lock, and are an expected consequence of using locks to control access to shared storage; stores to other locations in the reservation granule can cause needless reservation loss.) Such allocation can most easily be accomplished by allocating an entire reservation granule for the lock and wasting all but one word. Because reservation granule size is implementation-dependent, portable code must do such allocation dynamically.

Similar considerations apply to other data that are shared directly using *lwarx* and *stwcx.* (e.g., pointers in certain linked lists; see Section B.3, “List Insertion” on page 1121).

### 1.7.2.2 Forward Progress

Forward progress in loops that use *lwarx* and *stwcx.* is achieved by a cooperative effort among hardware, system software, and application software.

The architecture guarantees that when a processor executes a *lwarx* to obtain a reservation for location X and then a *stwcx.* to store a value to location X, either

1. the *stwcx.* succeeds and the value is written to location X, or
2. the *stwcx.* fails because some other processor or mechanism modified location X, or
3. the *stwcx.* fails because the processor’s reservation was lost for some other reason.

In Cases 1 and 2, the system as a whole makes progress in the sense that some processor successfully modifies location X. Case 3 covers reservation loss required for correct operation of the rest of the system. This includes cancellation caused by some other processor or mechanism writing elsewhere in the reservation granule, cancellation caused by the operating system in managing certain limited resources such as real storage, and cancellation caused by any of the other effects listed in see Section 1.7.2.1.

An implementation may make a forward progress guarantee, defining the conditions under which the system as a whole makes progress. Such a guarantee must specify the possible causes of reservation loss in Case 3. While the architecture alone cannot provide such a guarantee, the characteristics listed in Cases 1 and 2 are necessary conditions for any forward progress

guarantee. An implementation and operating system can build on them to provide such a guarantee.

Section 1.8.1, “Concurrent Modification and Execution of Instructions” on page 1053.

#### Virtualized Implementation Note

On a virtualized implementation, Case 3 includes reservation loss caused by the virtualization software. Thus, on a virtualized implementation, a reservation may be lost at any time without apparent cause. The virtualization software participates in any forward progress assurances, as described above.

#### Programming Note

The architecture does not include a “fairness guarantee”. In competing for a reservation, two processors can indefinitely lock out a third.

## 1.8 Instruction Storage

The instruction execution properties and requirements described in this section, including its subsections, apply only to instruction execution that is required by the sequential execution model.

In this section, including its subsections, it is assumed that all instructions for which execution is attempted are in storage that is not Caching Inhibited and (unless instruction address translation is disabled; see Book III) is not Guarded, and from which instruction fetching does not cause the system error handler to be invoked (e.g., from which instruction fetching is not prohibited by the “address translation mechanism” or the “storage protection mechanism”; see Book III).

#### Programming Note

The results of attempting to execute instructions from storage that does not satisfy this assumption are described in Section 1.6.2 and Section 1.6.4 of this Book and in Book III.

The instruction cache is not necessarily kept consistent with the data cache or with main storage. It is the responsibility of software to ensure that instruction storage is consistent with data storage when such consistency is required for program correctness.

After one or more bytes of a storage location have been modified and before an instruction located in that storage location is executed, software must execute the appropriate sequence of instructions to make instruction storage consistent with data storage. Otherwise the result of attempting to execute the instruction is boundedly undefined except as described in

## Programming Note

Following are examples of how to make instruction storage consistent with data storage. Because the optimal instruction sequence to make instruction storage consistent with data storage may vary between systems, many operating systems will provide a system service to perform this function.

**Case 1:** The given program does not modify instructions executed by another program nor does another program modify the instructions executed by the given program.

Assume that location X previously contained the instruction A0; the program modified one or more bytes of that location such that, in data storage, the location contains the instruction A1; and location X is wholly contained in a single cache block. The following instruction sequence will make instruction storage consistent with data storage such that if the *isync* was in location X-4, the instruction A1 in location X would be executed immediately after the *isync*.

```
dcbst X      #copy the block to main storage
sync        #order copy before invalidation
icbi X      #invalidate copy in instr cache
isync       #discard prefetched instructions
```

**Case 2:** One or more programs execute the instructions that are concurrently being modified by another program.

Assume program A has modified the instruction at location X and other programs are waiting for program A to signal that the new instruction is ready to execute. The following instruction sequence will make instruction storage consistent with data storage and then set a flag to indicate to the waiting programs that the new instruction can be executed.

```
li    r0,1    #put a 1 value in r0
dcbst X      #copy the block in main storage
sync     #order copy before invalidation
icbi X      #invalidate copy in instr cache
sync     #order invalidation before store
        # to flag
stw r0,flag  #set flag indicating instruction
        # storage is now consistent
```

The following instruction sequence, executed by the waiting program, will prevent the waiting programs from executing the instruction at location X until location X in instruction storage is consistent with data storage, and then will cause any prefetched instructions to be discarded.

```
lwz    r0,flag #loop until flag = 1 (when 1 is
cmpwi  r0,1    # loaded, location X in inst'n
bne    $-8     # storage is consistent with
        # location X in data storage)
isync   #discard any prefetched inst'ns
```

In the preceding instruction sequence any context synchronizing instruction (e.g., *rfid*) can be used instead of *isync*. (For Case 1 only *isync* can be used.)

For both cases, if two or more instructions in separate data cache blocks have been modified, the *dcbst* instruction in the examples must be replaced by a sequence of *dcbst* instructions such that each block containing the modified instructions is copied back to main storage. Similarly, for *icbi* the sequence must invalidate each instruction cache block containing a location of an instruction that was modified. The *sync* instruction that appears above between “*dcbst* X” and “*icbi* X” would be placed between the sequence of *dcbst* instructions and the sequence of *icbi* instructions.

## 1.8.1 Concurrent Modification and Execution of Instructions

The phrase “concurrent modification and execution of instructions” (CMODX) refers to the case in which a processor fetches and executes an instruction from instruction storage which has not been made consistent with data storage. This section describes the only case in which executing this instruction under these conditions produces defined results.

### Programming Note

The architecture does not support CMODX modification of an entire prefixed instruction because it may be unaligned and therefore impossible to modify atomically. Furthermore, no need has arisen to motivate the creation of special cases where it must work. The architecture also does not support CMODX modification of the suffix of a prefixed instruction.

In the remainder of this section the following terminology is used.

- Location X is an arbitrary four-byte word-aligned storage location.
- $X_0$  is the value of the contents of location X for which software has made the location X in instruction storage consistent with data storage.
- $X_1, X_2, \dots, X_n$  are the sequence of the first n values occupying location X after  $X_0$ .
- $X_n$  is the first value of X subsequent to  $X_0$  for which software has again made instruction storage consistent with data storage.
- The “patch class” of words consists of the following.
  - the I-form *Branch* instruction (***b***[I][a])
  - the preferred no-op instruction (***ori*** 0,0,0)
  - the prefix of the Prefixed No-op instruction (***pnop***)
  - the D-form and X-form *Trap* instructions for which TO = 0b11111
- The “instruction from location X” includes both the case of a word instruction contained in location X and the case of a prefixed instruction for which the prefix is contained in location X.

If the instruction from location X is executed after the copy of location X in instruction storage is made consistent for the value  $X_0$  and before it is made consistent for the value  $X_n$ , the results of executing the instruction are defined if and only if the following conditions are satisfied.

1. The stores that place the values  $X_1, \dots, X_n$  into location X are atomic stores that modify all four bytes of location X.
2. The sequence of  $X_i$  values is one of two types:
  - any sequence in which each  $X_i$  is a patch class word, or
  - any sequence that is comprised of exactly two unique word values, at least one of which is a patch class word.
3. If a sequence of  $X_i$  values contains a prefix, the only word instructions the sequence can contain are the patch class *Branch* and patch class *Trap* instructions. In this use, the target of the *Branch* instruction must not be the word following the *Branch* instruction.
4. Location X is in storage that is Memory Coherence Required.

### Programming Note

If the instruction from location X is a prefixed instruction, it should obey the rules for prefixed instructions. In particular:

- The instruction should not cross a 64-byte boundary. (Thus if the EA of location X is equal to 60 modulo 64, none of the  $X_i$  should be prefixes.)
- If the instruction is ***pnop***, the word at location X+4 should not be a *Branch* instruction, ***rfebb***, a context synchronizing instruction other than ***isync***, or a “Service Processor Attention” instruction.

If these conditions are satisfied, each execution of an instruction from location X will use some  $X_i$ ,  $0 \leq i \leq n$ . The value of the ordinate i associated with each value executed may be different and the sequence of ordinates i associated with a sequence of values executed is not constrained, (e.g., a valid sequence of executions of the instruction from location X could use the sequence  $X_i, X_{i+2}$ , then  $X_{i-1}$ ). If these conditions are not satisfied, the results of each such execution of an instruction from location X are boundedly undefined, and may include causing inconsistent information to be presented to the system error handler.

### Programming Note

An example of how failure to satisfy the requirements given above can cause inconsistent information to be presented to the system error handler is as follows. If the value  $X_0$  (an illegal instruction) is executed, causing the system illegal instruction handler to be invoked, and before the error handler can load  $X_0$  into a register,  $X_0$  is replaced with  $X_1$ , an *Add Immediate* instruction, it will appear that a legal instruction caused an illegal instruction exception.

**Programming Note**

It is possible to apply a patch or to instrument a given program without the need to suspend or halt the program. This can be accomplished by modifying the example shown in the Programming Note at the end of Section 1.8 where one program is creating instructions to be executed by one or more other programs.

In place of the *Store* to a flag to indicate to the other programs that the code is ready to be executed, the program that is applying the patch would replace an instruction in the original program with an I-form *Branch* instruction that would cause any program executing the *Branch* to branch to the newly created code. The first instruction in the newly created code must be an *isync*, which will cause any prefetched instructions to be discarded, ensuring that the execution is consistent with the newly created code. The instruction storage location containing the *isync* instruction in the patch area must be consistent with data storage with respect to the processor that will execute the patched code before the *Store* which stores the new *Branch* instruction is performed.

**Programming Note**

The ability to modify instructions that may be being executed provides opportunities for significant performance benefits in interpretive environments (e.g., Java), and can be used to instrument code dynamically to isolate critical hardware and software bugs.

## Chapter 2. Instruction Restart

In this section, “*Load* instruction” includes the *Cache Management* and other instructions that are stated in the instruction descriptions to be “treated as a *Load*”, and similarly for “*Store* instruction”.

The following instructions are never restarted after having accessed any portion of the storage operand (unless the instruction causes a “Data Address Watchpoint match”, for which the corresponding rules are given in Book III).

1. A *Store* instruction that causes an atomic access
2. A *Load* instruction that causes an atomic access to storage that is both Caching Inhibited and Guarded

Any other *Load* or *Store* instruction may be partially executed and then aborted after having accessed a portion of the storage operand, and then re-executed (i.e., restarted, by the processor or the operating system). If an instruction is partially executed, the contents of registers are preserved to the extent that the correct result will be produced when the instruction is re-executed. Additional restrictions on the partial execution of instructions are described in Section 7.6 of Book III.

### Programming Note

In order to ensure that the contents of registers are preserved to the extent that a partially executed instruction can be re-executed correctly, the registers that are preserved must satisfy the following conditions. For any given instruction, zero or more of the conditions applies.

- For a fixed-point *Load* instruction that is not a multiple or string form, if  $RT=RA$  or  $RT=RB$  then the contents of register  $RT$  are not altered.
- For an update form *Load* or *Store* instruction, the contents of register  $RA$  are not altered.

### Programming Note

There are many events that might cause a *Load* or *Store* instruction to be restarted. For example, a hardware error may cause execution of the instruction to be aborted after part of the access has been performed, and the recovery operation could then cause the aborted instruction to be re-executed.

When an instruction is aborted after being partially executed, the contents of the instruction pointer indicate that the instruction has not been executed, however, the contents of some registers may have been altered and some bytes within the storage operand may have been accessed. The following are examples of an instruction being partially executed and altering the program state even though it appears that the instruction has not been executed.

1. *Load Multiple*, *Load String*: Some registers in the range of registers to be loaded may have been altered.
2. Any *Store* instruction, ***dcbz***: Some bytes of the storage operand may have been altered.

## Chapter 3. Management of Shared Resources

The facilities described in this section provide the means to control the use of resources that are shared with other processors.

### 3.1 Program Priority Registers

The Program Priority Register (PPR) is a 64-bit register that controls the program's priority. The PPR provides access to the full 64-bit PPR, and the Program Priority Register 32-bit (PPR32) provides access to the upper 32 bits of the PPR. The layouts of the PPR and PPR32 are shown in Figure 1.

Bit(s)	Description
11:13	<b>Program Priority (PRI)</b> (PPR32 <sub>43:45</sub> )
001	very low
010	low
011	medium low
100	medium
101	medium high

Programs can always set the PRI field to very low, low, medium low, and medium priorities; programs may be allowed to set the PRI field to medium high priority during certain time intervals. (See Section 5.3.6.) If the program priority is medium high when the time interval expires or if an attempt is made to set the priority to medium high when it is not allowed, the PRI field is set to medium.

If other values are written to this field, the PRI field is not changed. (See Section 5.3.5 of Book III for additional information.)

All other fields are reserved.

**Figure 1. Program Priority Register**

#### Programming Note

The ability to access the low-order half of the PPR (and thus the use of *mfppr* and *mtppr*) might be phased out in a future version of the architecture.

#### Programming Note

By setting the PRI field, a programmer may be able to improve system throughput by causing system resources to be used more efficiently.

E.g., if a program is waiting on a lock (see Section B.2), it could set low priority, with the result that more processor resources would be diverted to the program that holds the lock. This diversion of resources may enable the lock-holding program to complete the operation under the lock more quickly, and then relinquish the lock to the waiting program.

#### Programming Note

*or Rx,Rx,Rx* can be used to modify the PRI field; see Section 3.2.

#### Programming Note

When the system error handler is invoked, the PRI field may be set to an undefined value.

## 3.2 “or” Instruction

### Setting the PPR

The *or Rx,Rx,Rx* (see Book I) instruction can be used to set  $PPR_{PRI}$  as shown in Table 1. *or Rx,Rx,Rx* does not set  $PPR_{PRI}$ .

Rx	$PPR_{PRI}$	Priority
31	001	very low
1	010	low
6	011	medium low
2	100	medium
5	101	medium high

Table 1: Priority levels for *or Rx,Rx,Rx*

Programs can always set the PRI field to very low, low, medium low, and medium priorities; programs may be allowed to set the PRI field to medium high priority during certain time intervals. (See Section 5.3.6 of Book III.) If the program priority is medium high when the time interval expires or if an attempt is made to set the priority to medium high when it is not allowed, the PRI field is set to medium.

#### Programming Note

**Warning:** Other forms of *or Rx,Rx,Rx* that are not described in this section and in Section 4.3.3 may also cause program priority to change. Use of these forms should be avoided except when software explicitly intends to alter program priority. If a no-op is needed, the preferred no-op (*ori 0,0,0*) should be used.

## Chapter 4. Storage Control Instructions

### 4.1 Parameters Useful to Application Programs

It is suggested that the operating system provide a service that allows an application program to obtain the following information.

1. The virtual page sizes
2. Coherence block size
3. Reservation granule size
4. An indication of the cache model implemented (e.g., Harvard-style cache, combined cache)
5. Instruction cache size
6. Data cache size
7. Instruction cache block size
8. Data cache block size
9. Instruction cache associativity
10. Data cache associativity
11. Number of stream IDs supported for the stream variant of *dcbt*
12. Factors for converting the Time Base to seconds

If the caches are combined, the same value should be given for an instruction cache attribute and the corresponding data cache attribute.

### 4.2 Data Stream Control Register (DSCR)

The layout of the Data Stream Control Register (DSCR) is shown in Figure 2 below.

//		SWTE	HWTE	STE	LTE	SWUE	HWUE	UNIT CNT	URG	LSD	SNSE	SSE	DPFD			
0	38	39	40	41	42	43	44	45	54	55	57	58	59	60	61	63

**Figure 2. Data Stream Control Register**

#### Bit(s) Description

- 39 **Software Transient Enable (SWTE)**
- 0 SWTE is disabled.
  - 1 Applies the transient attribute to software-defined streams.

- 40 **Hardware Transient Enable (HWTE)**
- 0 HWTE is disabled.
  - 1 Applies the transient attribute to hardware-detected streams.

- 41 **Store Transient Enable (STE)**
- 0 STE is disabled.
  - 1 Applies the transient attribute to store streams.

- 42 **Load Transient Enable (LTE)**
- 0 LTE is disabled.
  - 1 Applies the transient attribute to load streams.

- 43 **Software Unit count Enable (SWUE)**
- 0 SWUE is disabled.
  - 1 Applies the unit count to software-defined streams.

- 44 **Hardware Unit count Enable (HWUE)**
- 0 HWUE is disabled.
  - 1 Applies the unit count to hardware-detected streams.

- 45:54 **Unit Count (UNITCNT)**  
Number of units in data stream.

- 55:57 **Depth Attainment Urgency (URG)**  
This field indicates how quickly the prefetch depth should be reached for hardware-detected streams. Values and their meanings are as follows.

- 0 default
- 1 not urgent
- 2 least urgent
- 3 less urgent
- 4 medium
- 5 urgent
- 6 more urgent
- 7 most urgent

- 58 **Load Stream Disable (LSD)**
- 0 No effect.
  - 1 Disables hardware detection and initiation of load streams.

- 59 **Stride-N Stream Enable** (SNSE)
- 0 No effect.
  - 1 Enables the hardware detection and initiation of load and store streams that have a stride greater than a single cache block. Such load streams are detected only when LSD is also zero. Such store streams are detected only when SSE is also one.

- 60 **Store Stream Enable** (SSE)
- 0 No effect.
  - 1 Enables hardware detection and initiation of store streams.

- 61:63 **Default Prefetch Depth** (DPFD)
- This field supplies a prefetch depth for hardware-detected streams and for software-defined streams for which a depth of zero is specified or for which *dcbt/dcbtst* with TH=1010 is *not* used in their description. Values and their meanings are as follows.

- 0 default (LPCR<sub>DPFD</sub>)
- 1 none
- 2 shallowest
- 3 shallow
- 4 medium
- 5 deep
- 6 deeper
- 7 deepest

The contents of the DSCR affect how a processor handles hardware-detected and software-defined data streams. The DSCR provides the only means by which software can control or supply information for hardware-detected data streams. The DPFD, UNITCNT, and transient fields may also be used instead of the TH=01010 variant of *dcbt* for software-defined data streams, especially when multiple streams have these attributes in common. See Section 4.3.2, “Data Cache Instructions” on page 1063, for information on streams and how software may specify them.

#### Programming Note

The URG, LSD, SNSE and SSE fields do not affect the initiation of streams specified using the *dcbt* and *dcbtst* instructions.

Note that even when SNSE is not set, hardware may detect Stride-N streams in intervals when they access elements that map to sequential cache blocks.

#### Programming Note

In order for the DSCR to apply the transient attribute to streams, at least two of the four enable bits must be set: one to choose a type of access (load or store), and one to choose a kind of prefetching (software-defined or hardware-detected).

#### Programming Note

The purpose of Depth Attainment Urgency is to regulate the rate of prefetch generation from the cycle at which the hardware first detects an incipient stream until the cycle when the prefetch Depth is reached. A more urgent setting will benefit applications that are dominated by short to medium length streams, because otherwise prefetching does not occur rapidly enough to benefit them. In contrast, applications that frequently cause unproductive prefetches due to stream mispredicts will benefit from a less urgent setting.

Unlike the Depth, the Depth Attainment Urgency applies only to hardware-detected streams. Furthermore, the DSCR provides the only point of control for this parameter. Software-defined streams are assumed not to have the correctness risk associated with hardware streams, and therefore are set to reach their depth relatively quickly.

#### Programming Note

In versions of the architecture that precede Version 2.07, *mtspr* specifying the DSCR caused all active and nascent data streams to cease to exist. In those versions of the architecture, the DSCR was used as an overall control mechanism to specify a single global profile for all streams. Beginning with Version 2.07, the DSCR is intended to control and accelerate the creation of new streams without disturbing existing streams.

## 4.3 Cache Management Instructions

The *Cache Management* instructions obey the sequential execution model except as described in Section 4.3.1.

In the instruction descriptions the statements “this instruction is treated as a *Load*” and “this instruction is treated as a *Store*” mean that the instruction is treated as a *Load (Store)* from (to) the addressed byte with respect to address translation, the definition of program order on page 1039, storage protection, reference and change recording, the storage access ordering described in Section 1.7.1, and Performance Monitor events (see Section 11.4.5 of Book III).

Some *Cache Management* instructions contain a CT field that is used to specify a cache level within a cache hierarchy or a portion of a cache structure to which the instruction is to be applied. The correspondence between the CT value specified and the cache level is shown below.

CT Field Value	Cache Level
0	Primary Cache
2	Secondary Cache

CT values not shown above may be used to specify implementation-dependent cache levels or implementation-dependent portions of a cache structure.

### 4.3.1 Instruction Cache Instructions

#### ***Instruction Cache Block Invalidate X-form***

icbi RA, RB

0	31	///	RA	RB	982	/
	6		11	16	21	31

Let the effective address (EA) be the sum (RA|0)+(RB).

If the block containing the byte addressed by EA is in storage that is Memory Coherence Required and a block containing the byte addressed by EA is in the instruction cache of any processors, the block is invalidated in those instruction caches.

If the block containing the byte addressed by EA is in storage that is not Memory Coherence Required and the block is in the instruction cache of this processor, the block is invalidated in that instruction cache.

The function of this instruction is independent of whether the block containing the byte addressed by EA is in storage that is Write Through Required or Caching Inhibited.

This instruction is treated as a *Load* (see Section 4.3), except that reference and change recording need not be done.

#### **Special Registers Altered:**

None

#### **Programming Note**

Because the instruction is treated as a *Load*, the effective address is translated using translation resources that are used for data accesses, even though the block being invalidated was copied into the instruction cache based on translation resources used for instruction fetches (see Book III).

#### **Programming Note**

The invalidation of the specified block need not have been performed with respect to the processor executing the *icbi* instruction until a subsequent *isync* instruction has been executed by that processor. No other instruction or event has the corresponding effect.

#### ***Instruction Cache Block Touch X-form***

icbt CT, RA, RB

0	31	/	CT	RA	RB	22	/
	6	7	11	16	21	31	

Let the effective address (EA) be the sum (RA|0)+(RB).

The *icbt* instruction provides a hint that the program will probably soon execute code from the block containing the byte addressed by EA, and that the block containing the byte addressed by EA is to be loaded into the cache specified by the CT field. (See Section 4.3 of Book II.) If the CT field is set to a value not supported by the implementation, no operation is performed.

The hint is ignored if the block is Caching Inhibited.

This instruction treated as a *Load* (see Section 4.3), except that the system data storage error handler is not invoked, and reference and change recording need not be done.

#### **Special Registers Altered:**

None

## 4.3.2 Data Cache Instructions

The Data Cache instructions control various aspects of the data cache.

### TH field in the *dcbt* and *dcbtst* instructions

Described below are the TH field values for the *dcbt* and *dcbtst* instructions. For all TH field values which are not listed, the hint provided by the instruction is undefined.

#### TH=0b00000

If TH=0b00000, the *dcbt/dcbtst* instruction provides a hint that the program will probably soon access the block containing the byte addressed by EA.

#### TH=0b01000 - 0b01111

The *dcbt/dcbtst* instructions provide hints regarding a sequence of accesses to data elements, or indicate the expected use thereof. Such a sequence is called a “data stream”, and a *dcbt/dcbtst* instruction in which TH is set to one of these values is said to be a “data stream variant” of *dcbt/dcbtst*. In the remainder of this section, “data stream” may be abbreviated to “stream”.

A data stream to which a program may perform *Load* accesses is said to be a “load data stream”, and is described using the data stream variants of the *dcbt* instruction. A data stream to which a program may perform *Store* accesses is said to be a “store data stream”, and is described using the data stream variants of the *dcbtst* instruction.

When, and how often, effective addresses for a data stream are translated is implementation-dependent.

Each data element is associated with a *unit* of storage, which is the aligned 128-byte location in storage that contains the first byte of the element. The data stream variants may be used to specify the address of the beginning of the data stream, the displacement (stride) between the first byte of successive elements, and the number of unique units of storage that are associated with all of the data elements. If the stride is specified, both the stride and the address of the first element are specified at 4 byte granularity. If the stride is not specified, the address of the first element is the address of the first unit.

#### Programming Note

The architecture does not provide a way to specify the size of the data elements that compose a stream. An implementation may assume some fixed size for all data elements. As a result, depending on the offset, stride, and size (and in particular whether the elements are aligned), the implementation may reduce the latency for accessing only a portion of some of the elements. A future version of the architecture may enable the specification of element size to avoid this limitation.

Each such data stream is associated, by software, with a stream ID, which is a resource that the processor uses to distinguish the data stream from other such data streams. The number of stream IDs is an implementation-dependent value in the range 1:16. Stream IDs are numbered sequentially starting from 0.

#### Programming Note

The number of stream IDs available for a program to use may be dependent on the current degree of multithreading of a processor in the system.

The encodings of the TH field and of the corresponding EA values are as follows. In the EA layout diagrams, fields shown as “/”s are reserved. These reserved fields are treated in the same manner as the corresponding case for instruction fields (see Section 1.3.3 of Book I). If a reserved value is specified for a defined EA field, or if a TH value is specified that is not explicitly defined below, the hint provided by the instruction is undefined.

#### TH Description

**01000** The *dcbt/dcbtst* instruction provides a hint that describes certain attributes of a data stream, and may indicate that the program will probably soon access the stream.

The EA is interpreted as follows.

EATRUNC		D	U	G	/	ID
0		57	59	60	63	

#### Bit(s) Description

##### 0:56 *EATRUNC*

High-order 57 bits of the effective address of the first element of the data stream. (i.e., the effective address of the first unit of the stream is  $EATRUNC \parallel 70$ )

##### 57 *Direction* (D)

0 Subsequent elements have increasing addresses.  
1 Subsequent elements have decreasing addresses.

- 58 **Unlimited/GO** (UG)
  - 0 No information is provided by the UG field.
  - 1 The number of elements in the data stream is unlimited, the elements are adjacent to each other, the program's need for each element of the stream is not likely to be transient, and the program will probably soon access the stream.

- 59 Reserved
- 60:63 **Stream ID** (ID)

Stream ID to use for this data stream.

**01010** The ***dcbt/dcbtst*** instruction provides a hint that describes certain attributes of a data stream, or indicates that the program will probably soon access data streams that have been described using data stream variants of the ***dcbt/dcbtst*** instruction, or will probably no longer access such data streams.

The EA is interpreted as follows. If GO=1 and S≠0b00 the hint provided by the instruction is undefined; the remainder of this instruction description assumes that this combination is not used.

///	GO	S	/	DEP	//	UNITCNT	T	U	/	ID
0	32	35	36	39	47	57	59	60	63	

**Bit(s) Description**

- 0:31 Reserved
- 32 **GO**
  - 0 No information is provided by the GO field.
  - 1 For ***dcbt***, the program will probably soon access all nascent load and store data streams that have been completely described, and will probably no longer access all other nascent load and store data streams. All other fields of the EA are ignored. ("Nascent" and "completely described" are defined below.) For ***dcbtst***, this field value holds no meaning and is treated as though it were zero.
- 33:34 **Stop** (S)
  - 00 No information is provided by the S field.
  - 01 Reserved
  - 10 The program will probably no longer access the data stream (if any) associated with the specified

- stream ID. (All other fields of the EA except the ID field are ignored.)
- 11 For ***dcbt***, the program will probably no longer access the load and store data streams associated with all stream IDs. (All other fields of the EA are ignored.) For ***dcbtst***, this field value holds no meaning, and is treated as though it were 0b00.

- 35 Reserved
- 36:38 **Depth** (DEP)

The DEP field provides a relative estimate of how many elements ahead of the point of stream use the latency-reducing actions should go. This value reflects a comparison of the rate of consumption of the elements of the data stream and the latency to bring an arbitrary element of the stream into cache. The values are as follows.

- 0 default = DSCR<sub>D<sub>DPFD</sub></sub>
- 1 none
- 2 shallowest
- 3 shallow
- 4 medium
- 5 deep
- 6 deeper
- 7 deepest

- 39:46 Reserved
- 47:56 **UNITCNT**
  - Number of units in data stream.

- 57 **Transient** (T)
  - If T=1, the program's need for each element of the data stream is likely to be transient (i.e., the time interval during which the program accesses the element is likely to be short).

- 58 **Unlimited** (U)
  - If U=1, the number of units in the data stream is unlimited (and the UNITCNT field is ignored).

- 59 Reserved
- 60:63 **Stream ID** (ID)
  - Stream ID to use for this data stream (GO=0 and S=0b00), or stream ID associated with the data stream which the program will probably no longer access(S=0b10).

**Programming Note**

To maximize the utility of the Depth control mechanism, the architecture provides a hierarchy of three ways to program it. The DPFID field in the LPCR is used by the provisory/firmware to set a safe or appropriate default depth for unaware operating systems and applications. The DPFID field in the DSCR may be initialized by the aware OS and overwritten by an application via the OS-provided service when per stream control is unnecessary or unaffordable. The DEP field in the EA specification when TH=0b01010 may be used by the application to specify the depth on a per-stream basis.

The number of elements ahead of the point of stream use indicated by a given depth value may differ across implementations, as may the latency to bring a given element into the cache. To achieve optimum performance, some experimentation with different depth values may be necessary.

**01011** The *dcbt/dcbtst* instruction provides a hint that describes certain attributes of a data stream.

The EA is interpreted as follows.

///	STRIDE	OFFSET	//	ID
0	32	50	56	60 63

**Bit(s) Description**

0:31 Reserved

32:49 **Stride**

The displacement, in words, between the first byte of successive elements in the stream. The effective address of the N<sup>th</sup> element in the stream is

$$(N-1) \times \text{STRIDE} \times 4$$

greater than or less than the effective address of the first element of the stream, depending on the direction specified for the stream.

50 Reserved

51:55 **Offset**

The word-offset of the first element of the stream in its unit (i.e., the effective address of the first element of the stream is (EATRUNC || OFFSET || 0b00)).

56:59 Reserved

60:63 **Stream ID (ID)**

Stream ID to use for this data stream.

**Programming Note**

A program should use a *dcbt/dcbtst* instruction with TH=0b01011 only when the stride is larger than 128 bytes. Otherwise, consecutive units will be accessed, so the additional stream information has no benefit.

If the specified stream ID value is greater than m-1, where m is the number of stream IDs provided by the implementation, and either (a) TH=0b01000 or TH=0b01011, or (b) TH=0b01010 with GO=0 and S≠0b11, no hint is provided by the instruction.

The following terminology is used to describe the state of a data stream. Except as described in the paragraph after the next paragraph, the state of a data stream at a given time is determined by the most recently provided hint(s) for the stream.

- A data stream for which only descriptive hints have been provided (by *dcbt/dcbtst* instructions with TH=0b01000 and UG=0, TH=0b01010 and GO=0 and S=0b00, and/or with TH=0b01011) is said to be “nascent”. A nascent data stream for which all relevant descriptive hints have been provided (by the *dcbt/dcbtst* usages listed in the preceding sentence) is considered to be “completely described”. The order of descriptive hints with respect to one another is unimportant.
- A data stream for which a hint has been provided (by a *dcbt/dcbtst* instruction with TH=0b01000 and UG=1 or *dcbt* with TH=0b01010 and GO=1) that the program will probably soon access it is said to be “active”.
- A data stream that is either nascent or active is considered to “exist”.
- A data stream for which a hint has been provided (e.g., by a *dcbt* instruction with TH=0b01010 and S≠0b00) that the program will probably no longer access it is considered no longer to exist.

The hint provided by a *dcbt/dcbtst* instruction with TH=0b01000 and UG=1 implicitly includes a hint that the program will probably no longer access the data stream (if any) previously associated with the specified stream ID. The hint provided by a *dcbt/dcbtst* instruction with TH=0b01000 and UG=0, or with TH=0b01010 and GO=0 and S=0b00, or with TH=0b01011 implicitly includes a hint that the program will probably no longer access the *active* data stream (if any) previously associated with the specified stream ID.

If a data stream is specified without using a *dcbt/dcbtst* instruction with TH=0b01010 and GO=0 and S=0b00, then the number of elements in the stream is unlimited, and the program’s need for each element of the stream is not likely to be transient. If a data stream is specified without using a *dcbt/dcbtst* instruction with

TH=0b01011, then the stream will access consecutive units of storage.

A context switch on a particular thread causes all existing data streams for that thread to cease to exist. The mechanism of detection of a context switch is implementation-dependent. In addition, depending on the implementation, certain conditions and events may cause an existing data stream to cease to exist; for example, in some implementations an existing data stream ceases to exist when it comes to the end of a page.

## Programming Note

To obtain the best performance across the widest range of implementations that support the data stream variants of ***dcbt/dcbtst***, the programmer should assume the following model when using those variants.

- The processor's response to a hint that the program will probably soon access a given data stream is to take actions that reduce the latency of accesses to the first few elements of the stream. (Such actions may include prefetching cache blocks into levels of the storage hierarchy that are "near" the processor.) Thereafter, as the program accesses each successive element of the stream, the processor takes latency-reducing actions for additional elements of the stream, pacing these actions with the program's accesses (i.e., taking the actions for only a limited number of elements ahead of the element that the program is currently accessing).

The processor's response to a hint that the program will probably no longer access a given data stream, or to the cessation of existence of a data stream, is to stop taking latency-reducing actions for the stream.

- A data stream having finite length ceases to exist when the latency-reducing actions have been taken for all elements of the stream.
- If the program ceases to need a given data stream before having accessed all elements of the stream (always the case for streams having unlimited length), performance may be improved if the program then provides a hint that it will no longer access the stream (e.g., by executing the appropriate ***dcbt*** instruction with TH=0b01010 and S≠0b00).

- At each level of the storage hierarchy that is "near" the processor, elements of a data stream that is specified as transient are most likely to be replaced. As a result, it may be desirable to stagger addresses of streams (choose addresses that map to different cache congruence classes) to reduce the likelihood that an element of a transient stream will be replaced prior to being accessed by the program.
- Processors that comply with versions of the architecture that do not support the TH field at all treat TH = 0b01000, 0b01010, and 0b01011 as if TH = 0b00000.
- A single set of stream IDs is shared between the ***dcbt*** and ***dcbtst*** instructions.
- On some implementations, data streams that are not specified by software may be detected by the processor. Such data streams are called "hardware-detected data streams". On some such implementations, data stream resources (resources that are used primarily to support data streams) are shared between software-specified data streams and hardware-detected data streams. On these latter implementations, the programming model includes the following.
  - Software-specified data streams take precedence over hardware-detected data streams in use of data stream resources.
  - The processor's response to a hint that the program will probably no longer access a given data stream, or to the cessation of existence of a data stream, includes releasing the associated data stream resources, so that they can be used by hardware-detected data streams.

**Programming Note**

The latency-reducing actions taken in response to a program's hints about access to a data stream, including the depth and urgency parameters, may vary based on its behavior and on the behavior of other programs sharing platform resources, as well as on the design of the platform resources they use. Without actually changing the stream specification or DSCR parameters, the processor may adjust its actions (e.g. slow down prefetches or be more selective choosing them) based on their effectiveness and on the availability of storage bandwidth. In general, the goal of this variation is to improve overall system performance and fairness across the set of programs that share resources. There often will be a performance benefit, however, from adjusting stream specifications to the platform and co-resident programs to adjust for these actions by the processor.

## Programming Note

This Programming Note describes several aspects of using the data stream variants of the ***dcbt*** and ***dcbtst*** instructions.

- A non-transient data stream having unlimited length and which will access consecutive units in storage can be completely specified, including providing the hint that the program will probably soon access it, using one ***dcbt*** instruction. The corresponding specification for a data stream having other attributes requires two or three ***dcbt/dcbtst*** instructions to describe the stream and one additional ***dcbt*** instruction to start the stream. However, one ***dcbt*** instruction with TH=0b01010 and GO=1 can apply to a set of the data streams described in the preceding sentence, so the corresponding specification for n such data streams requires 2×n to 3×n ***dcbt/dcbtst*** instructions plus one ***dcbt*** instruction. (There is no need to execute a ***dcbt/dcbtst*** instruction with TH=0b01010 and S=0b10 for a given stream ID before using the stream ID for a new data stream; the implicit portion of the hint provided by ***dcbt/dcbtst*** instructions that describe data streams suffices.)
- If it is desired that the hint provided by a given ***dcbt/dcbtst*** instruction be provided in program order with respect to the hint provided by another ***dcbt/dcbtst*** instruction, the two instructions must be separated by an ***eieio*** instruction. For example, if a ***dcbt*** instruction with TH=0b01010 and GO=1 is intended to indicate that the program will probably soon access nascent data streams described (completely) by preceding ***dcbt/dcbtst*** instructions, and is intended *not* to indicate that the program will probably soon access nascent data streams described (completely) by following ***dcbt/dcbtst*** instructions, an ***eieio*** instruction must separate the ***dcbt*** instruction with GO=1 from the preceding ***dcbt/dcbtst*** instructions, and another ***eieio*** instruction must separate that ***dcbt*** instruction from the following ***dcbt/dcbtst*** instructions.
- In practice, the second ***eieio*** described above can sometimes be omitted. For example, if the program consists of an outer loop that contains the ***dcbt/dcbtst*** instructions and an inner loop that contains the *Load* or *Store* instructions that access the data streams, the characteristics of the inner loop and of the implementation's branch prediction mechanisms may make it highly unlikely that hints corresponding to a given iteration of the outer loop will be provided out of program order with respect to hints corresponding to the previous iteration of the outer loop. (Also, any providing of hints out of program order affects only performance, not program correctness.)
- To mitigate the effects of context switches on data streams, it may be desirable to specify a given "logical" data stream as a sequence of shorter, component data streams. Similar considerations apply to conditions and events that, depending on the implementation, may cause an existing data stream to cease to exist; for example, in some implementations an existing data stream ceases to exist when it comes to the end of a virtual page.
- If it is desired to specify data streams without regard to the number of stream IDs provided by the implementation, stream IDs should be assigned to data streams in order of decreasing stream importance (stream ID 0 to the most important stream, stream ID 1 to the next most important stream, etc.). This order ensures that the hints for the most important data streams will be provided.
- In practice, it is usually the case that it is preferable for data streams of the main or parent application running on a particular thread to be prioritized over data streams of a leaf or child application or function call. As an example, a library function call would usually fall under the category of a leaf function whose data streams should be treated with lower priority than those of the parent. As such, it is advised that programmers writing library functions or other functions which are expected to have leaf routing use the lowest stream priority possible. For example, if a leaf-type function instantiates two data streams, best practice is to use stream ID 14 for its most important data stream, and stream ID 15 for its second most important stream.

### TH=0b10000

If TH=0b10000, the ***dcbt*** instruction provides a hint that the program will probably soon load from the block containing the byte addressed by EA, and that the program's need for the block will be transient (i.e., the time

interval during which the program accesses the block is likely to be short).

**Programming Note**

The processor's response to the hint that access to the block will be transient is to prefetch data into the cache hierarchy in a way that minimizes the displacement of data that has not been identified as transient.

**TH=0b10001**

If TH=0b10001, the *dcbt* instruction provides a hint that the program will probably not access the block containing the byte addressed by EA for a relatively long period of time.

## Data Cache Block Touch X-form

dcbt RA, RB, TH

31	TH	RA	RB	278	/
0	6	11	16	21	31

Let the effective address (EA) be the sum (RA|0)+(RB).

The **dcbt** instruction provides a hint that describes a block or data stream to which the program may perform a *Load* access. The instruction is also used to indicate imminent access or end of access to described load and store data streams. A hint that the program will probably soon load from a given storage location is ignored if the location is Caching Inhibited or Guarded.

The only operation that is “caused” by the **dcbt** instruction is the providing of the hint. The actions (if any) taken by the processor in response to the hint are not considered to be “caused by” or “associated with” the **dcbt** instruction (e.g., **dcbt** is considered not to cause any data accesses). No means are provided by which software can synchronize these actions with the execution of the instruction stream. For example, these actions are not ordered by memory barriers.

The **dcbt** instruction may complete before the operation it causes has been performed.

The nature of the hint depends, in part, on the value of the TH field, as specified at the beginning of this section. If TH≠0b01010 and TH≠0b01011, this instruction is treated as a *Load* (see Section 4.3), except that the system data storage error handler is not invoked, and reference and change recording need not be done.

### Special Registers Altered:

None

### Extended Mnemonics:

Extended mnemonics are provided for the *Data Cache Block Touch* instruction so that it can be coded with the TH value as the last operand for all categories, and so that the transient hint can be specified without coding the TH field explicitly.

<b>Extended:</b>	<b>Equivalent to:</b>
dcbtct RA, RB, TH	dcbt for TH values of 0b00000 - 0b00111; other TH values are invalid.
dcbt ds RA, RB, TH	dcbt for TH values of 0b00000 or 0b01000 - 0b01111; other TH values are invalid.
dcbt tt RA, RB	dcbt for TH value of 0b10000
dcbt na RA, RB	dcbt for TH value of 0b10001

### Programming Notes

New programs should avoid using the **dcbt** and **dcbtst** mnemonics; one of the extended mnemonics should be used exclusively.

If the **dcbt** mnemonic is used with only two operands, the TH operand is assumed to be 0b00000.

Processors that comply with versions of the architecture that precede Version 2.01 do not necessarily ignore the hint provided by **dcbt** and **dcbtst** if the specified block is in storage that is Guarded and not Caching Inhibited.

### Programming Note

See the Programming Notes at the beginning of this section.

## Data Cache Block Touch for Store X-form

dcbtst RA, RB, TH

0	31	TH	RA	RB	246	/
	6	11	16	21		31

Let the effective address (EA) be the sum (RA|0)+(RB).

The **dcbtst** instruction provides a hint that describes a block or data stream to which the program may perform a *Store* access, or indicates the expected use thereof. A hint that the program will soon store to a given storage location is ignored if the location is Caching Inhibited or Guarded.

The only operation that is “caused by” the **dcbtst** instruction is the providing of the hint. The actions (if any) taken by the processor in response to the hint are not considered to be “caused by” or “associated with” the **dcbtst** instruction (e.g., **dcbtst** is considered not to cause any data accesses). No means are provided by which software can synchronize these actions with the execution of the instruction stream. For example, these actions are not ordered by memory barriers.

The **dcbtst** instruction may complete before the operation it causes has been performed.

The nature of the hint depends, in part, on the value of the TH field, as specified at the beginning of this section. If TH≠0b01010 and TH≠0b01011, this instruction is treated as a *Store* (see Section 4.3), except that the system data storage error handler is not invoked, reference recording need not be done, and change recording is not done.

### Special Registers Altered:

None

### Extended Mnemonics:

Extended mnemonics are provided for the *Data Cache Block Touch for Store* instruction so that it can be coded with the TH value as the last operand for all categories, and so that the transient hint can be specified without coding the TH field explicitly.

#### Extended:

#### Equivalent to:

dcbtstct RA, RB, TH	dcbtst for TH values of 0b00000 or 0b00000 - 0b00111; other TH values are invalid.
dcbtstds RA, RB, TH	dcbtst for TH values of 0b00000 or 0b01000 - 0b01111; other TH values are invalid.
dcbtstt RA, RB	dcbtst for TH value of 0b10000.

### Programming Note

See the Programming Notes at the beginning of this section.

**Data Cache Block set to Zero X-form**

dcbz RA, RB

0	31	///	RA	RB	1014	/
	6		11	16	21	31

```

if RA = 0 then b ← 0
else          b ← (RA)
EA ← b + (RB)
n ← block size (bytes)
m ← log2(n)
ea ← EA0:63-m || m0
MEM(ea, n) ← n0x00

```

Let the effective address (EA) be the sum (RA|0)+(RB).

All bytes in the block containing the byte addressed by EA are set to zero.

This instruction is treated as a Store (see Section 4.3).

**Special Registers Altered:**

None

**Programming Note**

**dcbz** does not cause the block to exist in the data cache if the block is in storage that is Caching Inhibited.

For storage that is neither Write Through Required nor Caching Inhibited, **dcbz** provides an efficient means of setting blocks of storage to zero. It can be used to initialize large areas of such storage, in a manner that is likely to consume less memory bandwidth than an equivalent sequence of *Store* instructions.

For storage that is either Write Through Required or Caching Inhibited, **dcbz** is likely to take significantly longer to execute than an equivalent sequence of *Store* instructions. For example, on some implementations **dcbz** for such storage may cause the system alignment error handler to be invoked; on such implementations the system alignment error handler sets the specified block to zero using *Store* instructions.

See Section 6.9.1 of Book III for additional information about **dcbz**.

**Data Cache Block Store X-form**

dcbst RA, RB

0	31	///	RA	RB	54	/
	6		11	16	21	31

Let the effective address (EA) be the sum (RA|0)+(RB).

If the block containing the byte addressed by EA is in storage that is Memory Coherence Required and a block containing the byte addressed by EA is in the data cache of any processor and any locations in the block are considered to be modified there, those locations are written to main storage, additional locations in the block may be written to main storage, and the block ceases to be considered to be modified in that data cache.

If the block containing the byte addressed by EA is in storage that is not Memory Coherence Required and the block is in the data cache of this processor and any locations in the block are considered to be modified there, those locations are written to main storage, additional locations in the block may be written to main storage, and the block ceases to be considered to be modified in that data cache.

The function of this instruction is independent of whether the block containing the byte addressed by EA is in storage that is Write Through Required or Caching Inhibited.

This instruction is treated as a *Load* (see Section 4.3), except that reference and change recording need not be done.

**Special Registers Altered:**

None

**Programming Note**

*Data Cache Block Store to Persistent Storage* is encoded as a variant of *Data Cache Block Flush*. This was necessary so that the instruction has the correct behavior on processors that implement Version 3.0C. The extended mnemonic (**dcbstps**) indicates the intended function. (There is expected to be no interest in attaching persistent storage to processors that comply with versions of the architecture that precede Version 3.0C.)

## Data Cache Block Flush X-form

dcbf RA, RB, L

31	//	L	RA	RB	86	/
0	6	8	11	16	21	31

Let the effective address (EA) be the sum (RA|0)+(RB).

### L=0

If the block containing the byte addressed by EA is in storage that is Memory Coherence Required and a block containing the byte addressed by EA is in the data cache of any processor and any locations in the block are considered to be modified there, those locations are written to main storage and additional locations in the block may be written to main storage. The block is invalidated in the data caches of all processors.

If the block containing the byte addressed by EA is in storage that is not Memory Coherence Required and the block is in the data cache of this processor and any locations in the block are considered to be modified there, those locations are written to main storage and additional locations in the block may be written to main storage. The block is invalidated in the data cache of this processor.

### L=1 (“dcbf local”)

The L=1 form of the **dcbf** instruction permits a program to limit the scope of the “flush” operation to the data cache of this processor. If the block containing the byte addressed by EA is in the data cache of this processor, it is removed from this cache. The coherence of the block is maintained to the extent required by the Memory Coherence Required storage attribute.

### L = 3 (“dcbf local primary”)

The L=3 form of the **dcbf** instruction permits a program to limit the scope of the “flush” operation to the primary data cache of this processor. If the block containing the byte addressed by EA is in the primary data cache of this processor, it is removed from this cache. The coherence of the block is maintained to the extent required by the Memory Coherence Required storage attribute.

### L = 4 (“data cache block flush to persistent storage”)

The L=4 form of the **dcbf** instruction performs all of the functions of **dcbf** with L=0. After all writes to main storage, caused by these functions, have updated main storage, if the block maps to main storage that is backed by persistent storage then all locations in the block in main storage that are considered to be modified relative to persistent storage are written to persistent storage and addi-

tional locations in the block in main storage may be written to persistent storage.

### L = 6 (“data cache block store to persistent storage”)

The L=6 form of the **dcbf** instruction performs all of the functions of **dcbst**. After all writes to main storage, caused by these functions, have updated main storage, if the block maps to main storage that is backed by persistent storage then all locations in the block in main storage that are considered to be modified relative to persistent storage are written to persistent storage and additional locations in the block in main storage may be written to persistent storage.

#### Programming Note

This form of the **dcbf** instruction is considered to be a functional extension of **dcbst**, and its extended mnemonic reflects that association.

For the L operand, the values 2, 5, and 7 are reserved. The results of executing a **dcbf** instruction with L=2, 5, or 7 are boundedly undefined.

The function of this instruction is independent of whether the block containing the byte addressed by EA is in storage that is Write Through Required or Caching Inhibited.

This instruction is treated as a *Load* (see Section 4.3), except that reference and change recording need not be done.

#### Special Registers Altered:

None

#### Extended Mnemonics:

Extended mnemonics are provided for the *Data Cache Block Flush* instruction so that it can be coded with the L value as part of the mnemonic rather than as a numeric operand. These are shown as examples with the instruction. See Appendix A. “Assembler Extended Mnemonics” on page 1115. The extended mnemonics are shown below.

Extended:	Equivalent to:
dcbf RA, RB	dcbf RA, RB, 0
dcbfl RA, RB	dcbf RA, RB, 1
dcbflp RA, RB	dcbf RA, RB, 3
dcbfps RA, RB	dcbf RA, RB, 4
dcbstps RA, RB	dcbf RA, RB, 6

Except in the **dcbf** instruction description in this section, references to “**dcbf**” in Books I-III imply L=0 unless otherwise stated or obvious from context; “**dcbfl**” is used for L=1, “**dcbflp**” is used for L=3, “**dcbfps**” is used for L=4, and “**dcbstps**” is used for L=6.

**Programming Note**

**dcbf** serves as both a basic and an extended mnemonic. The Assembler will recognize a **dcbf** mnemonic with three operands as the basic form, and a **dcbf** mnemonic with two operands as the extended form. In the extended form the L operand is omitted and assumed to be 0.

**Programming Note**

**dcbf** with L=1 can be used to provide a hint that a block in this processor's data cache will not be reused soon.

**dcbf** with L=3 can be used to flush a block from the processor's primary data cache but reduce the latency of a subsequent access. For example, the block may be evicted from the primary data cache but a copy retained in a lower level of the cache hierarchy.

Programs which manage coherence in software must use **dcbf** with L=0 or L=4.

### 4.3.2.1 Obsolete Data Cache Instructions

The *Data Stream Touch* (**dst**), *Data Stream Touch for Store* (**dstst**), and *Data Stream Stop* (**dss**) instructions (primary opcode 31, extended opcodes 342, 374, and 822 respectively), which were proposed for addition to the Power ISA and were implemented by some processors, must be treated as no-ops (rather than as illegal instructions).

The treatment of these instructions is independent of whether other Vector instructions are available (i.e., is independent of the contents of MSR<sub>VEC</sub> (see Book III).

**Programming Note**

These instructions merely provided hints, and thus were permitted to be treated as no-ops even on processors that implemented them.

The treatment of these instructions is independent of whether other Vector instructions are available because, on processors that implemented the instructions, the instructions were available even when other Vector instructions were not.

The extended mnemonics for these instructions were **dstt**, **dststt**, and **dssall**.

### 4.3.3 “or” Instruction

#### “or” Cache Control Hint

*or* 26,26,26

This form of **or** provides a hint that stores caused by preceding **Store** and **dcbz** instructions should be performed with respect to other processors and mechanisms as soon as is feasible.

#### Extended Mnemonics:

Additional extended mnemonic for the **or** hint:

Extended:	Equivalent to:
miso	or 26,26,26

“miso” is short for “make it so.”

#### Programming Note

**Warning:** Other forms of *or Rx,Rx,Rx* that are not described in this section and in Section 3.2 may also cause program priority to change. Use of these forms should be avoided except when software explicitly intends to alter program priority. If a no-op is needed, the preferred no-op (*ori 0,0,0*) should be used.

#### Programming Note

This form of the **or** instruction can be used to reduce latency in producer-consumer applications by requesting that modified data be made visible to other processors quickly. In this example it is assumed that the base register is GPR3.

#### Producer:

```
addi r1,r0,0x1234
sth r1,0x1000(r3) # store data value 0x1234
lwsync           # order data store before
                 # flag store
```

```
addi r2,r0,0x0001
stb r2,0x1002(r3) # store nonzero flag byte
or r26,r26,r26   # miso
```

#### p\_loop:

```
lbz r2,0x1002(r3) # load flag byte
andi. r2,r2,0x00FF
bne p_loop        # wait for consumer to clear
                 # flag
```

#### Consumer:

```
c_loop:
lbz r2,0x1002(r3) # load flag byte
andi. r2,r2,0x00FF
beq c_loop        # wait for producer to set
                 # flag to nonzero
lwsync           # order flag load before
                 # data load
lhz r1,0x1000(r3) # load data value
lwsync           # order data load before
                 # flag store
addi r2,r0,0x0000
stb r2,0x1002(r3) # clear flag byte
or r26,r26,r26   # miso
```

## 4.4 Copy-Paste Facility

The Copy-Paste Facility provides a means to copy a block of data from one storage location to another. Depending on the platform configuration, other alternatives such as posting a work element to a device's queue in control memory or copying a block to another system may be supported. The facility uses pairs of instructions, **copy** followed by **paste.**, to define the data transfers. (See Section 1.7.1.1, "Storage Ordering of Copy/Paste-Initiated Data Transfers" for the memory model characteristics of these data transfers.)

The requirements for use of the platform-specific functionality may vary across implementations. The specific details are beyond the scope of the Architecture. Authority to use a device is generally established through a call to the hypervisor. The format of the work element is device-specific. Mappings for transfers between systems are generally managed by the operating system. Each transfer preserves the order of bytes in storage and is not affected by the endian mode of the processor.

Since the buffer that holds the block until a data transfer is performed is hidden state (cannot be saved and restored) and there is no way to save the state of the **copy**, any disruption of program execution (e.g. interrupts, event-based branch) has the potential to prevent the data transfer from completing correctly. The software that handles the disruption is responsible for executing **cpabort** to clear the state associated with an outstanding data transfer if it will use the Copy-Paste Facility itself or transfer control to another program that might use the facility prior to returning control to the original program.

### Programming Note

A **paste.** instruction is ordered with respect to its preceding **copy** by a dependency on the copy buffer. No explicit synchronization or barrier is required.

Correct use of the Copy-Paste Facility consists of a series of **copy/paste.** pairs. The two instructions in a pair need not be adjacent in the instruction stream. Two or more **copy** instructions with no intervening **paste.** produces a "copy-paste sequence error." Similarly, a bare **paste.** with no preceding **copy** produces a copy-paste sequence error. Copy-paste sequence errors are reported by the **paste.** for the malformed sequence of instructions.

### Programming Note

WARNING: In rare circumstances, **paste.** may falsely report successful completion when the copy-paste sequence is coded incorrectly. This may occur if the instruction sequence includes a redundant **copy** and the sequence is interrupted just prior to the redundant **copy**. Since interrupts should be rare, any sequence that returns a false positive CR0 value should fail for most executions.

### Programming Note

It is always best to avoid unnecessary instructions between the **copy** and the **paste.**

Successful transfers are indicated when **paste.** returns 0b001x in CR0. Transient errors (a copy-paste sequence error, a translation conflict (**slbie[g]**, **slbia**, **tlbie[l]**) during the transfer, or an implementation-specific transient problem) are indicated by a CR0 value of 0b000x, indicating the sequence should be retried. (A sequence error is considered transient because it could have been caused by an interruption between the **copy** and **paste.**) Fatal errors unique to the Copy-Paste Facility (attempting to copy from control memory or attempting to use control memory that has not been properly configured) cause the system data storage error handler to be invoked when the (associated) **paste.** instruction is executed. **paste.** instructions that cause or report transient errors, fatal errors unique to the Copy-Paste Facility, or successful transfer completion reset the state of the facility so that a subsequent copy-paste sequence can begin with a clean slate.

### Programming Note

For **paste.** to address space mapped to another system, OS control over that mapping is deemed to be a sufficient check on the configuration of the channel to the other system, so that a unique data storage interrupt type is not required.

**Programming Note**

A failure of a data transfer may be the result of a shortage of the resources required to complete the operation. (Such failures should only take place for transfers to control memory.) When the resources are known to be shared by multiple programs, a credit-based system is frequently used to improve quality of service. If such a credit system is in use, or if the resources are not shared, the program should continually repeat the **copy/paste** pair until it succeeds. However, if no credit system is in use for shared resources, it may be appropriate to apply some sort of backoff algorithm after having retried the **copy/paste** pair a few times.

The Copy-Paste Facility is the only means to address control memory. If any other storage access (implicit or explicit, instruction or data) addresses control memory, a Machine Check exception will result. Unlike other Machine Check exceptions, this one will generally be presented with ordering and priority similar to that for a storage protection exception.

**Programming Note**

Control memory is to be marked No-execute by the hypervisor, so that an instruction fetch will violate storage protection rather than causing a Machine Check.

**Copy X-form**

copy RA, RB

31	///	1	RA	RB	774	/
0	6 9	10 11	16	21		31

```
if RA = 0 then b ← 0
else b ← (RA)
EA ← b +(RB)
copy_buffer ← memory(EA,128) || MEM_metadata(EA,128)
```

Let the effective address (EA) be the sum (RA|0)+(RB).

The 128 bytes in storage, and associated metadata, addressed by EA is loaded into the copy buffer.

If the EA is not a multiple of 128, the system alignment error handler is invoked.

If the specified block is in storage that is Caching Inhibited, the system data storage error handler is invoked

This instruction is treated as a *Load* (see Section 4.3, “Cache Management Instructions”), except that the data transfer ordering is described in Section 1.7.1.1, “Storage Ordering of Copy/Paste-Initiated Data Transfers”.

**Special Registers Altered:**

None

**Paste X-form**

paste. RA, RB, L

31	///	L	RA	RB	902	1
0	6 9	10 11	16	21		31

```
if there was a copy-paste sequence error or a
translation conflict
CR0 ← 0b000 || XER_SO
else
if RA = 0 then b ← 0
else b ← (RA)
EA ← b +(RB)
if L=1 then
copy_buffer.md ← 0 /* clear metadata in buffer
post (MEM(EA,128) || MEM_metadata(EA,128)) ← copy_buffer
wait for completion status
if there was a data transfer problem
CR0 ← 0b000 || XER_SO
else
CR0 ← 0b001 || XER_SO
clear the state of the Copy-Paste Facility
```

If there was a copy-paste sequence error or a translation conflict, set CR0 to indicate failure. Otherwise, continue as follows.

Let the effective address (EA) be the sum (RA|0)+(RB).

If L=1, then set metadata bits in the copy buffer to zero.

The physical target of the operation, and by implication the function to be performed, is determined by the real address that is translated from EA. If the real address is in the platform’s system memory, a simple copy is performed. If the real address has an associated mapping to another system, the copy buffer is transmitted to the other system. If the real address is control memory for a device, the contents of the copy buffer is queued to the device. There is a wait for completion status on the data transfer. CR0 is set as follows based on the completion status.

CR0	Description
0b000  XER <sub>SO</sub>	Data transfer failed due to a sequence error, a conflict with <b>slbie[g]</b> , <b>slbia</b> , or <b>tlbie[l]</b> , or some implementation-specific problem.
0b001  XER <sub>SO</sub>	Data transfer successful.

The state of the Copy-Paste Facility is cleared.

If MSR<sub>PR</sub>=1, paste. with L=0 is an invalid form.

If the EA is not a multiple of 128, the system alignment error handler is invoked.

If the specified block is in storage that is Caching Inhibited, the system data storage error handler is invoked.

If the associated **copy** specified control memory or the **paste** specifies control memory that was not properly configured, the data storage error handler will be invoked.

This instruction is treated as a Store (see Section 4.3, “Cache Management Instructions”), except that the data transfer ordering is described in Section 1.7.1.1, “Storage Ordering of Copy/Paste-Initiated Data Transfers”.

**Special Registers Altered:**

CR0

**Extended Mnemonics:**

Extended mnemonic for **paste**..:

**Extended:**  
paste. RA,RB

**Equivalent to:**  
paste. RA,RB,1

**Copy-Paste Abort X-form**

cpabort

31	///	///	///	838	/
0	6	11	16	21	31

clear the state of the Copy-Paste Facility

The **cpabort** instruction causes a data transfer to fail if one is in progress.

Any pending errors in the Copy-Paste Facility are cleared and the state is reset to prepare for a new **copy**.

**Special Registers Altered:**

None

## 4.5 Atomic Memory Operations

The Atomic Memory Operation (AMO) facility may be used to optimize performance when many software threads are manipulating shared control structures concurrently. In such situations, accessing the shared data frequently involves transferring the data from one processor's cache to another. The latency of such transfers can become the limiting factor in the performance of some environments. Rather than moving the data to the work, AMOs move the work to the data. The mental model is of an agent consisting of an execution unit and a work queue near memory that receives atomic update requests from all the processors in the system.

Despite that AMOs are performed at memory, their function is only defined for storage that is not Caching Inhibited. This is done so that software can transparently access the same data using normal loads and stores. But furthermore, AMOs generally behave as typical explicit storage accesses performed by the thread, with respect to storage access ordering. The few complications are described below. Since the performance advantage of AMOs derives from avoiding time of flight through cache hierarchies, software should avoid frequent mixing of normal loads and stores and AMOs to the same storage locations. AMOs are also restricted to storage that is not Guarded and storage that is not Write Through Required to limit implementation complexity.

The facility specifies a set of atomic update operations that a processor may send, accompanied by operands from GPRs, to the memory to be performed. The operations are expressed using the *Load Atomic* (LAT) and *Store Atomic* (STAT) instructions. Each of these instructions performs an atomic update operation (load followed by some manipulation and a store) on some location in storage. As a result, these instructions are considered to be both fixed-point *Load* instructions and fixed-point *Store* instructions, and any reference elsewhere in the architecture to fixed-point *Load* or fixed-point *Store* instructions apply to these instructions as well, unless otherwise stated or obvious from context. For example, in order to perform an AMO, it is necessary to have both read and write access to the storage location. Another example is that the DAWR will detect a match if either Data Read or Data Write is selected. Yet another example is that a Trace interrupt will indicate both a *Load* and a *Store* instruction have been executed. Barrier action will be based on whether the barrier would give a load or a store the stronger ordering. The difference between the *Load Atomic* instructions and the *Store Atomic* instructions is simply that the *Load Atomic* instructions return a result to a GPR, while the *Store Atomic* instructions do not. In the RTL in the following subsections, the “lat” and “stat” functions represent the manipulations performed by the memory agent. The parameters shown are the maximum storage footprint, the maximum list of registers,

and the function code that are provided to the agent. If the specified registers wrap (e.g. RT=R31 and RT+1=R0), the wrapping is permitted. Such an instruction is not an invalid form. Destructive encodings are also permitted (i.e. a LAT specified with RT=RA).

Except in this section, references to “atomic update” in Books I-III imply use of the *Load And Reserve* and *Store Conditional* instructions unless otherwise stated or obvious from context.

### Programming Note

The best performance for the Atomic Memory Operations will be realized when the targeted storage locations are accessed only using AMOs. If it is necessary to perform other I=0 loads and stores to those addresses, the result will still be correct, but performance will suffer. In such circumstances, it is not helpful to performance to flush the data to memory using *dcbf*.

### Programming Note

Note that the descriptions of AMO operations are Endian independent. The only effect of Endian on these operations is the obvious one that byte significance within an individual datum reflects the Endian mode.

### 4.5.1 Load Atomic

The Atomic Loads perform an atomic update to an aligned memory location and return a value to a GPR. The manipulation performed on the memory value and the value that is returned in the GPR are determined by the function code (FC) specified by the instruction. The name of each function and its associated RTL are shown in Figure 3.

Function Code	GPR operands	Storage operands	Function name and RTL
00000	RT, RT+1	mem(EA,s)	Fetch and Add $t \leftarrow \text{mem}(EA, s)$ $t2 \leftarrow t + (RT+1)$ $\text{mem}(EA,s) \leftarrow t2$ $RT \leftarrow t$
00001	RT, RT+1	mem(EA,s)	Fetch and XOR $t \leftarrow \text{mem}(EA, s)$ $t2 \leftarrow t \oplus (RT+1)$ $\text{mem}(EA,s) \leftarrow t2$ $RT \leftarrow t$
00010	RT, RT+1	mem(EA,s)	Fetch and OR $t \leftarrow \text{mem}(EA, s)$ $t2 \leftarrow t \mid (RT+1)$ $\text{mem}(EA,s) \leftarrow t2$ $RT \leftarrow t$
00011	RT, RT+1	mem(EA,s)	Fetch and AND $t \leftarrow \text{mem}(EA, s)$ $t2 \leftarrow t \& (RT+1)$ $\text{mem}(EA,s) \leftarrow t2$ $RT \leftarrow t$
00100	RT, RT+1	mem(EA,s)	Fetch and Maximum Unsigned $t \leftarrow \text{mem}(EA, s)$ if $(RT+1) >^u t$ then $\text{mem}(EA,s) \leftarrow (RT+1)$ $RT \leftarrow t$
00101	RT, RT+1	mem(EA,s)	Fetch and Maximum Signed $t \leftarrow \text{mem}(EA, s)$ if $(RT+1) > t$ then $\text{mem}(EA,s) \leftarrow (RT+1)$ $RT \leftarrow t$
00110	RT, RT+1	mem(EA,s)	Fetch and Minimum Unsigned $t \leftarrow \text{mem}(EA, s)$ if $(RT+1) <^u t$ then $\text{mem}(EA,s) \leftarrow (RT+1)$ $RT \leftarrow t$
00111	RT, RT+1	mem(EA,s)	Fetch and Minimum Signed $t \leftarrow \text{mem}(EA, s)$ if $(RT+1) < t$ then $\text{mem}(EA,s) \leftarrow (RT+1)$ $RT \leftarrow t$
01000	RT, RT+1	mem(EA,s)	Swap $t \leftarrow \text{mem}(EA, s)$ $\text{mem}(EA,s) \leftarrow (RT+1)$ $RT \leftarrow t$
10000	RT, RT+1, RT+2	mem(EA,s)	Compare and Swap Not Equal $t \leftarrow \text{mem}(EA, s)$ if $t \neq (RT+1)$ then $\text{mem}(EA,s) \leftarrow (RT+2)$ $RT \leftarrow t$
11000	RT	mem(EA,s) mem(EA+s, s)	Fetch and Increment Bounded $t \leftarrow \text{mem}(EA, s)$ $t2 \leftarrow \text{mem}(EA+s, s)$ if $t \neq t2$ then $\text{mem}(EA,s) \leftarrow t+1$ $RT \leftarrow t$ else $RT \leftarrow 1 \ll (s*8-1)$

11001	RT	mem(EA,s) mem(EA+s, s)	Fetch and Increment Equal $t \leftarrow \text{mem}(EA, s)$ $t2 \leftarrow \text{mem}(EA+s, s)$ if $t = t2$ then $\text{mem}(EA,s) \leftarrow t+1$ $RT \leftarrow t$ else $RT \leftarrow 1 \ll (s*8-1)$
11100	RT	mem(EA-s,s) mem(EA, s)	Fetch and Decrement Bounded $t \leftarrow \text{mem}(EA, s)$ $t2 \leftarrow \text{mem}(EA-s, s)$ if $t \neq t2$ then $\text{mem}(EA,s) \leftarrow t-1$ $RT \leftarrow t$ else $RT \leftarrow 1 \ll (s*8-1)$
<b>Notes:</b> s = operand size in number of bytes Function codes not listed in this table are reserved. For word atomics, only the least significant word of each source register is used, and the least significant word of the target register is updated with the result, while the upper word is set to zero.			

**Figure 3. Load Atomic function codes**

**Load Word Atomic X-form****lwat** RT,RA,FC

0	31	RT	RA	FC	582	/
	6	11	16	21		31

```

if RA=0 then EA ← 0
else      EA ← (RA)
(RT32:63, mem(EA, 4)) ← lat(mem(EA-4, 12), RT+132:63,
RT+232:63, FC)
RT0:31 ← 0

```

Let the effective address (EA) be (RA). The least significant word of RT and the word of storage at EA are updated as specified by load atomic function code FC. The most significant word of RT is set to zero. Input operands are function code specific, and may include the least significant words of RT+1 and RT+2, and mem(EA-4,12)

Figure 3 contains the defined function codes. An attempt to execute **lwat** specifying a reserved function code will cause the system data storage error handler to be invoked.

EA must be a multiple of 4, and the portion of mem(EA-4,12) accessed by the instruction must be contained within an aligned 32-byte block of storage. If either of these requirements is not satisfied, the system alignment error handler is invoked.

**Special Registers Altered:**

None

```

if RA=0 then EA ← 0
else      EA ← (RA)
(RT, mem(EA, 8)) ← lat(mem(EA-8, 24), RT+1, RT+2, FC)

```

Let the effective address (EA) be (RA). RT and the doubleword of storage at EA are updated as specified by load atomic function code FC. Input operands are function code specific, and may include RT+1, RT+2, and mem(EA-8,24)

Figure 3 contains the defined function codes. An attempt to execute **ldat** specifying a reserved function code will cause the system data storage error handler to be invoked.

EA must be a multiple of 8, and the portion of mem(EA-8,24) accessed by the instruction must be contained within an aligned 32-byte block of storage. If either of these requirements is not satisfied, the system alignment error handler is invoked.

**Special Registers Altered:**

None

## 4.5.2 Store Atomic

The Atomic Stores perform an atomic update to an aligned memory location. The manipulation performed

on the memory value is determined by the function code (FC) specified by the instruction. The name of each function and its associated RTL are shown in Figure 4.

Function Code	GPR operands	Storage operands	Function name and RTL
00000	RS	mem(EA,s)	Store Add $t \leftarrow \text{mem}(EA, s)$ $t2 \leftarrow t + (RS)$ $\text{mem}(EA, s) \leftarrow t2$
00001	RS	mem(EA,s)	Store XOR $t \leftarrow \text{mem}(EA, s)$ $t2 \leftarrow t \oplus (RS)$ $\text{mem}(EA, s) \leftarrow t2$
00010	RS	mem(EA,s)	Store OR $t \leftarrow \text{mem}(EA, s)$ $t2 \leftarrow t \mid (RS)$ $\text{mem}(EA, s) \leftarrow t2$
00011	RS	mem(EA,s)	Store AND $t \leftarrow \text{mem}(EA, s)$ $t2 \leftarrow t \& (RS)$ $\text{mem}(EA, s) \leftarrow t2$
00100	RS	mem(EA,s)	Store Maximum Unsigned $t \leftarrow \text{mem}(EA, s)$ $\text{if } (RS) >^u t \text{ then } \text{mem}(EA, s) \leftarrow (RS)$
00101	RS	mem(EA,s)	Store Maximum Signed $t \leftarrow \text{mem}(EA, s)$ $\text{if } (RS) > t \text{ then } \text{mem}(EA, s) \leftarrow (RS)$
00110	RS	mem(EA,s)	Store Minimum Unsigned $t \leftarrow \text{mem}(EA, s)$ $\text{if } (RS) <^u t \text{ then } \text{mem}(EA, s) \leftarrow (RS)$
00111	RS	mem(EA,s)	Store Minimum Signed $t \leftarrow \text{mem}(EA, s)$ $\text{if } (RS) < t \text{ then } \text{mem}(EA, s) \leftarrow (RS)$
11000	RS	mem(EA,s) mem(EA+s, s)	Store Twin $t \leftarrow \text{mem}(EA, s)$ $t2 \leftarrow \text{mem}(EA+s, s)$ $\text{if } t = t2 \text{ then}$ $\text{mem}(EA, s) \leftarrow (RS)$ $\text{mem}(EA+s, s) \leftarrow (RS)$
<b>Notes:</b> s = operand size in number of bytes Function codes not listed in this table are reserved. For word atomics, only the least significant word of each source register is used.			

Figure 4. Store Atomic function codes

## 4.6 Synchronization Instructions

The synchronization instructions are used to ensure that certain instructions have completed before other

instructions are initiated, or to control storage access ordering, or to support debug operations.

### 4.6.1 Instruction Synchronize Instruction

#### *Instruction Synchronize XL-form*

*isync*

0	19	///	///	///	150	/
	6	11	16	21		31

Executing an *isync* instruction ensures that all instructions preceding the *isync* instruction have completed before the *isync* instruction completes, and that no subsequent instructions are initiated until after the *isync* instruction completes. It also ensures that all instruction cache block invalidations caused by *icbi* instructions preceding the *isync* instruction have been performed with respect to the processor executing the *isync* instruction, and then causes any prefetched instructions to be discarded.

Except as described in the preceding sentence, the *isync* instruction may complete before storage accesses associated with instructions preceding the *isync* instruction have been performed.

This instruction is context synchronizing (see Book III).

#### Special Registers Altered:

None

### 4.6.2 Load And Reserve and Store Conditional Instructions

The *Load And Reserve* and *Store Conditional* instructions can be used to construct a sequence of instructions that appears to perform an atomic update operation on an aligned storage location. See Section 1.7.2, “Atomic Update” for additional information about these instructions.

The *Load And Reserve* and *Store Conditional* instructions are fixed-point *Storage Access* instructions; see Section 3.3.1, “Fixed-Point Storage Access Instructions”, in Book I.

The storage location specified by the *Load And Reserve* and *Store Conditional* instructions must be in storage that is Memory Coherence Required if the location may be modified by another processor or mechanism. If the specified location is in storage that is Write Through Required or Caching Inhibited, the system data storage error handler is invoked.

The *Load And Reserve* instructions include an Exclusive Access hint (EH), which can be used to indicate that the instruction sequence being executed is implementing one of two types of algorithms:

#### Atomic Update (EH=0)

This hint indicates that the program is using a fetch and operate (e.g., fetch and add) or some similar algorithm and that all programs accessing the shared variable are likely to use a similar operation to access the shared variable for some time.

#### Exclusive Access (EH=1)

This hint indicates that the program is attempting to acquire a lock and if it succeeds, will perform another store to the lock variable (releasing the lock) before another program attempts to modify the lock variable.

#### Programming Note

The Memory Coherence Required attribute on other processors and mechanisms ensures that their stores to the reservation granule will cause the reservation created by the *Load And Reserve* instruction to be lost.

**Programming Note**

Because the *Load And Reserve* and *Store Conditional* instructions have implementation dependencies (e.g., the granularity at which reservations are managed), they must be used with care. The operating system should provide system library programs that use these instructions to implement the high-level synchronization functions (Test and Set, Compare and Swap, locking, etc.; see Appendix B) that are needed by application programs. Application programs should use these library programs, rather than use the *Load And Reserve* and *Store Conditional* instructions directly.

**Programming Note**

EH = 1 should be used when the program is obtaining a lock variable which it will subsequently release before another program attempts to perform a store to it. When contention for a lock is significant, using this hint may reduce the number of times a cache block is transferred between processor caches.

EH = 0 should be used when all accesses to a mutex variable are performed using an instruction sequence with *Load And Reserve* followed by *Store Conditional* (e.g., emulating atomic update primitives such as “Fetch and Add;” see Appendix B). The processor may use this hint to optimize the cache to cache transfer of the block containing the mutex variable, thus reducing the latency of performing an operation such as ‘Fetch and Add’.

**Programming Note**

**Warning:** On some processors that comply with versions of the architecture that precede Version 2.00, executing a *Load And Reserve* instruction in which EH = 1 will cause the illegal instruction error handler to be invoked.

**Load Byte And Reserve Indexed X-form**

lbarx RT,RA,EB,EH

0	31	RT	RA	RB	52	EH
	6	11	16	21		31

```

if RA = 0 then b ← 0
else          b ← (RA)
EA ← b +(RB)
RESERVE ← 1
RESERVE_LENGTH ← 1
RESERVE_ADDR ← real_addr(EA)
RT ← 560 || MEM(EA, 1)

```

Let the effective address (EA) be the sum (RA|0)+(RB). The byte in storage addressed by EA is loaded into RT<sub>56:63</sub>. RT<sub>0:55</sub> are set to 0.

This instruction creates a reservation for use by a **stbcx**. or **waitrsv** instruction. A real address computed from the EA as described in Section 1.7.2.1 is associated with the reservation, and replaces any address previously associated with the reservation. A length of 1 byte is associated with the reservation, and replaces any length previously associated with the reservation.

The value of EH provides a hint as to whether the program will perform a subsequent store to the byte in storage addressed by EA before some other processor attempts to modify it.

- 0 Other programs might attempt to modify the byte in storage addressed by EA regardless of the result of the corresponding **stbcx**. instruction.
- 1 Other programs will not attempt to modify the byte in storage addressed by EA until the program that has acquired the lock performs a subsequent store releasing the lock.

**Special Registers Altered:**

None

**Programming Note**

**lbarx** serves as both a basic and an extended mnemonic. The Assembler will recognize a **lbarx** mnemonic with four operands as the basic form, and a **lbarx** mnemonic with three operands as the extended form. In the extended form the EH operand is omitted and assumed to be 0.

### Load Halfword And Reserve Indexed X-form

*lharx* RT,RA,RB,EH

31	RT	RA	RB	116	EH
0	6	11	16	21	31

```

if RA = 0 then b ← 0
else          b ← (RA)
EA ← b +(RB)
RESERVE ← 1
RESERVE_LENGTH ← 2
RESERVE_ADDR ← real_addr(EA)
RT ← 480 || MEM(EA, 2)

```

Let the effective address (EA) be the sum (RA|0)+(RB). The halfword in storage addressed by EA is loaded into RT<sub>48:63</sub>. RT<sub>0:47</sub> are set to 0.

This instruction creates a reservation for use by a ***sthcx*** or ***waitrsv*** instruction. A real address computed from the EA as described in Section 1.7.2.1 is associated with the reservation, and replaces any address previously associated with the reservation. A length of 2 bytes is associated with the reservation, and replaces any length previously associated with the reservation.

The value of EH provides a hint as to whether the program will perform a subsequent store to the halfword in storage addressed by EA before some other processor attempts to modify it.

- 0 Other programs might attempt to modify the halfword in storage addressed by EA regardless of the result of the corresponding ***sthcx*** instruction.
- 1 Other programs will not attempt to modify the halfword in storage addressed by EA until the program that has acquired the lock performs a subsequent store releasing the lock.

EA must be a multiple of 2. If it is not, either the system alignment error handler is invoked or the results are boundedly undefined.

#### Special Registers Altered:

None

#### Programming Note

***lharx*** serves as both a basic and an extended mnemonic. The Assembler will recognize a ***lharx*** mnemonic with four operands as the basic form, and a ***lharx*** mnemonic with three operands as the extended form. In the extended form the EH operand is omitted and assumed to be 0.

### Load Word And Reserve Indexed X-form

*lwarx* RT,RA,RB,EH

31	RT	RA	RB	20	EH
0	6	11	16	21	31

```

if RA = 0 then b ← 0
else          b ← (RA)
EA ← b +(RB)
RESERVE ← 1
RESERVE_LENGTH ← 4
RESERVE_ADDR ← real_addr(EA)
RT ← 320 || MEM(EA, 4)

```

Let the effective address (EA) be the sum (RA|0)+(RB). The word in storage addressed by EA is loaded into RT<sub>32:63</sub>. RT<sub>0:31</sub> are set to 0.

This instruction creates a reservation for use by a ***sthcx*** or ***waitrsv*** instruction. A real address computed from the EA as described in Section 1.7.2.1 is associated with the reservation, and replaces any address previously associated with the reservation. A length of 4 bytes is associated with the reservation, and replaces any length previously associated with the reservation.

The value of EH provides a hint as to whether the program will perform a subsequent store to the word in storage addressed by EA before some other processor attempts to modify it.

- 0 Other programs might attempt to modify the word in storage addressed by EA regardless of the result of the corresponding ***sthcx*** instruction.
- 1 Other programs will not attempt to modify the word in storage addressed by EA until the program that has acquired the lock performs a subsequent store releasing the lock.

EA must be a multiple of 4. If it is not, either the system alignment error handler is invoked or the results are boundedly undefined.

#### Special Registers Altered:

None

#### Programming Note

***lwarx*** serves as both a basic and an extended mnemonic. The Assembler will recognize a ***lwarx*** mnemonic with four operands as the basic form, and a ***lwarx*** mnemonic with three operands as the extended form. In the extended form the EH operand is omitted and assumed to be 0.

**Store Byte Conditional Indexed X-form**

stbcx. RS,RA,RB

31	RS	RA	RB	694	1
0	6	11	16	21	31

```

if RA = 0 then b ← 0
else          b ← (RA)
EA ← b + (RB)
if RESERVE then
  if RESERVE_LENGTH = 1 &
    RESERVE_ADDR = real_addr(EA) then
    MEM(EA, 1) ← (RS)56:63
    undefined_case ← 0
    store_performed ← 1
  else
    z ← smallest real page size supported by
        implementation
    if RESERVE_ADDR ÷ z = real_addr(EA) ÷ z then
      undefined_case ← 1
    else
      undefined_case ← 0
      store_performed ← 0
else
  undefined_case ← 0
  store_performed ← 0
if undefined_case then
  u1 ← undefined 1-bit value
  if u1 then
    MEM(EA, 1) ← (RS)56:63
  u2 ← undefined 1-bit value
  CR0 ← 0b00 || u2 || XERSO
else
  CR0 ← 0b00 || store_performed || XERSO
RESERVE ← 0

```

Let the effective address (EA) be the sum (RA|0)+(RB).

If a reservation exists, the length associated with the reservation is 1 byte, and the real storage location specified by the **stbcx.** is the same as the real storage location specified by the **lbarx** instruction that established the reservation, (RS)<sub>56:63</sub> are stored into the byte in storage addressed by EA.

If a reservation exists, and either the length associated with the reservation is not 1 byte or the real storage location specified by the **stbcx.** is not the same as the real storage location specified by the **lbarx** instruction that established the reservation, the following applies. Let z denote the smallest real page size supported by the implementation. If the real storage location specified by the **stbcx.** is in the same aligned z-byte block of real storage as the real storage location specified by the **lbarx** instruction that established the reservation, it is undefined whether (RS)<sub>56:63</sub> are stored into the byte in storage addressed by EA. Otherwise, no store is performed.

If a reservation does not exist, no store is performed.

CR Field 0 is set as follows. n is a 1-bit value that indicates whether the store was performed, except that if, per the preceding description, it is undefined whether

the store is performed, the value of n is undefined (and need not reflect whether the store was performed).

$$CR0_{LT\ GT\ EQ\ SO} = 0b00 || n || XER_{SO}$$

The reservation is cleared.

**Special Registers Altered:**

CR0

### Store Halfword Conditional Indexed X-form

sthcx. RS,RA,RB

31	RS	RA	RB	726	1
0	6	11	16	21	31

```

if RA = 0 then b ← 0
else      b ← (RA)
EA ← b + (RB)
if RESERVE then
  if RESERVE_LENGTH = 2 &
    RESERVE_ADDR = real_addr(EA) then
    MEM(EA, 2) ← (RS)48:63
    undefined_case ← 0
    store_performed ← 1
  else
    z ← smallest real page size supported by
      implementation
    if RESERVE_ADDR ÷ z = real_addr(EA) ÷ z then
      undefined_case ← 1
    else
      undefined_case ← 0
      store_performed ← 0
else
  undefined_case ← 0
  store_performed ← 0
if undefined_case then
  u1 ← undefined 1-bit value
  if u1 then
    MEM(EA, 2) ← (RS)48:63
    u2 ← undefined 1-bit value
    CR0 ← 0b00 || u2 || XERSO
  else
    CR0 ← 0b00 || store_performed || XERSO
RESERVE ← 0

```

Let the effective address (EA) be the sum (RA|0)+(RB).

If a reservation exists, the length associated with the reservation is 2 bytes, and the real storage location specified by the **sthcx**. is the same as the real storage location specified by the **lharx** instruction that established the reservation, (RS)<sub>48:63</sub> are stored into the halfword in storage addressed by EA.

If a reservation exists, and either the length associated with the reservation is not 2 bytes or the real storage location specified by the **sthcx**. is not the same as the real storage location specified by the **lharx** instruction that established the reservation, the following applies. Let z denote the smallest real page size supported by the implementation. If the real storage location specified by the **sthcx**. is in the same aligned z-byte block of real storage as the real storage location specified by the **lharx** instruction that established the reservation, it is undefined whether (RS)<sub>48:63</sub> are stored into the halfword in storage addressed by EA. Otherwise, no store is performed.

If a reservation does not exist, no store is performed.

CR Field 0 is set as follows. n is a 1-bit value that indicates whether the store was performed, except that if,

per the preceding description, it is undefined whether the store is performed, the value of n is undefined (and need not reflect whether the store was performed).

$CR0_{LT\ GT\ EQ\ SO} = 0b00 || n || XER_{SO}$

The reservation is cleared.

EA must be a multiple of 2. If it is not, either the system alignment error handler is invoked or the results are boundedly undefined.

      undefined_case ← 0
      store_performed ← 0
else
  undefined_case ← 0
  store_performed ← 0
if undefined_case then
  u1 ← undefined 1-bit value
  if u1 then
    MEM(EA, 4) ← (RS)32:63
  u2 ← undefined 1-bit value
  CRO ← 0b00 || u2 || XERSO
else
  CRO ← 0b00 || store_performed || XERSO
RESERVE ← 0

```

Let the effective address (EA) be the sum (RA|0)+(RB).

If a reservation exists, the length associated with the reservation is 4 bytes, and the real storage location specified by the **stwcx**. is the same as the real storage location specified by the **lwarx** instruction that established the reservation, (RS)<sub>32:63</sub> are stored into the word in storage addressed by EA.

If a reservation exists, and either the length associated with the reservation is not 4 bytes or the real storage location specified by the **stwcx**. is not the same as the real storage location specified by the **lwarx** instruction that established the reservation, the following applies. Let z denote the smallest real page size supported by the implementation. If the real storage location specified by the **stwcx**. is in the same aligned z-byte block of real storage as the real storage location specified by the **lwarx** instruction that established the reservation, it is undefined whether (RS)<sub>32:63</sub> are stored into the word in storage addressed by EA. Otherwise, no store is performed.

If a reservation does not exist, no store is performed.

CR Field 0 is set as follows. n is a 1-bit value that indicates whether the store was performed, except that if, per the preceding description, it is undefined whether

the store is performed, the value of n is undefined (and need not reflect whether the store was performed).

$$CRO_{LT\ GT\ EQ\ SO} = 0b00 || n || XER_{SO}$$

The reservation is cleared.

EA must be a multiple of 4. If it is not, either the system alignment error handler is invoked or the results are boundedly undefined.

**Special Registers Altered:**

CRO

### 4.6.2.1 64-Bit Load And Reserve and Store Conditional Instructions

#### Load Doubleword And Reserve Indexed X-form

ldarx      RT,RA,RB,EH

```

if RA = 0 then b ← 0
else            b ← (RA)
EA ← b +(RB)
RESERVE ← 1
RESERVE_LENGTH ← 8
RESERVE_ADDR ← real_addr(EA)
RT ← MEM(EA, 8)

```

Let the effective address (EA) be the sum (RA|0)+(RB). The doubleword in storage addressed by EA is loaded into RT.

This instruction creates a reservation for use by a **stdcx.** or **waitrsv** instruction. A real address computed from the EA as described in Section 1.7.2.1 is associated with the reservation, and replaces any address previously associated with the reservation. A length of 8 bytes is associated with the reservation, and replaces any length previously associated with the reservation.

The value of EH provides a hint as to whether the program will perform a subsequent store to the doubleword in storage addressed by EA before some other processor attempts to modify it.

- 0 Other programs might attempt to modify the doubleword in storage addressed by EA regardless of the result of the corresponding **stdcx.** instruction.
- 1 Other programs will not attempt to modify the doubleword in storage addressed by EA until the program that has acquired the lock performs a subsequent store releasing the lock.

EA must be a multiple of 8. If it is not, either the system alignment error handler is invoked or the results are boundedly undefined.

#### Special Registers Altered:

None

#### Programming Note

**ldarx** serves as both a basic and an extended mnemonic. The Assembler will recognize a **ldarx** mnemonic with four operands as the basic form, and a **ldarx** mnemonic with three operands as the extended form. In the extended form the EH operand is omitted and assumed to be 0.

#### Store Doubleword Conditional Indexed X-form

stdcx.      RS,RA,RB

```

if RA = 0 then b ← 0
else            b ← (RA)
EA ← b + (RB)
if RESERVE then
  if RESERVE_LENGTH = 8 &
    RESERVE_ADDR = real_addr(EA) then
    MEM(EA, 8) ← (RS)
    undefined_case ← 0
    store_performed ← 1
  else
    z ← smallest real page size supported by
        implementation
    if RESERVE_ADDR ÷ z = real_addr(EA) ÷ z then
      undefined_case ← 1
    else
      undefined_case ← 0
      store_performed ← 0
else
  undefined_case ← 0
  store_performed ← 0
if undefined_case then
  u1 ← undefined 1-bit value
  if u1 then
    MEM(EA, 8) ← (RS)
  u2 ← undefined 1-bit value
  CR0 ← 0b00 || u2 || XERSO
else
  CR0 ← 0b00 || store_performed || XERSO
RESERVE ← 0

```

Let the effective address (EA) be the sum (RA|0)+(RB).

If a reservation exists, the length associated with the reservation is 8 bytes, and the real storage location specified by the **stdcx.** is the same as the real storage location specified by the **ldarx** instruction that established the reservation, (RS) is stored into the doubleword in storage addressed by EA.

If a reservation exists, and either the length associated with the reservation is not 8 bytes or the real storage location specified by the **stdcx.** is not the same as the real storage location specified by the **ldarx** instruction that established the reservation, the following applies. Let z denote the smallest real page size supported by the implementation. If the real storage location specified by the **stdcx.** is in the same aligned z-byte block of real storage as the real storage location specified by the **ldarx** instruction that established the reservation, it is undefined whether (RS) is stored into the doubleword in storage addressed by EA. Otherwise, no store is performed.

If a reservation does not exist, no store is performed.

CR Field 0 is set as follows.  $n$  is a 1-bit value that indicates whether the store was performed, except that if, per the preceding description, it is undefined whether the store is performed, the value of  $n$  is undefined (and need not reflect whether the store was performed).

$CR0_{LTGT EQ SO} = 0b00 \parallel n \parallel XER_{SO}$

The reservation is cleared.

EA must be a multiple of 8. If it is not, either the system alignment error handler is invoked or the results are boundedly undefined.

**Special Registers Altered:**

CR0

## 4.6.2.2 128-bit Load And Reserve and Store Conditional Instructions

For *lqarx*, the quadword in storage addressed by EA is loaded into an even-odd pair of GPRs as follows. In Big-Endian mode, the even-numbered GPR is loaded with the doubleword from storage addressed by EA and the odd-numbered GPR is loaded with the doubleword addressed by EA+8. In Little-Endian mode, the even-numbered GPR is loaded with the byte-reversed doubleword from storage addressed by EA+8 and the odd-numbered GPR is loaded with the byte-reversed doubleword addressed by EA.

In the preferred form of the *Load Quadword* instruction RA  $\neq$  RTP+1 and RB  $\neq$  RTP+1.

For *stqcx*, the contents of an even-odd pair of GPRs is stored into the quadword in storage addressed by EA as follows. In Big-Endian mode, the even-numbered GPR is stored into the doubleword in storage addressed by EA and the odd-numbered GPR is stored into the doubleword addressed by EA+8. In Little-Endian mode, the even-numbered GPR is stored byte-reversed into the doubleword in storage addressed by EA+8 and the odd-numbered GPR is stored byte-reversed into the doubleword addressed by EA.

### Load Quadword And Reserve Indexed X-form

*lqarx*      RTP,RA,EB,EH

31	RTP	RA	RB	276	EH
0	6	11	16	21	31

```

if RA = 0 then b  $\leftarrow$  0
else            b  $\leftarrow$  (RA)
EA  $\leftarrow$  b +(RB)
RESERVE  $\leftarrow$  1
RESERVE_LENGTH  $\leftarrow$  16
RESERVE_ADDR  $\leftarrow$  real_addr(EA)
RTP  $\leftarrow$  MEM(EA, 16)

```

Let the effective address (EA) be the sum (RA|0)+(RB). The quadword in storage addressed by EA is loaded into RTP.

This instruction creates a reservation for use by a *stqcx* or *waitrsv* instruction. A real address computed from the EA as described in Section 1.7.2.1 is associated with the reservation, and replaces any address previously associated with the reservation. A length of 16 bytes is associated with the reservation, and replaces any length previously associated with the reservation.

The value of EH provides a hint as to whether the program will perform a subsequent store to the doubleword in storage addressed by EA before some other processor attempts to modify it.

- 0 Other programs might attempt to modify the doubleword in storage addressed by EA regardless of the result of the corresponding *stqcx* instruction.
- 1 Other programs will not attempt to modify the doubleword in storage addressed by EA until the program that has acquired the lock performs a subsequent store releasing the lock.

EA must be a multiple of 16. If it is not, either the system alignment error handler is invoked or the results are boundedly undefined.

If RTP is odd, RTP=RA, or RTP=RB the instruction form is invalid. If RTP=RA or RTP=RB, an attempt to execute this instruction will invoke the system illegal instruction error handler. (The RTP=RA case includes the case of RTP=RA=0.)

#### Special Registers Altered:

None

#### Programming Note

*lqarx* serves as both a basic and an extended mnemonic. The Assembler will recognize a *lqarx* mnemonic with four operands as the basic form, and a *lqarx* mnemonic with three operands as the extended form. In the extended form the EH operand is omitted and assumed to be 0.

## Store Quadword Conditional Indexed X-form

stqcx. RSp,RA,RB

31	RSp	RA	RB	182	1
0	6	11	16	21	31

```

if RA = 0 then b ← 0
else      b ← (RA)
EA ← b + (RB)
if RESERVE then
  if RESERVE_LENGTH = 16 &
    RESERVE_ADDR = real_addr(EA) then
    MEM(EA, 16) ← (RSp)
    undefined_case ← 0
    store_performed ← 1
  else
    z ← smallest real page size supported by
      implementation
    if RESERVE_ADDR ÷ z = real_addr(EA) ÷ z then
      undefined_case ← 1
    else
      undefined_case ← 0
      store_performed ← 0
else
  undefined_case ← 0
  store_performed ← 0
if undefined_case then
  u1 ← undefined 1-bit value
  if u1 then
    MEM(EA, 16) ← (RSp)
  u2 ← undefined 1-bit value
  CR0 ← 0b00 || u2 || XERSO
else
  CR0 ← 0b00 || store_performed || XERSO
RESERVE ← 0

```

Let the effective address (EA) be the sum (RA|0)+(RB).

If a reservation exists, the length associated with the reservation is 16 bytes, and the real storage location specified by the **stqcx.** is the same as the real storage location specified by the **lqarx** instruction that established the reservation, (RSp) is stored into the quadword in storage addressed by EA.

If a reservation exists, and either the length associated with the reservation is not 16 bytes or the real storage location specified by the **stqcx.** is not the same as the real storage location specified by the **lqarx** instruction that established the reservation, the following applies. Let z denote the smallest real page size supported by the implementation. If the real storage location specified by the **stqcx.** is in the same aligned z-byte block of real storage as the real storage location specified by the **lqarx** instruction that established the reservation, it is undefined whether (RSp) is stored into the quadword in storage addressed by EA. Otherwise, no store is performed.

If a reservation does not exist, no store is performed.

CR Field 0 is set as follows. n is a 1-bit value that indicates whether the store was performed, except that if,

per the preceding description, it is undefined whether the store is performed, the value of n is undefined (and need not reflect whether the store was performed).

$CR0_{LTGT EQ SO} = 0b00 || n || XERSO$

The reservation is cleared.

EA must be a multiple of 16. If it is not, either the system alignment error handler is invoked or the results are boundedly undefined.

If RSp is odd, the instruction form is invalid.

### Special Registers Altered:

CR0

### 4.6.3 Memory Barrier Instructions

The *Memory Barrier* instructions can be used to control the order in which storage accesses and data transfers are performed. Additional information about these

instructions and about related aspects of storage management can be found in Book III.

#### Synchronize X-form

sync L,SC

31	//	L	///	SC	///	598	/
0	6	8	11	14	16	21	31

```
if SC10 then switch(SC)
  case(1): stncisync
  case(2): stcisync
  case(3): stsync
else switch(L)
  case(0): hwsync
  case(1): lwsync
  case(2): ptesync
  case(4): phwsync
  case(5): plwsync
```

The **sync** instruction creates a memory barrier (see Section 1.7.1). The set of storage accesses and/or data transfers that is ordered by the memory barrier depends on the contents of the L and SC fields as follows.

#### SC≠0

- **SC=1 (“store not caching inhibited sync”)**  
The memory barrier provides an ordering function for the storage accesses caused by Store and dcbz instructions that are executed by the processor executing the sync instruction and for which the specified storage location is in storage that is not Caching Inhibited. The applicable pairs are all pairs  $a_i, b_j$  of such storage accesses.
- **SC=2 (“store caching inhibited sync”)**  
The memory barrier provides an ordering function for the storage accesses caused by Store and dcbz instructions that are executed by the processor executing the sync instruction and for which the specified storage location is in storage that is Caching Inhibited. The applicable pairs are all pairs  $a_i, b_j$  of such storage accesses.
- **SC=3 (“store sync”)**  
The memory barrier provides an ordering function for the storage accesses caused by Store and dcbz instructions that are executed by the processor executing the sync instruction. The applicable pairs are all pairs  $a_i, b_j$  of such storage accesses.

#### SC=0

- **L=0 (“heavyweight sync”)**

The memory barrier provides an ordering function for the storage accesses and data transfers associated with all instructions that are executed by the processor executing the sync instruction with the exception of **dcbfps** and **dcbstps**. The applicable pairs are all pairs  $a_i, b_j$  of such storage accesses and data transfers in which  $b_j$  is a data access or data transfer, except that if  $a_i$  is the storage access caused by an **icbi** instruction then  $b_j$  may be performed with respect to the processor executing the **sync** instruction before  $a_i$  is performed with respect to that processor.

- **L=1 (“lightweight sync”)**

The memory barrier provides an ordering function for the storage accesses caused by *Load*, *Store*, and **dcbz** instructions that are executed by the processor executing the sync instruction and for which the specified storage location is in storage that is Memory Coherence Required and is neither Write Through Required nor Caching Inhibited. The applicable pairs are all pairs  $a_i, b_j$  of such storage accesses except those in which  $a_i$  is an access caused by a *Store* or **dcbz** instruction and  $b_j$  is an access caused by a *Load* instruction.

- **L=2 (“ptesync”)**

The set of storage accesses that is ordered by the memory barrier is described in Section 6.9.2 of Book III, as are additional properties of the **sync** instruction with L=2.

- **L=4 (“persistent heavyweight sync”)**

The ordering done by the memory barrier is the same as for **sync** with L=0, but extended by adding accesses caused by **dcbfps** and **dcbstps** to both the set A and the set B of the barrier. In addition, the memory barrier ensures that all stores for which the modifications are written to persistent storage by preceding **dcbfps** and **dcbstps** instructions have updated persistent storage before any data access or data transfer caused by subsequent instructions is initiated.

- **L=5 (“persistent lightweight sync”)**

The ordering done by the memory barrier is the same as for **sync** with L=1, but extended by adding accesses caused by **dcbfps** and **dcbstps** to both the set A and the set B of the barrier. In addition, the memory barrier ensures that all stores for which the modifica-

tions are written to persistent storage by preceding **dcbfps** and **dcbstps** instructions have updated persistent storage before any store in set B updates persistent storage.

The ordering done by the memory barrier is cumulative (regardless of the L and SC values).

If L=0 or L=4 (or L=2), the **sync** instruction has the following additional properties.

- Executing the **sync** instruction ensures that all instructions preceding the **sync** instruction have completed before the **sync** instruction completes, and that no subsequent instructions are initiated until after the **sync** instruction completes.
- The **sync** instruction is execution synchronizing (see Book III). However, address translation and reference and change recording (see Book III) associated with subsequent instructions may be performed before the **sync** instruction completes.
- The memory barrier provides the additional ordering function such that if a given instruction that is the result of a store in set B is executed, all applicable storage accesses in set A have been performed with respect to the processor executing the instruction to the extent required by the associated memory coherence properties. The single exception is that any storage access in set A that is caused by an **icbi** instruction executed by the pro-

cessor executing the **sync** instruction (P1) may not have been performed with respect to P1 (see the description of the **icbi** instruction on page 1062).

The cumulative properties of the memory barrier apply to the execution of the given instruction as they would to a load that returned a value that was the result of a store in set B.

#### Programming Note

Section 1.8 contains a detailed description of how to modify instructions such that a well-defined result is obtained.

The L values 3, 6, and 7 are reserved.

The **sync** instruction may complete before storage accesses associated with instructions preceding the **sync** instruction have been performed.

Figure 5 shows the valid combinations of SC and L values. Instructions that use any of these combinations will execute correctly on processors that comply with versions of the architecture that precede Version 3.1 (in which versions the L field is two bits long, the SC field does not exist, and bits 8 and 14:15 of the **sync** instruction are reserved) and on processors that comply with Version 3.1 and subsequent versions of the architecture. If any other combination is used, the instruction form is invalid.

SC	L	Intended barrier for processors that comply with V. 3.1 or later	Intended barrier for processors that comply with V. 3.0C or earlier
1	1	stncisync	lwsync
2	0	stcisync	hwsync
3	0	stsync	hwsync
0	0	hwsync	hwsync
0	1	lwsync	lwsync
0	2	ptesync	ptesync
0	4	phwsync	hwsync*
0	5	plwsync	lwsync*

\* depends on details of the bus interface design to have proper persistent storage semantics

Figure 5. Interpretation of the L and SC fields

#### Special Registers Altered:

None

#### Extended Mnemonics:

Extended mnemonics for *Synchronize*:

Extended:	Equivalent to:
sync	sync 0,0
sync x	sync x,0
hwsync	sync 0,0

#### Extended:

lwsync	sync 1,0
ptesync	sync 2,0
phwsync	sync 4,0
plwsync	sync 5,0
stncisync	sync 1,1
stcisync	sync 0,2
stsync	sync 0,3

#### Equivalent to:

Except in the **sync** instruction description in this section, references to "**sync**" in Books I-III imply L=0

unless otherwise stated or obvious from context; the appropriate extended mnemonics are used when other L values are intended. Throughout Books I-III, references to the L field imply SC=0 unless otherwise stated or obvious from context. The SC field is mentioned explicitly, or the appropriate extended mnemonics are used, when non-zero SC values are intended. Some programming examples and recommendations assume a programming model that does not include the store-specific variants of **sync**. Improved performance may be achieved through the use of store-specific memory barriers in some cases.

#### Programming Note

**sync** serves as both a basic and an extended mnemonic. The Assembler will recognize a **sync** mnemonic with two operands as the basic form, and a **sync** mnemonic with one operand or with no operand as an extended form. In the extended form with one operand the SC operand is omitted and assumed to be 0. In the extended form with no operand the L and SC operands are omitted and assumed to be 0.

#### Programming Note

The **sync** instruction can be used to ensure that all stores into a data structure, caused by *Store* instructions executed in a “critical section” of a program, will be performed with respect to another processor before the store that releases the lock is performed with respect to that processor; see Section B.2, “Lock Acquisition and Release, and Related Techniques” on page 1119.

The memory barrier created by a **sync** instruction with L=1 (or with SC≠0) does not order implicit storage accesses or instruction fetches. The memory barrier created by a **sync** instruction with L=0 (or L=2) orders implicit storage accesses and instruction fetches associated with instructions preceding the **sync** instruction but not those associated with instructions following the **sync** instruction.

In order to obtain the best performance across the widest range of implementations, the programmer should use the **sync** instruction with L=1 or with SC≠0, or the **eieio** instruction, if any of these is sufficient for his needs; otherwise he should use **sync** with L=0 (or with L=4 or L=5 if he needs to order accesses to persistent storage). **sync** with L=2 should not be used by application programs.

#### Programming Note

The functions provided by **sync** with L=1 and with SC≠0 are a strict subset of those provided by **sync** with L=0. (The functions provided by **sync** with L=2 are a strict superset of those provided by **sync** with L=4; see Book III.)

## Enforce In-order Execution of I/O X-form

**eieio**

0	31	///	///	///	854	/
	6		11	16	21	31

The **eieio** instruction creates a memory barrier (see Section 1.7.1, “Storage Access Ordering”), which provides an ordering function for the storage accesses caused by *Load*, *Store*, and **dcbz** instructions executed by the processor executing the **eieio** instruction. These storage accesses are divided into the two sets listed below. The storage access caused by a **dcbz** instruction is ordered as a store.

1. Loads and stores to storage that is both Caching Inhibited and Guarded, and stores to main storage caused by stores to storage that is Write Through Required.

The applicable pairs are all pairs  $a_i, b_j$  of such accesses.

2. Stores to storage that is Memory Coherence Required and is neither Write Through Required nor Caching Inhibited.

The applicable pairs are all pairs  $a_i, b_j$  of such accesses.

The operations caused by the stream variants of the **dcbt** and **dcbtst** instructions (i.e., the providing of hints) are ordered by **eieio** as a third set of operations, the operations caused by **tlbie** and **tlbsync** instructions (see Book III) are ordered by **eieio** as a fourth set of operations, and the operations caused by **slbieg** or **slbiag** and **slbsync** instructions (see Book III) are ordered by **eieio** as a fifth set of operations.

Each of the five sets of storage accesses or operations is ordered independently of the other four sets. The ordering done by **eieio**'s memory barrier for the second set is cumulative; the ordering done by **eieio**'s memory barrier for the other four sets is not cumulative.

The **eieio** instruction may complete before storage accesses associated with instructions preceding the **eieio** instruction have been performed. The **eieio** instruction may complete before operations caused by **dcbt** and **dcbtst** instructions preceding the **eieio** instruction have been performed.

#### Special Registers Altered:

None

**Programming Note**

The ***eieio*** instruction is intended for use in doing memory-mapped I/O). Because loads, and separately stores, to storage that is both Caching Inhibited and Guarded are performed in program order (see Section 1.7.1, “Storage Access Ordering” on page 1044), ***eieio*** is needed for such storage only when loads must be ordered with respect to stores.

For the ***eieio*** instruction, accesses in set 1,  $a_i$  and  $b_j$  need not be the same kind of access or be to storage having the same storage control attributes. For example,  $a_i$  can be a load to Caching Inhibited, Guarded storage, and  $b_j$  a store to Write Through Required storage.

If stronger ordering is desired than that provided by ***eieio***, the ***sync*** instruction must be used, with the appropriate value in the L field.

**Programming Note**

The functions provided by ***eieio*** for its second set are a strict subset of those provided by ***sync*** with L=1.

## 4.6.4 Wait Instruction

The wait instruction is used to stop instruction fetching and execution until certain events occur. These events include exceptions (see Section 1.2.1 of Book III),

event-based branch exceptions (see Section 1.1), the passage of a specified amount of time, and the modification of a storage location.

### Wait X-form

wait WC,PL

0	31	??	/	WC	///	PL	///	30	/	31
		6	8	9	11	14	16	21		

The **wait** instruction causes instruction fetching and execution to be suspended under certain conditions, depending on the values of the WC and PL fields. Instruction fetching and execution are resumed when the events specified by the WC field occur or in the rare case of an implementation-dependent event.

The values of the WC field are as follows.

- 0 Resume instruction fetching and execution when an exception or event-based branch exception occurs.
- 1 Resume instruction fetching and execution when an exception or event-based branch exception occurs, or when a reservation made by the processor does not exist (see Section 1.7.2.1).
- 2 Resume instruction fetching and execution when an exception or event-based branch exception occurs, or when the amount of time specified by the PL field has passed.
- 3 Reserved.

The values of the PL field are as follows.

- 0b00 A short wait time is specified.
- 0b01:11 Reserved.

If WC=0, or if WC=1 and a reservation made by the processor exists, or if WC=2 and a value for PL that is not reserved is specified, the following applies.

- Upon completion of the instruction, instruction fetching and execution is suspended.
- Instruction fetching and execution resumes when any of the following conditions are met.
  - An exception or event-based branch exception occurs.
  - WC=1 and a reservation made by the processor does not exist.
  - WC=2 and the specified amount of time has passed.
  - An implementation-dependent event occurs.

#### Programming Note

Because the waiting begins when the instruction completes, if the waiting is ended by an exception that causes a change of control flow (interrupt, event-based branch), the SPR that is set to reflect the point in the instruction stream at which the change of control flow occurred (e.g., SRR0 for a Decrementer interrupt) will contain the EA of the instruction following the **wait** instruction.

If WC=1 and a reservation made by the processor does not exist, or if WC=2 and a reserved value of PL is specified, the instruction is treated as a no-op.

#### Programming Note

Bits 6 and 7 of the **wait** instruction may be used in some implementations for an implementation-dependent field. Unless the intention is to use the implementation-dependent field, these bits must be coded zero.

#### Special Registers Altered:

None

#### Extended Mnemonics:

Examples of extended mnemonics for **wait**:

Extended:	Equivalent to:
wait	wait 0,0
wait 0	wait 0,0
wait 1	wait 1,0
waitrsv	wait 1,0
pause_short	wait 2,0

Except in this section, references to “**wait**” in Books I-III include all defined forms of **wait** unless otherwise stated or obvious from context.

#### Programming Note

**wait** serves as both a basic and an extended mnemonic. The Assembler will recognize a **wait** mnemonic with two operands as the basic form and a **wait** mnemonic with one operand or with no operand as an extended form. In the extended form with one operand the PL operand is omitted and assumed to be 0. In the extended form with no operand the WC and PL operands are omitted and assumed to be 0.

**Programming Note**

The **wait** instruction frees computational resources which might be allocated to another program or converted into power savings.

**Programming Note**

Since exceptions corresponding to system-caused interrupts (see Section 7.4 of Book III) may occur at any time, including immediately prior to the **wait** instruction, applications should not depend on them to cause **wait** to resume. In order to ensure timely resumption, therefore, applications should execute **wait** only in order to suspend processing until an event-based branch exception or loss of reservation occurs or a specified amount of time has passed.

Also, since exceptions corresponding to interrupts can cause **wait** to resume at any time without any EBB exception or loss of reservation having occurred, and in consideration of the possibility of resuming because of an implementation-dependent event, programs that execute **wait** should check that the expected condition has actually occurred after the **wait** instruction completes. If the expected condition has not occurred, **wait** should be re-executed. An example code usage is shown below.

```
while (!expected condition), wait
```

**Programming Note**

Applications that execute **wait** in order to suspend processing until an external event-based branch exception occurs (see Section 6.2) should enable external event-based branch exceptions (by setting  $BESCR_{EE}=1$ ) and disable event-based branches (by setting  $BESCR_{GE}=0$ ) before executing **wait**. If  $BESCR_{GE}=1$ , then the expected event-based branch exception may cause the corresponding event-based branch to occur immediately prior to execution of the **wait** instruction. This will result in a hang condition since the EBB exception that was expected to cause **wait** to resume will have already occurred.

## Chapter 5. Time Base

The Time Base (TB) is a 64-bit register (see Figure 6) containing a 64-bit unsigned integer that is incremented periodically as described below.

Field	Description
TBU	Upper 32 bits of Time Base
TBL	Lower 32 bits of Time Base

**Figure 6. Time Base**

The Time Base monotonically increments until its value becomes 0xFFFF\_FFFF\_FFFF\_FFFF ( $2^{64} - 1$ ); at the next increment its value becomes 0x0000\_0000\_0000\_0000. There is no interrupt or other indication when this occurs.

The suggested frequency at which the time base increments is 512 MHz, however, variation from this rate is allowed provided the following requirements are met.

- The contents of the Time Base differ by no more than +/- four counts from what they would be if they incremented at the required frequency.
- Bit 63 of the Time Base is set to 1 between 30% and 70% of the time over any time interval of at least 16 counts.

The Power ISA does not specify a relationship between the frequency at which the Time Base is updated and other frequencies, such as the CPU clock or bus clock. The Time Base update frequency is not required to be constant. What *is* required, so that system software can keep time of day and operate interval timers, is one of the following.

- The system provides an (implementation-dependent) interrupt to software whenever the update frequency of the Time Base changes, and a means to determine what the current update frequency is.
- The update frequency of the Time Base is under the control of the system software.

### Programming Note

If the operating system initializes the Time Base on power-on to some reasonable value and the update frequency of the Time Base is constant, the Time Base can be used as a source of values that increase at a constant rate, such as for time stamps in trace entries.

Even if the update frequency is not constant, values read from the Time Base are monotonically increasing (except when the Time Base wraps from  $2^{64}-1$  to 0). If a trace entry is recorded each time the update frequency changes, the sequence of Time Base values can be post-processed to become actual time values.

Successive readings of the Time Base may return identical values.

## 5.1 Time Base Instructions

### Move From Time Base *XFX-form*

mftb RT,TBR  
[Phased-Out]

31	RT	tbr	371	/
0	6	11	21	31

This instruction behaves as if it were an *mf spr* instruction; see the *mf spr* instruction description in Section 3.3.19 of Book I.

#### Special Registers Altered:

None

#### Extended Mnemonics:

Extended mnemonics for *Move From Time Base*:

Extended:	Equivalent to:
mftb Rx	mftb Rx,268 mf spr Rx,268
mftbu Rx	mftb Rx,269 mf spr Rx,269

#### Programming Note

New programs should use *mf spr* instead of *mftb* to access the Time Base.

#### Programming Note

*mftb* serves as both a basic and an extended mnemonic. The Assembler will recognize an *mftb* mnemonic with two operands as the basic form, and an *mftb* mnemonic with one operand as the extended form. In the extended form the TBR operand is omitted and assumed to be 268 (the value that corresponds to TB).

#### Programming Note

The *mf spr* instruction can be used to read the Time Base on all processors that comply with Version 2.01 of the architecture or with any subsequent version.

It is believed that the *mf spr* instruction can be used to read the Time Base on most processors that comply with versions of the architecture that precede Version 2.01. Processors for which *mf spr* cannot be used to read the Time Base include the following.

- 601
- POWER3

(601 implements neither the Time Base nor *mftb*, but depends on software using *mftb* to read the Time Base, so that the attempt causes the Illegal Instruction error handler to be invoked and thereby permits the operating system to emulate the Time Base.)

## Programming Note

Since the update frequency of the Time Base is implementation-dependent, the algorithm for converting the current value in the Time Base to time of day is also implementation-dependent.

As an example, assume that the Time Base increments at the constant rate of 512 MHz. (Note, however, that programs should allow for the possibility that some implementations may not increment the least-significant 4 bits of the Time Base at a constant rate.) What is wanted is the pair of 32-bit values comprising a POSIX standard clock:<sup>1</sup> the number of whole seconds that have passed since 00:00:00 January 1, 1970, UTC, and the remaining fraction of a second expressed as a number of nanoseconds.

Assume that:

- The value 0 in the Time Base represents the start time of the POSIX clock (if this is not true, a simple 64-bit subtraction will make it so).
- The integer constant *ticks\_per\_sec* contains the value 512,000,000, which is the number of times the Time Base is updated each second.
- The integer constant *ns\_adj* contains the value

$$\frac{1,000,000,000}{512,000,000} \times 2^{32} / 2 = 4194304000$$

which is the number of nanoseconds per tick of the Time Base, multiplied by  $2^{32}$  for use in *mulhwu* (see below), and then divided by 2 in order to fit, as an unsigned integer, into 32 bits.

When the processor is in 64-bit mode, The POSIX clock can be computed with an instruction sequence such as this:

```

mfspr  Ry,268 # Ry = Time Base
lwz    Rx,ticks_per_sec
divdu  Rz,Ry,Rx # Rz = whole seconds
stw    Rz,posix_sec
mulld  Rz,Rz,Rx # Rz = quotient * divisor
sub    Rz,Ry,Rz # Rz = excess ticks
lwz    Rx,ns_adj
slwi   Rz,Rz,1 # Rz = 2 * excess ticks
mulhwu Rz,Rz,Rx # mul by (ns/tick)/2 * 232
stw    Rz,posix_ns# product[0:31] = excess ns

```

### Non-constant update frequency

In a system in which the update frequency of the Time Base may change over time, it is not possible to convert an isolated Time Base value into time of day. Instead, a Time Base value has meaning only with respect to the current update frequency and the time of day that the update frequency was last changed. Each time the update frequency changes, either the system software is notified of the change via an interrupt (see Book III), or the change was instigated by the system software itself. At each such change, the system software must compute the current time of day using the old update frequency, compute a new value of *ticks\_per\_sec* for the new frequency, and save the time of day, Time Base value, and tick rate. Subsequent calls to compute Time of Day use the current Time Base Value and the saved value.

1. Described in POSIX Draft Standard P1003.4/D12, *Draft Standard for Information Technology -- Portable Operating System Interface (POSIX) -- Part 1: System Application Program Interface (API) - Amendment 1: Real-time Extension [C Language]*. Institute of Electrical and Electronics Engineers, Inc., Feb. 1992.

## Chapter 6. Event-Based Branch Facility

### 6.1 Event-Based Branch Overview

The Event-Based Branch facility allows application programs to enable hardware to change the effective address of the next instruction to be executed when certain events occur to an effective address specified by the program.

The operation of the Event-Based Branch facility is summarized as follows:

- The Event-Based Branch facility is available only when the system software has made it available. See Section 11.5 of Book III for additional information.
- When the Event-Based Branch facility is available, event-based branches are caused by event-based exceptions. Event-based exceptions can be enabled to occur by setting bits in the BESCR.
- When an event-based exception occurs, the bit in the BESCR control field corresponding to the event-based exception is set to 0 and the bit in the Event Status field in the BESCR corresponding to the event-based exception is set to 1.
- If the global enable bit in the BESCR is set to 1 when any of the bits in the status field are set to 1 (i.e., when an event-based exception exists), an event-based branch occurs.
- The event-based branch causes the following to occur.
  - The global enable bit is set to 0.
  - Bits 0:61 of the EBBRR are set to the effective address of the instruction that would have attempted to execute next if the event-based branch did not occur.
  - Instruction fetch and execution continues at the effective address contained in the EBBHR.
- The event-based branch handler performs the necessary processing in response to the event, and then executes an *rfebb* instruction in order to resume execution at the instruction at the address indicated in the EBBRR. See the Programming Notes in Section 6.3 for an example sequence of operations of the event-based branch handler.

Additional information about the Event-Based Branch facility is given in Section 4.4 of Book III.

#### Programming Note

Since system software controls the availability of the Event-Based Branch facility (see Section 11.5 of Book III), an interface must be provided that enables applications to request access to the facility and determine when it is available.

#### Programming Note

In order to initialize the Event-Based Branch facility for Performance Monitor event-based exceptions, software performs the following operations.

- Software requests control of the Event-Based Branch facility from the system software.
- Software requests the system software to initialize the Performance Monitor as desired.
- Software sets the EBBHR to the effective address of the event-based branch handler.
- Software enables Performance Monitor event-based exceptions by setting  $BESCR_{PME} = 1$  and  $BESCR_{PMEO} = 1$ , and also sets  $MMCR0_{PMAE} = 1$  and  $MMCR0_{PMAO} = 1$ . See Section 11.4.4 of Book III for the description of MMCR0.
- Software sets the GE bit in the BESCR to enable event-based branches.

Initializing the Event-Based Branch facility for External EBB exceptions follows a similar process except that EBB exceptions for these facilities are controlled by different bits in the BESCR.

### 6.2 Event-Based Branch Registers

#### 6.2.1 Branch Event Status and Control Register

The Branch Event Status and Control Register (BESCR) is a 64-bit register that contains control and status information about the Event-Based Branch facility.

Figure 7. Branch Event Status and Control Register (BESCR)

Figure 8. Branch Event Status and Control Register Upper (BESCRU)

System software controls whether or not event-based branches occur regardless of the contents of the BESCR. See Section 11.4.4 of Book III and Section 7.2.13 of Book III.

The entire BESCR can be read or written using SPR 806. Individual bits of the BESCR can be set or reset using two sets of additional SPR numbers.

- When *mtspr* indicates SPR 800 (Branch Event Status and Control Set, or BESCRS), the bits in BESCR which correspond to “1” bits in the source register are set to 1; all other bits in the BESCR are unaffected. SPR 801 (BESCRSU) provides the same capability to each of the upper 32 bits of the BESCR.
- When *mtspr* indicates SPR 802 (Branch Event Status and Control Reset, or BESCRU), the bits in BESCR which correspond to “1” bits in the source register are set to 0; all other bits in the BESCR are unaffected. SPR 803 (BESCRU) provides the same capability to each of the upper 32 bits of the BESCR.

When *mfspr* indicates any of the above SPR numbers, the current value of the register is returned.

Programming Note

Event-based branch handlers typically reset event status bits upon entry, and enable event enable bits after processing an event. Execution of *rfebb* then re-enables the GE bit so that additional event-based branches can occur.

- 0 **Global Enable (GE)**
  - 0 Event-based branches are disabled
  - 1 Event-based branches are enabled.

When an event-based branch occurs, GE is set to 0 and is not altered by hardware until *rfebb* 1 is executed or software sets GE=1 and another event-based branch occurs.
- 1:31 **Event Control**
  - 1:29 **Reserved**

30 **External Event-Based Exception Enable (EE)**

- 0 External event-based (EBB) exceptions are disabled.
- 1 External EBB exceptions are enabled until an external event-based exception occurs, at which time:
  - EE is set to 0
  - EEO is set to 1

External event-based exceptions exist in any privilege state when an external EBB input from the platform is active. See the system documentation for information about the external EBB input.

31 **Performance Monitor Event-Based Exception Enable (PME)**

- 0 Performance Monitor event-based exceptions are disabled.
- 1 Performance Monitor event-based exceptions are enabled until a Performance Monitor event-based exception occurs, at which time:
  - PME is set to 0
  - PMEO is set to 1

See Chapter 11 of Book III for information about Performance Monitor event-based exceptions and about the effects of this bit on the Performance Monitor.

Programming Note

Performance Monitor event-based exceptions can only occur in problem state. See Section 11.2 of Book III.

32:33 **Reserved**

Programming Note

Bits 32:33 must contain 0b00 when *rfebb* is executed; otherwise the instruction is treated as if the instruction form were invalid.

34:63 **Event Status**

34:61 **Reserved**

62 **External Event-Based Exception Occurred (EEO)**

- 0 An external EBB exception has not occurred since the last time software set this bit to 0.
- 1 An external EBB exception has occurred since the last time software set this bit to 0.

**Programming Note**

As part of processing an External EBB exception, it may also be necessary to perform additional operations to manage the external EBB input from the system. See the system documentation for details.

**63 Performance Monitor Event-Based Exception Occurred (PMEO)**

- 0 A Performance Monitor event-based exception has not occurred since the last time software set this bit to 0.
- 1 A Performance Monitor event-based exception has occurred since the last time software set this bit to 0.

This bit is set to 1 by the hardware when a Performance Monitor event-based exception occurs. This bit can be set to 0 only by the *mtspr* instruction.

See Chapter 11 of Book III for information about Performance Monitor event-based exceptions and about the effects of this bit on the Performance Monitor.

**Programming Note**

After handling an event-based branch, software should set the “exception occurred” bit(s) corresponding to the event-based exception(s) that have occurred to 0. See the Programming Notes in Section 6.3 for additional information.

**6.2.2 Event-Based Branch Handler Register**

The Event-Based Branch Handler Register (EBBHR) is a 64-bit register that contains the 62 most significant bits of the effective address of the instruction that is executed next after an event-based branch occurs. Bits 62:63 must be available to be read and written by software.

**Figure 9. Event-Based Branch Handler Register (EBBHR)**

**Programming Note**

The EBBHR can be used by software as a scratch-pad register after entry into an event-based branch handler, provided that its contents are restored prior to executing *rfebb* 1. An example of such usage is as follows. In the example, SPRG3 is used to contain a pointer to a storage area where private application data may be saved, however, refer to the applicable operating system documentation to determine if an alternate register or storage area should be used.

```
E:mtspr EBBHR, r1    // Save r1 in EBBHR
mfspr r1, SPRG3     // Move SPRG3 to r1
std r2, r1,offset1  // Store r2
mfspr EBBHR,r2      // Copy original contents
                    // of r1 to r2
std r2,offset2(r1)  // save original r1
..                  // Store rest of state
...                 // Process event(s)
...                 // Restore all state except
                    // r1,r2
r2 = &E              // Generate original value
                    // of EBBHR in r2
mtspr EBBHR,r2      // Restore EBBHR
ld r2 offset1(r1)   // restore r2
ld r1 offset2(r1)   // restore r1
rfebb 1              // Return from handler
```

**6.2.3 Event-Based Branch Return Register**

The Event-Based Branch Return Register (EBBRR) is a 64-bit register that contains the 62 most significant bits of an instruction effective address as specified below.

**Figure 10. Event-Based Branch Return Register (EBBRR)**

When an event-based branch occurs, bits 0:61 of the EBBRR are set to the effective address of the instruction that would have attempted to execute next if the event-based branch did not occur.

Bits 62:63 are reserved.

## 6.3 Event-Based Branch Instructions

### Return from Event-Based Branch XL-form

rfebb S

19	///	///	///	S	146	/
0	6	11	16	20	21	31

$BESCR_{GE} \leftarrow S$   
 $NIA \leftarrow_{iea} EBBRR_{0:61} \parallel 0b00$

$BESCR_{GE}$  is set to S.

If there are no pending event-based exceptions, then the next instruction is fetched from the address  $EBBRR_{0:61} \parallel 0b00$  (when  $MSR_{SF}=1$ ) or  ${}^{32}0 \parallel EBBRR_{32:61} \parallel 0b00$  (when  $MSR_{SF}=0$ ). If one or more pending event-based exceptions exist, an event-based branch is generated; in this case the value placed into  $EBBRR$  by the Event-Based Branch facility is the address of the instruction that would have been executed next had the event-based branch not occurred.

If  $BESCR_{32:33} \neq 0b00$  the instruction is treated as if the instruction form were invalid.

See Section 4.4 of Book III for additional information about this instruction.

#### Special Registers Altered:

$BESCR$   
 $MSR$  (See Book III)

#### Extended Mnemonics:

<b>Extended:</b>	<b>Equivalent to:</b>
rfebb	rfebb 1

#### Programming Note

*rfebb* serves as both a basic and an extended mnemonic. The Assembler will recognize an *rfebb* mnemonic with one operand as the basic form, and an *rfebb* mnemonic with no operand as the extended form. In the extended form, the S operand is omitted and assumed to be 1.

#### Programming Note

When an event-based branch occurs, the event-based branch handler can execute the following sequence of operations. This sequence of operations assumes that the handler routine has access to a stack or other area in memory in which state information from the main program can be stored. Note also that in this example, the handler entry point is labeled “E,” r1 and r2 are used as scratch registers, and both external EBB and Performance Monitor EBB exceptions are enabled.

```
E:Save state           // This is the entry pt
mfspr r1, BESCR       // Check event status
if r163=1, then
  Process PM exception
  r2 ← 0x0000 0000 0000 0001
  mtspr BESCRr, r2    //Reset PMEO status bit
  r2 ← 0x0000 0001 0000 0000
  mtspr BESCRs, r1    //Re-enable PM exceptions
                      //Note: The PMAE bit of MMCR0 must also
                      //      be enabled. See Book III.
if r162=1, then
  Process external exception
  r2 ← 0x0000 0000 0000 0002
  mtspr BESCRr, r2    //Reset EEO status bit
  r2 ← 0x0000 0002 0000 0000
                      // De-activate external EBB
                      //      input from platform
  mtspr BESCRs, r1    //Re-enable external EBB
                      //      exceptions
                      // . . .
                      //Other exceptions
                      //are processed similarly.
                      // . . .

Restore state
rfebb 1               // return & global enable
```

Note that before resetting the  $BESCR_{EEO}$ , the external EBB input from the platform should be deactivated, and additional operations to manage the external EBB input may be required. See the system documentation for details.

In the above sequence, if other exceptions occur after they are enabled, another event-based branch will occur immediately after *rfebb* is executed.

## Chapter 7. Branch History Rolling Buffer

The Branch History Rolling Buffer (BHRB) is a buffer containing an implementation-dependent number of entries, referred to as BHRB Entries (BHRBEs), that contain information related to branches that have been taken. Entries are numbered from 0 through  $n$ , where  $n$  is implementation-dependent but no more than 1023. Entry 0 is the most-recently written entry. The BHRB is read by means of the *mfbhrbe* instruction.

System software typically controls the availability of the BHRB as well as the number of entries that it contains. If the BHRB is accessed when it is unavailable, the system facility unavailable error handler is invoked.

Various events or actions by the system software may result in the BHRB occasionally being cleared. If BHRB entries are read after this has occurred, 0s will be returned. See the description of the *mfbhrbe* instruction for additional information.

The BHRB is typically used in conjunction with Performance Monitor event-based branches. (See Chapter 6 of Book II.) When used in conjunction with this facility,  $BESCR_{PME}$  is set to 1 to enable Performance Monitor event-based exceptions, and Performance Monitor alerts are enabled to enable the writing of BHRB entries. When a Performance Monitor alert occurs, Performance Monitor alerts are disabled, BHRB entries are no longer written, and an event-based branch occurs. (See Chapter 11 of Book III for additional information on the Performance Monitor.) The event-based branch handler can then access the contents of the BHRB for analysis.

When the BHRB is written by hardware, only those *Branch* instructions that meet the filtering criteria are written. See Section 11.4.7 of Book III.

The following paragraphs describe the entries written into the BHRB for various types of *Branch* instructions for which the branch was taken. In some circumstances, however, the hardware may be unable to make the entry even though the following paragraphs require it. In such cases, the hardware sets the EA field to 0, and indicates any missed entries using the T and P fields. (See Section 7.1.)

When an I-form or B-form *Branch* instruction is entered into the BHRB, bits 0:61 of the effective address of the *Branch* instruction are written into the next available entry, except that the entry may or may not be written in the following cases.

- The effective address of the branch target exceeds the effective address of the *Branch* instruction by 4.
- The instruction is a B-form *Branch*, the effective address of the branch target exceeds the effective address of the *Branch* instruction by 8, and the instruction immediately following the *Branch* instruction is not another *Branch* instruction.

The determination of whether the effective address of the branch target exceeds the effective address of the *Branch* instruction by 4 or 8 is made modulo  $2^{64}$ .

### Programming Note

The cases described above, for which the BHRBE need not be written, are cases for which some implementations may optimize the execution of the *Branch* instruction (first case) or of the *Branch* instruction and the following instruction (second case) in a manner that makes writing the BHRBE difficult. Such implementations may provide a means by which system software can disable these optimizations, thereby ensuring that the corresponding BHRBEs are written normally.

When an XL-form *Branch* instruction is entered into the BHRB, bits 0:61 of the effective address of the *Branch* instruction are written into the next available entry if allowed by the filtering mode; subsequently, bits 0:61 of the effective address of the branch target are written into the following entry.

## 7.1 Branch History Rolling Buffer Entry Format

Branch History Rolling Buffer Entries (BHRBEs) have the following format.

**Figure 11. Branch History Rolling Buffer Entry**

### 0:61 Effective Address (EA)

When this field is set to a non-zero value, it contains bits 0:61 of the effective address of the instruction indicated by the T field; otherwise this field indicates that the entry is a marker with the meaning specified by the T and P fields.

When the EA field contains a non-zero value, bits 62:63 have the following meanings.

### 62 Target Address (T)

- 0 The EA field contains bits 0:61 of the effective address of a *Branch* instruction for which the branch was taken.
- 1 The EA field contains bits 0:61 of the branch effective address of the branch target of an XL-form *Branch* instruction for which the branch was taken.

### 63 Prediction (P)

When T=0, this field has the following meaning.

- 0 The outcome of the *Branch* instruction was correctly predicted.
- 1 The outcome of the *Branch* instruction was mispredicted.

When T=1, this field has the following meaning.

- 0 The *Branch* instruction was predicted to be taken and the target address was predicted correctly, or the target address was not predicted because the branch was predicted to be not taken.
- 1 The target address was mispredicted.

When the EA field contains a zero value, bits 62:63 specify the type of marker as described below.

#### Programming Note

It is expected that programs will not contain *Branch* instructions with instruction or target effective address equal to 0. If such instructions exist, programs cannot distinguish between entries that are markers and entries that correspond to instructions with instruction or target effective address 0.

### Value Meaning

- 00 This entry either is not implemented or has been cleared. There are no valid entries beyond the current entry.
- 01-11 Reserved.

## 7.2 Branch History Rolling Buffer Instructions

The Branch History Rolling Buffer instructions enable application programs to clear and read the BHRB. The availability of these instructions is controlled by the system software. (See Chapter 11 of Book III.) When an attempt is made to execute these instructions when

they are unavailable, the system facility unavailable error handler is invoked.

### Clear BHRB X-form

`clrbhrb`

31	///	///	///	430	/
0	6	11	16	21	31

for  $n = 0$  to  $(\text{number\_of\_BHRBEs implemented} - 1)$   
 $\text{BHRB}(n) \leftarrow 0$

All BHRB entries are set to 0s.

#### Special Registers Altered:

None.

### Move From Branch History Rolling Buffer Entry XFX-form

`mfbhrbe RT,BHRBE`

31	RT	BHRBE	302	/
0	6	11	21	31

$n \leftarrow \text{BHRBE}_0:9$   
 If  $n < \text{number of BHRBEs implemented}$  then  
 $\text{RT} \leftarrow \text{BHRBE}(n)$   
 else  
 $\text{RT} \leftarrow 64_0$

The BHRBE field denotes an entry in the BHRB. If the designated entry is within the range of BHRB entries implemented and Performance Monitor alerts are disable (see Section 11.5 of Book III), the contents of the designated BHRB entry are placed into register RT; otherwise, zero is placed into register RT.

In order to ensure that the current BHRB contents are read by this instruction, one of the following must have occurred prior to this instruction and after all previous *Branch* and *clrbhrb* instructions have completed.

- an event-based branch has occurred
- an *rfebb* (see Chapter 6 of Book II) has been executed
- a context synchronizing event (see Section 1.5 of Book III) other than *isync* (see Section 4.6.1 of Book II) has occurred.

#### Special Registers Altered:

None

#### Programming Note

In order to read all the BHRB entries containing information about taken branches, software should read the entries starting from entry number 0 and continuing until an entry containing all 0s is read or until all implemented BHRB entries have been read.

Since the number of BHRB entries may decrease or the BHRB may be cleared at any time, if a given entry,  $m$ , is read as not containing all 0s and is read again subsequently, the subsequent read may return all 0s even though the program has not executed *clrbhrb*.

## Appendix A. Assembler Extended Mnemonics

In order to make assembler language programs simpler to write and easier to understand, a set of extended mnemonics and symbols is provided for certain instructions. This appendix defines extended mnemonics and

symbols related to instructions defined in Book II. Assemblers should provide the extended mnemonics and symbols listed here, and may provide others.

### A.1 Data Cache Block Touch [for Store] Mnemonics

The TH field in the *Data Cache Block Touch* and *Data Cache Block Touch for Store* instructions control the actions performed by the instructions. Extended mnemonics are provided that represent the TH value in the mnemonic rather than requiring it to be coded as a numeric operand.

dcbtct RA, RB, TH	(equivalent to: dcbt for TH values of 0b00000 - 0b00111); other TH values are invalid.
dcbtds RA, RB, TH	(equivalent to: dcbt for TH values of 0b00000 or 0b01000 - 0b01111); other TH values are invalid.
dcbtt RA, RB	(equivalent to: dcbt for TH value of 0b10000)
dcbna RA, RB	(equivalent to: dcbt for TH value of 0b10001)
dcbtstct RA, RB, TH	(equivalent to: dcbtst for TH values of 0b00000 or 0b00000 - 0b00111); other TH values are invalid.
dcbtstds RA, RB, TH	(equivalent to: dcbtst for TH values of 0b00000 or 0b01000 - 0b01111); other TH values are invalid.
dcbtstt RA, RB	(equivalent to: dcbtst for TH value of 0b10000)

### A.2 Data Cache Block Flush Mnemonics

The L field in the *Data Cache Block Flush* instruction controls the scope of the flush function performed by the instruction, or the scope of the store function when L=6. Extended mnemonics are provided that represent

the L value in the mnemonic rather than requiring it to be coded as a numeric operand.

**Note:** *dcbf* serves as both a basic and an extended mnemonic. The Assembler will recognize a *dcbf* mnemonic with three operands as the basic form, and a *dcbf* mnemonic with two operands as the extended form. In the extended form the L operand is omitted and assumed to be 0.

dcbf RA, RB	(equivalent to: dcbf RA, RB, 0)
dcbfl RA, RB	(equivalent to: dcbf RA, RB, 1)
dcbflp RA, RB	(equivalent to: dcbf RA, RB, 3)
dcbfps RA, RB	(equivalent to: dcbf RA, RB, 4)
dcbstps RA, RB	(equivalent to: dcbf RA, RB, 6)

### A.3 Or Mnemonics

The three register fields in the *or* instruction can be used to specify a hint indicating how the processor should handle stores caused by previous *Store* or *dcbz* instructions. An extended mnemonic is supported that represents the operand values in the mnemonic rather than requiring them to be coded as numeric operands.

miso	(equivalent to: or 26, 26, 26)
------	--------------------------------

### A.4 Load And Reserve Mnemonics

The EH field in the *Load And Reserve* instructions provides a hint regarding the type of algorithm implemented by the instruction sequence being executed. Extended mnemonics are provided that allow the EH value to be omitted and assumed to be 0b0.

**Note:** *lbarx*, *lharx*, *lwarx*, *ldarx*, and *lqarx* serve as both basic and extended mnemonics. The Assembler will recognize these mnemonics with four operands as the basic form, and these mnemonics with three oper-

ands as the extended form. In the extended form the EH operand is omitted and assumed to be 0.

lbarx RT,RA,RB (equivalent to: lbarx RT,RA,RB,0)  
 lharx RT,RA,RB (equivalent to: lharx RT,RA,RB,0)  
 lwarx RT,RA,RB (equivalent to: lwarx RT,RA,RB,0)  
 ldarx RT,RA,RB (equivalent to: ldarx RT,RA,RB,0)  
 lqarx RT,RA,RB (equivalent to: lqarx RT,RA,RB,0)

## A.5 Synchronize Mnemonics

The L and SC fields in the *Synchronize* instruction control the scope of the synchronization function performed by the instruction. Extended mnemonics are provided that represent the L and SC values in the mnemonic rather than requiring them to be coded as numeric operands.

**Note:** *sync* serves as both a basic and an extended mnemonic. The Assembler will recognize a *sync* mnemonic with two operands as the basic form, and a *sync* mnemonic with one operand or with no operand as an extended form. In the extended form with one operand the SC operand is omitted and assumed to be 0. In the extended form with no operand the L and SC operands are omitted and assumed to be 0.

sync	(equivalent to: sync 0,0)
sync x	(equivalent to: sync x,0)
hwsync	(equivalent to: sync 0,0)
lwsync	(equivalent to: sync 1,0)
ptesync	(equivalent to: sync 2,0)
phwsync	(equivalent to: sync 4,0)
plwsync	(equivalent to: sync 5,0)
stncisync	(equivalent to: sync 1,1)
stcisync	(equivalent to: sync 0,2)
stsync	(equivalent to: sync 0,3)

## A.6 Wait Mnemonics

The WC field in the *wait* instruction determines the conditions under which instruction execution resumes. Extended mnemonics are provided that represent the WC and PL values in the mnemonic rather than requiring them to be coded as numeric operands.

**Note:** *wait* serves as both a basic and an extended mnemonic. The Assembler will recognize a *wait* mnemonic with two operands as the basic form and a *wait* mnemonic with one operand or with no operand as an extended form. In the extended form with one operand the PL operand is omitted and assumed to be 0. In the extended form with no operand the WC and PL operands are omitted and assumed to be 0.

wait	(equivalent to: wait 0,0)
waitrsv	(equivalent to: wait 1,0)
pause_short	(equivalent to: wait 2,0)

## A.7 Move To/From Time Base Mnemonics

The tbr field in the *Move From Time Base* instruction specifies whether the instruction reads the entire Time Base or only the high-order half of the Time Base.

mftb Rx	(equivalent to: mftb Rx,268) or: mfspr Rx,268
mftbu Rx	(equivalent to: mftb Rx,269) or: mfspr Rx,269

## A.8 Return From Event-Based Branch Mnemonic

The S field in the *Return from Event-Based Branch* instruction specifies the value to which the instruction sets the GE field in the BESCR. Extended mnemonics are provided that represent the S value in the mnemonic rather than requiring it to be coded as a numeric operand.

rfebb	(equivalent to: rfebb 1)
-------	--------------------------

**Note:** *rfebb* serves as both a basic and an extended mnemonic. The Assembler will recognize this mnemonic with one operand as the basic form, and this mnemonic with no operands as the extended form. In the extended form the S operand is omitted and assumed to be 1.

## Appendix B. Programming Examples for Sharing Storage

This appendix gives examples of how dependencies and the *Synchronization* instructions can be used to control storage access ordering when storage is shared between programs.

Many of the examples use extended mnemonics (e.g., ***bne***, ***bne-***, ***cmpw***) that are defined in Appendix C of Book I.

Many of the examples use the *Load And Reserve* and *Store Conditional* instructions, in a sequence that begins with a *Load And Reserve* instruction and ends with a *Store Conditional* instruction (specifying the same storage location as the *Load Conditional*) followed by a *Branch Conditional* instruction that tests whether the *Store Conditional* instruction succeeded.

In these examples it is assumed that contention for the shared resource is low; the conditional branches are optimized for this case by using “+” and “-” suffixes appropriately.

The examples deal with words; they can be used for doublewords by changing all word-specific mnemonics to the corresponding doubleword-specific mnemonics (e.g., ***lwarx*** to ***ldarx***, ***cmpw*** to ***cmpd***).

In this appendix it is assumed that all shared storage locations are in storage that is Memory Coherence Required, and that the storage locations specified by *Load And Reserve* and *Store Conditional* instructions are in storage that is neither Write Through Required nor Caching Inhibited.

### B.1 Atomic Update Primitives

This section gives examples of how the *Load And Reserve* and *Store Conditional* instructions can be used to emulate atomic read/modify/write operations.

An atomic read/modify/write operation reads a storage location and writes its next value, which may be a function of its current value, all as a single atomic operation. The examples shown provide the effect of an atomic read/modify/write operation, but use several instructions rather than a single atomic instruction.

#### Fetch and No-op

The “Fetch and No-op” primitive atomically loads the current value in a word in storage.

In this example it is assumed that the address of the word to be loaded is in GPR 3 and the data loaded are returned in GPR 4.

```
loop:
  lwarx  r4,0,r3 #load and reserve
  stwcx. r4,0,r3 #store old value if
           # still reserved
  bne-  loop    #loop if lost reservation
```

Note:

1. The ***stwcx.***, if it succeeds, stores to the target location the same value that was loaded by the preceding ***lwarx.*** While the store is redundant with respect to the value in the location, its success ensures that the value loaded by the ***lwarx*** is still the current value at the time the ***stwcx.*** is executed.

#### Fetch and Store

The “Fetch and Store” primitive atomically loads and replaces a word in storage.

In this example it is assumed that the address of the word to be loaded and replaced is in GPR 3, the new value is in GPR 4, and the old value is returned in GPR 5.

```
loop:
  lwarx  r5,0,r3 #load and reserve
  stwcx. r4,0,r3 #store new value if
           # still reserved
  bne-  loop    loop if lost reservation
```

## Fetch and Add

The “Fetch and Add” primitive atomically increments a word in storage.

In this example it is assumed that the address of the word to be incremented is in GPR 3, the increment is in GPR 4, and the old value is returned in GPR 5.

```
loop:
  lwarx  r5,0,r3 #load and reserve
  add    r0,r4,r5#increment word
  stwcx. r0,0,r3 #store new value if still res'ved
  bne-   loop   #loop if lost reservation
```

## Fetch and AND

The “Fetch and AND” primitive atomically ANDs a value into a word in storage.

In this example it is assumed that the address of the word to be ANDed is in GPR 3, the value to AND into it is in GPR 4, and the old value is returned in GPR 5.

```
loop:
  lwarx  r5,0,r3 #load and reserve
  and    r0,r4,r5#AND word
  stwcx. r0,0,r3 #store new value if still res'ved
  bne-   loop   #loop if lost reservation
```

Note:

1. The sequence given above can be changed to perform another Boolean operation atomically on a word in storage, simply by changing the **and** instruction to the desired Boolean instruction (**or**, **xor**, etc.).

## Test and Set

This version of the “Test and Set” primitive atomically loads a word from storage, sets the word in storage to a nonzero value if the value loaded is zero, and sets the EQ bit of CR Field 0 to indicate whether the value loaded is zero.

In this example it is assumed that the address of the word to be tested is in GPR 3, the new value (nonzero) is in GPR 4, and the old value is returned in GPR 5.

```
loop:
  lwarx  r5,0,r3 #load and reserve
  cmpwi  r5,0    #done if word not equal to 0
  bne-   exit
  stwcx. r4,0,r3 #try to store non-0
  bne-   loop   #loop if lost reservation
exit: ...
```

## Compare and Swap

The “Compare and Swap” primitive atomically compares a value in a register with a word in storage, if they are equal stores the value from a second register into the word in storage, if they are unequal loads the word from storage into the first register, and sets the EQ bit of CR Field 0 to indicate the result of the comparison.

In this example it is assumed that the address of the word to be tested is in GPR 3, the comparand is in GPR 4 and the old value is returned there, and the new value is in GPR 5.

```
loop:
  lwarx  r6,0,r3 #load and reserve
  cmpw   r4,r6   #1st 2 operands equal?
  bne-   exit    #skip if not
  stwcx. r5,0,r3 #store new value if still res'ved
  bne-   loop    #loop if lost reservation
exit:
  mr     r4,r6   #return value from storage
```

Notes:

1. The semantics given for “Compare and Swap” above are based on those of the IBM System/370 Compare and Swap instruction. Other architectures may define a Compare and Swap instruction differently.
2. “Compare and Swap” is shown primarily for pedagogical reasons. It is useful on machines that lack the better synchronization facilities provided by **lwarx** and **stwcx.** A major weakness of a System/370-style Compare and Swap instruction is that, although the instruction itself is atomic, it checks only that the old and current values of the word being tested are equal, with the result that programs that use such a Compare and Swap to control a shared resource can err if the word has been modified and the old value subsequently restored. The sequence shown above has the same weakness.
3. In some applications the second **bne-** instruction and/or the **mr** instruction can be omitted. The **bne-** is needed only if the application requires that if the EQ bit of CR Field 0 on exit indicates “not equal” then (r4) and (r6) are in fact not equal. The **mr** is needed only if the application requires that if the comparands are not equal then the word from storage is loaded into the register with which it was compared (rather than into a third register). If either or both of these instructions is omitted, the resulting Compare and Swap does not obey System/370 semantics.

## B.2 Lock Acquisition and Release, and Related Techniques

This section gives examples of how dependencies and the *Synchronization* instructions can be used to imple-

ment locks, import and export barriers, and similar constructs.

### B.2.1 Lock Acquisition and Import Barriers

An “import barrier” is an instruction or sequence of instructions that prevents storage accesses caused by instructions following the barrier from being performed before storage accesses that acquire a lock have been performed. An import barrier can be used to ensure that a shared data structure protected by a lock is not accessed until the lock has been acquired. A *sync* instruction can be used as an import barrier, but the approaches shown below will generally yield better performance because they order only the relevant storage accesses.

#### B.2.1.1 Acquire Lock and Import Shared Storage

If *lwarx* and *stwcx.* instructions are used to obtain the lock, an import barrier can be constructed by placing an *isync* instruction immediately following the loop containing the *lwarx* and *stwcx.*. The following example uses the “Compare and Swap” primitive to acquire the lock.

In this example it is assumed that the address of the lock is in GPR 3, the value indicating that the lock is free is in GPR 4, the value to which the lock should be set is in GPR 5, the old value of the lock is returned in GPR 6, and the address of the shared data structure is in GPR 9.

```
loop:
    lwarx  r6,0,r3,1 #load lock and reserve
    cmpw  r4,r6     #skip ahead if
    bne-  wait     # lock not free
    stwcx. r5,0,r3 #try to set lock
    bne-  loop     #loop if lost reservation
    isync                #import barrier
    lwz   r7,data1(r9)#load shared data
    .
wait...                #wait for lock to free
```

The hint provided with *lwarx* indicates that after the program acquires the lock variable (i.e., *stwcx.* is successful), it will release it (i.e., store to it) prior to another program attempting to modify it.

The second *bne-* does not complete until CR0 has been set by the *stwcx.*. The *stwcx.* does not set CR0 until it has completed (successfully or unsuccessfully). The lock is acquired when the *stwcx.* completes successfully. Together, the second *bne-* and the subse-

quent *isync* create an import barrier that prevents the load from “data1” from being performed until the branch has been resolved not to be taken.

If the shared data structure is in storage that is neither Write Through Required nor Caching Inhibited, an *lwsync* instruction can be used instead of the *isync* instruction. If *lwsync* is used, the load from “data1” may be performed before the *stwcx.*. But if the *stwcx.* fails, the second branch is taken and the *lwarx* is re-executed. If the *stwcx.* succeeds, the value returned by the load from “data1” is valid even if the load is performed before the *stwcx.*, because the *lwsync* ensures that the load is performed after the instance of the *lwarx* that created the reservation used by the successful *stwcx.*.

#### B.2.1.2 Obtain Pointer and Import Shared Storage

If *lwarx* and *stwcx.* instructions are used to obtain a pointer into a shared data structure, an import barrier is not needed if all the accesses to the shared data structure depend on the value obtained for the pointer. The following example uses the “Fetch and Add” primitive to obtain and increment the pointer.

In this example it is assumed that the address of the pointer is in GPR 3, the value to be added to the pointer is in GPR 4, and the old value of the pointer is returned in GPR 5.

```
loop:
    lwarx  r5,0,r3 #load pointer and reserve
    add   r0,r4,r5#increment the pointer
    stwcx. r0,0,r3 #try to store new value
    bne-  loop     #loop if lost reservation
    lwz   r7,data1(r5) #load shared data
```

The load from “data1” cannot be performed until the pointer value has been loaded into GPR 5 by the *lwarx*. The load from “data1” may be performed before the *stwcx.*. But if the *stwcx.* fails, the branch is taken and the value returned by the load from “data1” is discarded. If the *stwcx.* succeeds, the value returned by the load from “data1” is valid even if the load is performed before the *stwcx.*, because the load uses the pointer value returned by the instance of the *lwarx* that created the reservation used by the successful *stwcx.*.

An *isync* instruction could be placed between the *bne-* and the subsequent *lwz*, but no *isync* is needed if all accesses to the shared data structure depend on the value returned by the *lwarx*.

## B.2.2 Lock Release and Export Barriers

An “export barrier” is an instruction or sequence of instructions that prevents the store that releases a lock from being performed before stores caused by instructions preceding the barrier have been performed. An export barrier can be used to ensure that all stores to a shared data structure protected by a lock will be performed with respect to any other processor before the store that releases the lock is performed with respect to that processor.

### B.2.2.1 Export Shared Storage and Release Lock

A *sync* instruction can be used as an export barrier independent of the storage control attributes (e.g., presence or absence of the Caching Inhibited attribute) of the storage containing the shared data structure. Because the lock must be in storage that is neither Write Through Required nor Caching Inhibited, if the shared data structure is in storage that is Write Through Required or Caching Inhibited a *sync* instruction *must* be used as the export barrier.

In this example it is assumed that the shared data structure is in storage that is Caching Inhibited, the address of the lock is in GPR 3, the value indicating that the lock is free is in GPR 4, and the address of the shared data structure is in GPR 9.

```
stw    r7,data1(r9)#store shared data (last)
sync          #export barrier
stw    r4,lock(r3)#release lock
```

The *sync* ensures that the store that releases the lock will not be performed with respect to any other processor until all stores caused by instructions preceding the *sync* have been performed with respect to that processor.

### B.2.2.2 Export Shared Storage and Release Lock using *lwsync*

If the shared data structure is in storage that is neither Write Through Required nor Caching Inhibited, an *lwsync* instruction can be used as the export barrier. Using *lwsync* rather than *sync* will yield better performance in most systems.

In this example it is assumed that the shared data structure is in storage that is neither Write Through Required nor Caching Inhibited, the address of the lock is in GPR 3, the value indicating that the lock is free is in GPR 4, and the address of the shared data structure is in GPR 9.

```
stw    r7,data1(r9)#store shared data (last)
lwsync          #export barrier
stw    r4,lock(r3)#release lock
```

The *lwsync* ensures that the store that releases the lock will not be performed with respect to any other processor until all stores caused by instructions preceding the *lwsync* have been performed with respect to that processor.

## B.2.3 Safe Fetch

If a load must be performed before a subsequent store (e.g., the store that releases a lock protecting a shared data structure), a technique similar to the following can be used.

In this example it is assumed that the address of the storage operand to be loaded is in GPR 3, the contents of the storage operand are returned in GPR 4, and the address of the storage operand to be stored is in GPR 5.

```
lwz    r4,0(r3)#load shared data
cmpw   r4,r4    #set CR0 to "equal"
bne-   $-8     #branch never taken
stw    r7,0(r5)#store other shared data
```

An alternative is to use a technique similar to that described in Section B.2.1.2, by causing the *stw* to depend on the value returned by the *lwz* and omitting the *cmpw* and *bne-*. The dependency could be created by ANDing the value returned by the *lwz* with zero and then adding the result to the value to be stored by the *stw*. If both storage operands are in storage that is neither Write Through Required nor Caching Inhibited, another alternative is to replace the *cmpw* and *bne-* with an *lwsync* instruction.

## B.3 List Insertion

This section shows how the *lwarx* and *stwcx.* instructions can be used to implement simple insertion into a singly linked list. (Complicated list insertion, in which multiple values must be changed atomically, or in which the correct order of insertion depends on the contents of the elements, cannot be implemented in the manner shown below and requires a more complicated strategy such as using locks.)

The “next element pointer” from the list element after which the new element is to be inserted, here called the “parent element”, is stored into the new element, so that the new element points to the next element in the list; this store is performed unconditionally. Then the address of the new element is conditionally stored into the parent element, thereby adding the new element to the list.

In this example it is assumed that the address of the parent element is in GPR 3, the address of the new element is in GPR 4, and the next element pointer is at offset 0 from the start of the element. It is also assumed that the next element pointer of each list element is in a reservation granule separate from that of the next element pointer of all other list elements.

```
loop:
    lwarx r2,0,r3 #get next pointer
    stw   r2,0(r4)#store in new element
    lwsync or sync #order stw before stwcx
    stwcx. r4,0,r3 #add new element to list
    bne-  loop   #loop if stwcx. failed
```

In the preceding example, if two list elements have next element pointers in the same reservation granule then, in a multiprocessor, “livelock” can occur. (Livelock is a state in which processors interact in a way such that no processor makes forward progress.)

If it is not possible to allocate list elements such that each element's next element pointer is in a different reservation granule, then livelock can be avoided by using the following, more complicated, sequence.

```
    lwz   r2,0(r3)#get next pointer
loop1:
    mr    r5,r2 #keep a copy
    stw   r2,0(r4)#store in new element
    sync          #order stw before stwcx.
                and before lwarx
loop2:
    lwarx r2,0,r3 #get it again
    cmpw  r2,r5 #loop if changed (someone
    bne-  loop1 # else progressed)
    stwcx. r4,0,r3 #add new element to list
    bne-  loop2 #loop if failed
```

In the preceding example, livelock is avoided by the fact that each processor re-executes the *stw* only if some other processor has made forward progress.

## B.4 Notes

The following notes apply to Section B.1 through Section B.3.

1. To increase the likelihood that forward progress is made, it is important that looping on *lwarx/stwcx.* pairs be minimized. For example, in the “Test and Set” sequence shown in Section B.1, this is achieved by testing the old value before attempting the store; were the order reversed, more *stwcx.* instructions might be executed, and reservations might more often be lost between the *lwarx* and the *stwcx.*
2. The manner in which *lwarx* and *stwcx.* are communicated to other processors and mechanisms, and between levels of the storage hierarchy within a given processor, is implementation-dependent. In some implementations performance may be improved by minimizing looping on a *lwarx* instruction that fails to return a desired value. For example, in the “Test and Set” sequence shown in Section B.1, if the programmer wishes to stay in the loop until the word loaded is zero, he could change the “bne- exit” to “bne- loop”. However, in some implementations better performance may be obtained by using an ordinary Load instruction to do the initial checking of the value, as follows.

```
loop:
    lwz   r5,0(r3)#load the word
    cmpwi r5,0 #loop back if word
    bne-  loop # not equal to 0
    lwarx r5,0,r3 #try again, reserving
    cmpwi r5,0 # (likely to succeed)
    bne-  loop
    stwcx.r4,0,r3 #try to store non-0
    bne-  loop #loop if lost reserv'n
```

3. In a multiprocessor, livelock is possible if there is a *Store* instruction (or any other instruction that can clear another processor's reservation; see Section 1.7.2.1) between the *lwarx* and the *stwcx.* of a *lwarx/stwcx.* loop and any byte of the storage location specified by the Store is in the reservation granule. For example, the first code sequence shown in Section B.3 can cause livelock if two list elements have next element pointers in the same reservation granule.

## **Book III:**

# **Power ISA Operating Environment Architecture**

# Chapter 1. Introduction

---

## 1.1 Overview

Chapter 1 of Book I describes computation modes, document conventions, a general systems overview, instruction formats, and storage addressing. This chapter augments that description as necessary for the Power ISA Operating Environment Architecture.

## 1.2 Document Conventions

The notation and terminology used in Book I apply to this Book also, with the following substitutions.

- For “system alignment error handler” substitute “Alignment interrupt”.
- For “system data storage error handler” substitute “Data Storage interrupt”, “Hypervisor Data Storage interrupt”, or “Data Segment interrupt”, as appropriate.
- For “system error handler” substitute “interrupt”.
- For “system floating-point enabled exception error handler” substitute “Floating-Point Enabled Exception type Program interrupt”.
- For “system illegal instruction error handler” substitute “Hypervisor Emulation Assistance interrupt”.
- For “system instruction storage error handler” substitute “Instruction Storage interrupt”, “Hypervisor Instruction Storage interrupt”, or “Instruction Segment interrupt”, as appropriate.
- For “system privileged instruction error handler” substitute “Privileged Instruction type Program interrupt”.
- For “system service program” substitute “System Call interrupt” or “System Call Vectored interrupt”, as appropriate.
- For “system trap handler” substitute “Trap type Program interrupt”.
- For “system facility unavailable error handler” substitute “Facility Unavailable interrupt” or “Hypervisor Facility Unavailable interrupt.”

## 1.2.1 Definitions and Notation

The definitions and notation given in Book I and Book II are augmented by the following.

### ■ Threaded processor, single-threaded processor, thread

A threaded processor implements one or more “threads”, where a thread corresponds to the Book I/II concept of “processor”. That is, the definition of “thread” is the same as the Book I definition of “processor”, and “processor” as used in Books I and II can be thought of as either a single-threaded processor or as one thread of a multi-threaded processor. Except where the meaning is clear in context or the number of threads does not matter, the only unqualified uses of “processor” in Book III are in resource names (e.g. Processor Identification Register); such uses should be regarded as meaning “threaded processor”. The threads of a multi-threaded processor typically share certain resources, such as the hardware components that execute certain kinds of instructions (e.g., Fixed-Point instructions), certain caches, the address translation mechanism, and certain hypervisor and ultravisor resources.

### ■ real page

A unit of real storage that is aligned at a boundary that is a multiple of its size. The real page size is 4KB.

### ■ context of a program

The state (e.g., privilege and relocation) in which the program executes. The context is controlled by the contents of certain System Registers, such as the MSR and PTCR, of certain lookaside buffers, such as the SLB and TLB, and of the Page Table.

### ■ performed

The definition of “performed” given in Section 1.1 of Book II is extended to apply to implicit storage accesses and to invalidations of entries in caches of information derived from address translation tables, as follows.

- The definition of “load is performed” applies to accesses for performing address translation.

- The definition of “store is performed” applies to accesses for recording reference and change information.
  - A TLB entry invalidation by thread T1 is performed with respect to thread T2 when the instruction that requested the invalidation has caused the specified entry, if present, to be made invalid in T2’s TLB, and similarly for invalidations of entries in other caches of information derived from tables used in address translation.
- **exception**  
An error, unusual condition, or external signal, that may set a status bit and may or may not cause an interrupt, depending upon whether the corresponding interrupt is enabled.
  - **interrupt**  
The act of changing the machine state in response to an exception, as described in Chapter 7. “Interrupts” on page 1261.
    - ultravisor interrupt  
An interrupt that forces the thread into ultravisor state by explicitly setting  $MSR_{S\ HV\ PR}$  to 0b110 (see Section 4.2.1).
    - hypervisor interrupt  
An interrupt that forces the thread into hypervisor state by explicitly setting  $MSR_{HV\ PR}$  to 0b10 and is not an ultravisor interrupt.
 All interrupts explicitly set  $MSR_{PR}$  to 0.
  - **trap interrupt**  
An interrupt that results from execution of a *Trap* instruction.
  - **“must”**  
If software that runs in hypervisor state violates a rule that is stated using the word “must” (e.g., “this field must be set to 0”), and the rule pertains to the contents of a hypervisor resource, to executing an instruction that can be executed only in hypervisor state, or to accessing storage in real addressing mode, the results are undefined, and may include altering resources belonging to other partitions, causing the system to “hang”, etc. The same is true for software that runs in ultravisor state and violates a “must” rule pertaining to an ultravisor resource or instruction.
  - **hardware**  
Any combination of hard-wired implementation, emulation assist, or interrupt for software assistance. In the last case, the interrupt may be to an architected location or to an implementation-dependent location. Any use of emulation assists or interrupts to implement the architecture is implementation-dependent.

- **ultravisor privileged**  
A term used to describe an instruction or facility that is available when and only when the thread is in ultravisor state.
- **hypervisor privileged**  
A term used to describe an instruction or facility that is available when and only when the thread is in hypervisor state.

#### Programming Note

Because ultravisor state is also a hypervisor state, hypervisor privileged instructions and facilities are also available when the thread is in ultravisor state. (The distinct privilege states in which a hypervisor privileged instruction or facility is available are: hypervisor non-ultravisor state, and ultravisor state.)

- **privileged**  
A term used to describe an instruction or facility that is available when and only when the thread is in privileged state.

#### Programming Note

Because hypervisor state is also a privileged state, privileged instructions and facilities are also available when the thread is in hypervisor state (and when the thread is in ultravisor state). (The distinct privilege states in which a privileged instruction or facility is available are: privileged non-hypervisor state, hypervisor non-ultravisor state, and ultravisor state.)

- **privileged state and supervisor mode**  
Used interchangeably to refer to a state in which privileged facilities are available.
- **problem state and user mode**  
Used interchangeably to refer to a state in which privileged facilities are not available.
- */, //, ///, ...* denotes a field that is reserved in an instruction, in a register, or in an architected storage table.
- *?, ??, ???, ...* denotes a field that is implementation-dependent in an instruction, in a register, or in an architected storage table.

## 1.2.2 Reserved Fields

Book I’s description of the handling of reserved bits in System Registers, and of reserved values of defined fields of System Registers, applies also to the SLB. Book I’s description of the handling of reserved values of defined fields of System Registers applies also to architected storage tables (e.g., the Page Table).

Software should set reserved fields in the SLB and in architected storage tables to zero, because these fields may be assigned a meaning in some future version of the architecture.

Some fields of certain architected storage tables may be written to automatically by the hardware, e.g., Reference and Change bits in the Page Table. When the hardware writes to such a table, the following rules are obeyed.

- Unless otherwise stated, no defined field other than the one(s) specifically being updated are modified.
- Contents of reserved fields are either preserved or written as zero.

### 1.2.3 Deviations from the Sequential Execution Model

Additional exceptions to the rule that the thread obeys the sequential execution model, beyond those described in Section 2.2 of Book I and in the bullet defining “program order” in Section 1.1 of Book II, are the following.

- A system-caused or imprecise interrupt may occur. In general, the determination of whether an instruction is required by the sequential execution model is not affected by the potential occurrence of a system-caused or imprecise interrupt. (The determination is affected by the potential occurrence of any other kind of interrupt.)

The only exceptions to the preceding statement are synchronous Machine Check interrupts, which occur at specific points in the program as if they were instruction-caused and precise, and imprecise Floating-Point Enabled Exception type Program interrupts, which can be forced to occur not later than specific points in the program (see Section 4.6.10 of Book I)

- A context-altering instruction is executed (Chapter 13. “Synchronization Requirements for Context Alterations” on page 1353). The context alteration need not take effect until the required subsequent synchronizing operation has occurred.
- A Reference and Change bit is updated by the thread. The update need not be performed with respect to that thread until the required subsequent synchronizing operation has occurred.
- A *Branch* instruction is executed and the branch is taken. The update of the Come-From Address Register (see Section 10.2 of Book III) need not occur until a subsequent context synchronizing operation has occurred.

- A *mtdexcr* or *mthdexcr* is executed. The execution behavior change described by aspect 0 may not take effect for an indefinite length of time. The execution behavior change described by aspects 3 and 4 need not take effect until the required subsequent synchronization operation has occurred (Chapter 13 of Book III).

### 1.2.4 Restricting Out-of-Order Execution

Because some classes of security exploits use side-effects of out-of-order execution to infer behavior of or receive information from programs, it may sometimes be necessary to limit out-of-order execution beyond what's necessary to maintain the appearance of compliance with the sequential execution model. This may include restrictions on the otherwise-permitted deviations from the sequential execution model described in Section 1.2.3 and Section 6.5. The *Or Immediate* instruction described in Section 9.2.1 can be used to create a barrier to out-of-order execution.

## 1.3 General Systems Overview

The hardware contains the sequencing and processing controls for instruction fetch, instruction execution, and interrupt action. Most implementations also contain data and instruction caches. Instructions that the processing unit can execute fall into the following classes:

- instructions executed in the Branch Facility
- instructions executed in the Fixed-Point Facility
- instructions executed in the Floating-Point Facility
- instructions executed in the Vector Facility

Almost all instructions executed in the Branch Facility, Fixed-Point Facility, Floating-Point Facility, and Vector Facility are nonprivileged and are described in Book I. Book II may describe additional nonprivileged instructions (e.g., Book II describes some nonprivileged instructions for cache management). Instructions related to the privileged state, control of hardware resources, control of the storage hierarchy, and all other privileged instructions are described here or are implementation-dependent.

## 1.4 Exceptions

The following augments the exceptions defined in Book I that can be caused directly by the execution of an instruction:

- the execution of a floating-point instruction when  $MSR_{FP}=0$  (Floating-Point Unavailable interrupt)
- an attempt to modify a hypervisor resource when the thread is in privileged but non-hypervisor state (see Chapter 2), or an attempt to execute a hyper-

visor-only instruction (e.g., *tlbie*) when the thread is in privileged but non-hypervisor state

- an attempt to modify an ultravisor resource when the thread is in privileged but non-ultravisor state (see Chapter 3), or an attempt to execute an ultravisor-only instruction (e.g., *urfid*, *msgsndu*, *msgclru*) when the thread is in privileged but non-ultravisor state
- the execution of a traced instruction (Trace interrupt)
- the execution of a Vector instruction when the vector facility is unavailable (Vector Unavailable interrupt)

tions be discarded and that any effects and side effects of executing them out-of-order also be discarded, except as described in Section 6.5, “Performing Operations Out-of-Order”.)

#### Programming Note

A context synchronizing operation is necessarily execution synchronizing; see Section 1.5.2.

Unlike the *Synchronize* instruction, a context synchronizing operation does not affect the order in which storage accesses are performed.

Item 2 permits a choice only for *isync* (and *[p]hwsync* and *ptesync*; see Section 1.5.2) because all other execution synchronizing operations also alter context.

## 1.5 Synchronization

The synchronization described in this section refers to the state of the thread that is performing the synchronization.

### 1.5.1 Context Synchronization

An instruction or event is *context synchronizing* if it satisfies the requirements listed below. Such instructions and events are collectively called *context synchronizing operations*. The context synchronizing operations are the *isync* instruction, the *System Linkage* instructions, the *mtmsr[d]* instructions with L=0, and most interrupts (see Section 7.3).

1. The operation causes instruction dispatching (the issuance of instructions by the instruction fetching mechanism to any instruction execution mechanism) to be halted.
2. The operation is not initiated or, in the case of *isync*, does not complete, until all instructions that precede the operation have completed to a point at which they have reported all exceptions they will cause.
3. The operation ensures that the instructions that precede the operation will complete execution in the context (privilege, relocation, storage protection, etc.) in which they were initiated, except that the operation has no effect on the context in which the associated Reference and Change bit updates are performed.
4. If the operation directly causes an interrupt (e.g., *sc* directly causes a System Call interrupt) or is an interrupt, the operation is not initiated until no exception exists having higher priority than the exception associated with the interrupt (see Section 7.9).
5. The operation ensures that the instructions that follow the operation will be fetched and executed in the context established by the operation. (This requirement dictates that any prefetched instruc-

## 1.5.2 Execution Synchronization

An instruction is *execution synchronizing* if it satisfies items 2 and 3 of the definition of context synchronization (see Section 1.5.1). **[p]hwsync** and **ptesync** are treated like **isync** with respect to item 2. The execution synchronizing instructions are **[p]hwsync**, **ptesync**, the **mtmsr[d]** instructions with L=1, and all context synchronizing instructions.

### Programming Note

Unlike a context synchronizing operation, an execution synchronizing instruction does not ensure that the instructions following that instruction will execute in the context established by that instruction. This new context becomes effective sometime after the execution synchronizing instruction completes and before or at a subsequent context synchronizing operation.

## Chapter 2. Logical Partitioning (LPAR) and Thread Control

### 2.1 Overview

The Logical Partitioning (LPAR) facility permits threads and portions of real storage to be assigned to logical collections called *partitions*, such that a program executing on a thread in one partition cannot interfere with any program executing on a thread in a different partition. This isolation can be provided for both problem state and privileged non-hypervisor state programs, by using a layer of trusted software, called a *hypervisor* program (or simply a “hypervisor”), and the resources provided by this facility to manage system resources. (A hypervisor is a program that runs in hypervisor state; see below.)

The number of partitions supported is implementation-dependent.

A thread is assigned to one partition at any given time. A thread can be assigned to any given partition without consideration of the physical configuration of the system (e.g., shared registers, caches, organization of the storage hierarchy), except that threads that share certain hypervisor resources may need to be assigned to the same partition; see Section 2.6. The registers and facilities used to control Logical Partitioning are listed below and described in the following subsections.

Except in the following subsections, references to the “operating system” in this document include the hypervisor unless otherwise stated or obvious from context.

### 2.2 Logical Partitioning Control Register (LPCR)

The contents of the LPCR control a number of aspects of the operation of the thread with respect to a logical partition. Below are shown the bit definitions for the LPCR.

Bit	Description
0:3	<b>Virtualization Control</b> (VC)  Controls the virtualization of partition memory for partitions that use HPT translation. This field contains three subfields, VPM, ISL, and

KBV. Accesses that are initiated in hypervisor state (i.e.,  $MSR_{HV} PR=0b10$ ) are performed as if  $VPM=0$  and  $KBV=0$ . (ISL applies regardless of privilege.)

0 Reserved

#### 1 **Virtualized Partition Memory** (VPM)

Controls whether VPM mode is enabled when address translation is enabled as specified below.

- 0 - VPM mode disabled
- 1 - VPM mode enabled

When address translation is disabled, VPM mode is enabled. See Section 6.7.2, “Virtualized Partition Memory (VPM) Mode”, and Section 6.7.3.3, “Virtual Real Mode Addressing Mechanism”, for additional information on VPM mode.

#### Programming Note

VPM must be set to zero by hypervisors that use HPT translation and want to receive storage interrupts from applications running directly under them as DSIs and ISIs (instead of HDSIs and HISIs).

#### 2 **Ignore SLB Large Page Specification** (ISL)

Controls whether ISL mode is enabled as specified below.

- 0 - ISL mode disabled
- 1 - ISL mode enabled

When ISL mode is enabled and address translation is enabled, address translation is performed as if the contents of  $SLB_{LJLP}$  and  $PRTE_{STPS}$  were 0b000. When address translation is disabled, the setting of the ISL bit has no effect. ISL mode has no effect on SLB, TLB, and ERAT entry invalidations

caused by *slibe*, *slibeg*, *sliba*, *slibag*, *tlbie*, and *tlbiel*.

**Programming Note**

Specifying that L||LP=0b000 in PATE<sub>PS</sub> has the same effect on address translation when translation is disabled as enabling ISL mode when translation is enabled.

ISL mode is needed when a partition is running with address translation enabled because translation uses the SLB, and the contents of the SLB are controlled by the operating system and should not be modified by the hypervisor. ISL mode is not needed when a partition is running with address translation disabled since Virtual Real Mode address translation uses PATE<sub>PS</sub>, which is not visible to the operating system and is in complete control of the hypervisor.

Any PTE with a base page size of 4K satisfies the page size portion of the match criteria for HPT search.

**3 Key-Based Virtualization (KBV)**

Controls whether Key-Based Virtualization is enabled as specified below.

- 0 - KBV is disabled
- 1 - KBV is enabled

When KBV is enabled and MSR<sub>HV||PR</sub>≠0b10, Virtual Page Class Key Storage Protection exceptions that occur on storage operand accesses when VPM=0 cause Hypervisor Data Storage interrupts.

**Programming Note**

Key-Based Virtualization provides an efficient means for the hypervisor to intercept storage references, e.g. MMIO, that must be emulated. (The corresponding behavior for instruction fetching is not desired.) Virtual Page Class Key Storage Protection exceptions not handled by the hypervisor should be reflected to the operating system at its Data Storage interrupt vector with the hypervisor having set DSISR<sub>42</sub>.

4:8 Reserved

9:11 **Default Prefetch Depth (DPFD)**

The DPFD field is used as the default prefetch depth for data stream prefetching when DSCR<sub>DPFD</sub>=0; see page 1064.

12:16 Reserved

17:19 **Power-saving mode Exit Cause Enable (Upper Section) (PECE<sub>U</sub>)**

17 **Hypervisor Virtualization Exit Enable**

- 0 When the **stop** instruction is executed with PSSCR<sub>EC</sub>=1, Hypervisor Virtualization exceptions are not enabled to cause exit from power-saving mode.
- 1 When the **stop** instruction is executed with PSSCR<sub>EC</sub>=1, Hypervisor Virtualization exceptions are enabled to cause exit from power-saving mode.

18:19 Reserved

20:36 Reserved

37 **Hypervisor Alternate Interrupt Location (HAIL)**

Controls the effective address offset, or alternate effective address for System Call Vectored, of the interrupt handler and the relocation mode in which it begins execution for all interrupts received in hypervisor state except those subject to the overrides described below.

- 0 The interrupt is taken with MSR<sub>IR DR</sub> = 0b00 and no effective address offset or alternate effective address.
- 1 The interrupt is taken with MSR<sub>IR DR</sub> = 0b11. If the interrupt is not System Call Vectored, an effective address offset of 0xc000\_0000\_0000\_4000 is applied. System Call Vectored uses an alternate effective address of 0xc000\_0000\_0000\_3||LEV||0b0\_0000.

The overrides mentioned above are as follows. The list should be read from the top down; the first item matching a given situation applies.

- If the interrupt is received in ultravisor state, the interrupt is taken as if LPCR<sub>HAIL</sub>=0.
- Machine Check, System Reset, and Hypervisor Maintenance interrupts are taken as if LPCR<sub>HAIL</sub>=0.
- If the interrupt occurs when MSR<sub>HV</sub>=1 and either MSR<sub>IR</sub>=0 or MSR<sub>DR</sub>=0, the interrupt is taken as if LPCR<sub>HAIL</sub>=0.

38 **Interrupt Little-Endian (ILE)**

The contents of the ILE bit are copied into MSR<sub>LE</sub> by interrupts that set MSR<sub>HV</sub> to 0 (see

Section 7.5), to establish the Endian mode for the interrupt handler.

#### 39:40 **Alternate Interrupt Location (AIL)**

Controls the effective address offset, or alternate effective address for System Call Vectored, of the interrupt handler and the relocation mode in which it begins execution for all interrupts received in privileged non-hypervisor state except those subject to the overrides described below.

- 0 The interrupt is taken with  $MSR_{IR\ DR} = 0b00$  and no effective address offset or alternate effective address.
- 1 Reserved
- 2 Reserved
- 3 The interrupt is taken with  $MSR_{IR\ DR} = 0b11$ . If the interrupt is not System Call Vectored, an effective address offset of  $0xc000_0000_0000_4000$  is applied. System Call Vectored uses an alternate effective address of  $0xc000_0000_0000_3 \parallel LEV \parallel 0b0_0000$ .

The overrides mentioned above are as follows. The list should be read from the top down; the first item matching a given situation applies.

- If the interrupt occurs when  $MSR_{IR}=0$  or  $MSR_{DR}=0$ , the interrupt is taken as if  $LPCR_{AIL}=0$ .
- 

#### 41 **Use Process Table (UPRT)**

Controls whether Process Tables are used. For a radix-using partition, UPRT must be set to 1; UPRT=0 when HR=1 is an unsupported MMU configuration and causes a Hypervisor Data Storage or Hypervisor Instruction Storage interrupt (see Section 7.5.16 and Section 7.5.17). For a paravirtualized HPT partition, UPRT is set to 1 when the operating system does not require the use of the legacy software-managed SLB.

- 0 Process Table is not used. (Software-managed SLB in use, for paravirtualized HPT partition.)
- 1 Process Table is used. (Segment Table in use, for paravirtualized HPT partition.)

#### **Programming Note**

The POWER9 processor operates as though  $LPCR_{UPRT}=0$  for partitions that use HPT translation, requiring operating systems to fully manage the SLB in software. Nonetheless, operating systems may need to maintain segment tables for use by accelerators.

#### 42 **Enhanced Virtualization (EVIRT)**

Controls whether Enhanced Virtualization is enabled, as specified below.

- 0 Enhanced Virtualization is disabled: attempts to execute hypervisor-privileged instructions or access hypervisor resources, or PTCR, DAWRn, DAWRXn, or CIABR when they are ultravisor resources, in privileged non-hypervisor state cause a Privileged Instruction type Program interrupt; attempts to access undefined SPR numbers (using **mtspr** or **mfpsr**) other than 0, 4, 5, and 6 in privileged state are treated as no-ops.
- 1 Enhanced Virtualization is enabled: attempts to execute hypervisor-privileged instructions or access hypervisor resources, or PTCR, DAWRn, DAWRXn, or CIABR when they are ultravisor resources, in privileged non-hypervisor state cause a Hypervisor Emulation Assistance interrupt; attempts to access undefined SPR numbers (using **mtspr** or **mfpsr**) other than 0, 4, 5, and 6 in privileged state cause a Hypervisor Emulation Assistance interrupt.

#### **Programming Note**

Running with  $LPCR_{EVIRT}=1$  facilitates support of nested hypervisors (hypervisors that run with  $MSR_{HV\ PR}=0b00$  and have their use of hypervisor resources virtualized by a higher level hypervisor); see the relevant Programming Note in Section 7.5.18, "Hypervisor Emulation Assistance Interrupt". It also permits emulation of new SPRs on designs that do not support them in hardware.

All accesses to the reserved noop SPRs (808-811) are always treated as noops, independent of the value of EVIRT.

#### 43 **Host Radix (HR)**

Indicates whether the hypervisor uses Radix Tree translation for the partition, as specified below.

- 0 hypervisor uses HPT translation for this partition.

- 1 hypervisor uses Radix Tree translation for this partition.

The hypervisor must program HR to match the Host Radix bit in the Partition Table Entry for the partition indicated by LPIDR. If the values do not match and the thread is not in hypervisor real addressing mode or ultravisor real addressing mode, the results are undefined.

#### Programming Note

HR is duplicated in the LPCR because there are times such as immediately after a partition swap when it is difficult for hardware to quickly access the PATE.

The translation mode for the hypervisor is the same as the translation mode of the partition the hypervisor is serving. This is necessary for consistent, well-defined behavior when a hypervisor concurrently serves partitions using both translation modes, and it creates a requirement that HR=1 in the PATE for LPID=0 when Radix Tree Translation partitions exist in the system, because of the effLPID construct. The architecture may refer to the translation mode of the hypervisor rather than the HR value for the partition when the relationship to the hypervisor matters.

- 44 Reserved

45 **Online (ONL)**

- 0 The PURR and SPURR do not increment.  
1 The PURR and SPURR increment.

#### Programming Note

Typically, the hypervisor sets the ONL bit to 0 when the thread is not in a power saving mode, is not performing useful work, and is available for use. The hypervisor may take the state of the ONL bit into account when making course-grain load balancing and power management decisions.

46 **Large Decrementer (LD)**

- 0 Large Decrementer mode is not enabled.  
1 Large Decrementer mode is enabled.

See Section 8.4 for additional information.

47:51 **Power-saving mode Exit Cause Enable (Lower Section) (PECE<sub>L</sub>)**

47 **Privileged Doorbell Exit Enable**

- 0 When the **stop** instruction is executed with PSSCR<sub>EC</sub>=1, Directed Privileged Doorbell exceptions are not enabled to cause exit from power-saving mode

- 1 When the **stop** instruction is executed with PSSCR<sub>EC</sub>=1, Directed Privileged Doorbell exceptions are enabled to cause exit from power-saving mode.

48 **Hypervisor Doorbell Exit Enable**

- 0 When the **stop** instruction is executed with PSSCR<sub>EC</sub>=1, Directed Hypervisor Doorbell exceptions are not enabled to cause exit from power-saving mode  
1 When the **stop** instruction is executed with PSSCR<sub>EC</sub>=1, Directed Hypervisor Doorbell exceptions are enabled to cause exit from power-saving mode.

49 **External Exit Enable**

- 0 When the **stop** instruction is executed with PSSCR<sub>EC</sub>=1, External exceptions are not enabled to cause exit from power-saving mode.  
1 When the **stop** instruction is executed with PSSCR<sub>EC</sub>=1, External exceptions are enabled to cause exit from power-saving mode.

50 **Decrementer Exit Enable**

- 0 When the **stop** instruction is executed with PSSCR<sub>EC</sub>=1, Decrementer exceptions are not enabled to cause exit from power-saving mode.  
1 When the **stop** instruction is executed with PSSCR<sub>EC</sub>=1, Decrementer exceptions are enabled to cause exit from power-saving mode. (Decrementer exceptions do not occur if the state of the Decrementer is not maintained and updated as if the thread was not in power-saving mode.)

51 **Other Exit Enable**

- 0 When the **stop** instruction is executed with PSSCR<sub>EC</sub>=1, Machine Check, Hypervisor Maintenance, and certain implementation-specific exceptions are not enabled to cause exit from power-saving mode.  
1 When the **stop** instruction is executed with PSSCR<sub>EC</sub>=1, Machine Check, Hypervisor Maintenance, and certain implementation-specific exceptions are enabled to cause exit from power-saving mode.

If the state of the PECE field is lost during power-saving mode, implementations must provide the means to exit power-saving mode upon the occurrence of a System Reset exception and any of the exceptions that were enabled by the PECE field when the **stop** instruction was executed. In addition, they may also exit power-saving mode on exceptions that were disabled by the PECE field as well. See Section 7.5.1 and Section 7.5.2 for additional information about exit from power-saving mode.

#### 52 **Mediated External Exception Request (MER)**

**0** A Mediated External exception is not requested.

**1** A Mediated External exception is requested.

The exception effects of this bit are said to be consistent with the contents of this bit if one of the following statements is true.

- $LPCR_{MER} = 1$  and a Mediated External exception exists.
- $LPCR_{MER} = 0$  and a Mediated External exception does not exist.

A context synchronizing instruction or event that is executed or occurs when  $LPCR_{MER} = 0$  ensures that the exception effects of  $LPCR_{MER}$  are consistent with the contents of  $LPCR_{MER}$ . Otherwise, when an instruction changes the contents of  $LPCR_{MER}$ , the exception effects of  $LPCR_{MER}$  become consistent with the new contents of  $LPCR_{MER}$  reasonably soon after the change.

#### Programming Note

$LPCR_{MER}$  provides a means for the hypervisor to direct an external exception to a partition independent of the partition's  $MSR_{EE}$  setting. (When  $MSR_{EE}=0$ , it is inappropriate for the hypervisor to deliver the exception.) Using  $LPCR_{MER}$ , the partition can be interrupted upon enabling external interrupts. Without using  $LPCR_{MER}$ , the hypervisor must check the state of  $MSR_{EE}$  whenever it gets control, which will result in less timely delivery of the exception to the partition.

#### 53 **Guest Translation Shutdown Enable (GTSE)**

Controls whether the operating system is permitted to use **tlbie**, **slbieg**, and **sbiag** directly, or must issue a system call to the hypervisor.

**0** Guest is not permitted to use **tlbie**, **slbieg**, **sbiag**, **tlbsync**, and **slbsync**.

**1** Guest is permitted to use **tlbie**, **slbieg**, **sbiag**, **tlbsync**, and **slbsync**.

#### Programming Note

An operating system that uses HPT translation must know whether VPM is active in order to invalidate the translation for a specific page using **tlbie**[*l*]. See the related Programming Notes in the descriptions of **tlbie** and **tlbiel**.

#### 54 **Translation Control (TC)**

**0** The secondary Page Table search is enabled.

**1** The secondary Page Table search is disabled.

55:58 Reserved

#### 59 **Hypervisor External Interrupt Control (HEIC)**

**0** Direct External interrupts can occur in hypervisor state.

**1** Direct External interrupts cannot occur in hypervisor state.

#### Programming Note

By setting  $HEIC=1$ , the Hypervisor Interrupt Virtualization handler can prevent External interrupts from occurring during the Hypervisor Virtualization interrupt handler. See Section 7.5.7.1.

#### 60 **Logical Partitioning Environment Selector (LPES)**

**0** External interrupts set the HSRRs, set  $MSR_{HV}$  to 1, and leave  $MSR_{RI}$  unchanged.

**1** External interrupts set the SRRs, set  $MSR_{RI}$  to 0, and leave  $MSR_{HV}$  unchanged.

#### Programming Note

$LPES = 1$  should be used by operating systems not running under a hypervisor, so that external interrupts are directed to the SRRs rather than to the HSRRs.

#### Programming Note

In versions of the architecture that precede Version 2.07, LPES was a two-bit field, in which the second bit controlled significant aspects of storage accessing and interrupt handling.

61 Reserved

#### 62 **Hypervisor Virtualization Interrupt Conditionally Enable (HVICE)**

- 0 Hypervisor Virtualization interrupts are disabled.
  - 1 Hypervisor Virtualization interrupts are enabled if permitted by  $MSR_{EE}$ ,  $MSR_{HV}$ , and  $MSR_{PR}$ ; see Section 7.5.21.
- 63 **Hypervisor Decrementer Interrupt Conditionally Enable** (HDICE)
- 0 Hypervisor Decrementer interrupts are disabled.
  - 1 Hypervisor Decrementer interrupts are enabled if permitted by  $MSR_{EE}$ ,  $MSR_{HV}$ , and  $MSR_{PR}$ ; see Section 7.5.12 on page 1290.

See Section 7.5 on page 1274 for a description of how the setting of LPES affects the processing of interrupts.

## 2.3 Hypervisor Real Mode Offset Register (HRMOR)

The layout of the Hypervisor Real Mode Offset Register (HRMOR) is shown in Figure 1 below.

Bits	Name	Description
4:63	HRMO	Real Mode Offset

**Figure 1. Hypervisor Real Mode Offset Register**

All other fields are reserved.

The supported HRMO values are the non-negative multiples of  $2^r$ , where  $r$  is an implementation-dependent value and  $12 \leq r \leq 26$ .

The contents of the HRMOR affect how some storage accesses are performed as described in Section 6.7.3 on page 1192 and Section 6.7.5 on page 1196.

## 2.4 Logical Partition Identification Register (LPIDR)

The layout of the Logical Partition Identification Register (LPIDR) is shown in Figure 2 below.

Bits	Name	Description
32:63	LPID	Logical Partition Identifier

**Figure 2. Logical Partition Identification Register**

The contents of the LPIDR identify the partition to which the thread is assigned, affecting some aspects of translation. The number of LPIDR bits supported is implementation-dependent.

### Programming Note

Radix tree translation assigns special meaning to  $LPID=0$ , specifically indicating the hypervisor's own partition. When  $HR=1$ ,  $LPIDR$  should not be set to zero except when  $MSR_{HV}=1$ .

HPT translation provides special functionality for  $LPID=0$  when  $HV=1$ , as described in Section 6.9.3. A partition that uses HPT translation and requires the services of an adjunct should not be assigned  $LPID=0$ .

## 2.5 Processor Compatibility Register (PCR)

The layout of the Processor Compatibility Register (PCR) is shown in Figure 3 below.

**Figure 3. Processor Compatibility Register**

High-order PCR bits are assigned to control the availability of facilities. Low-order PCR bits are assigned to control the availability of resources that are new in a specified version of the Architecture. The two types of bits can interact. For example, if a facility is created in one version and extended in the next, the high-order bit enables the portion of the facility that was defined in the version of the architecture enabled in the low-order bits.

Each defined bit in the PCR controls whether certain instructions, SPRs, and other related facilities are available in problem state. Except as specified elsewhere in this section, the PCR has no effect on facilities when the thread is not in problem state, or on privileged facilities when the thread is in problem state. Facilities that are made unavailable by the PCR are treated as follows when the thread is in problem state.

- Except for *hashchk*, *hashst*, *mffsl*, *mffsce*, *mffsdrn*, *mffsdrni*, *mffsrn*, and *mffsrni*, non-privileged instructions are treated as illegal instructions.
- *mffsl*, *mffsce*, *mffsdrn*, *mffsdrni*, *mffsrn*, and *mffsrni* perform as if they are an *mffs* instruction.
- *hashchk*, *hashchkp*, *hashst*, and *hashstp* perform as if they are a no-op instruction.
- SPRs are treated as if they were not defined for the implementation.
- The “reserved SPRs” (see Section 1.3.3 of Book I) are treated as not defined for the implementation.

- Fields in instructions are treated as if they were 0s except for the L field in *paste*.
- Values of fields in instructions cause the instruction to be treated as an invalid form of the instruction.
- Unless the third item of this list applies, bits in system registers read back 0s for *mf spr* and *mt spr* operations have no effect on their values, except as described immediately below for bits 44:45 of the XER.

For bits 44:45 of the XER, two pairs of bits are provided, an “OV32-CA32” bit pair for XER<sub>OV32</sub> and XER<sub>CA32</sub> and a “reserved” bit pair for legacy XER bits 44:45 behavior.

Which bit pair is read by *mf xer* is controlled by the PCR. *mt xer* writes to both bit pairs, independent of the PCR. *mcrxr* reads the “OV32-CA32” bit pair.

Each bit in the “OV32-CA32” bit pair is implicitly set by instructions that implicitly set their respective XER<sub>OV</sub> or XER<sub>CA</sub>, independent of the PCR. The “reserved” bit pair for bits 44:45 of the XER are not altered by these instructions, independent of the PCR.

#### Programming Note

The “reserved” bit pair does not conform to the usual rules for reading (*mf spr*) reserved bits in registers (see Section 1.3.3 of Book I) because some early implementations used bits 44:45 of the XER for implementation-specific purposes. On these implementations, and on subsequent implementations that implemented versions of the architecture that precede V. 3.0, *mf xer* returned the contents of the bits, despite that the bits were defined as reserved.

A defined bit in the PCR may also control whether certain instructions, SPRs, and other related facilities are available in a privileged state (MSR<sub>PR</sub>=0). Affected facilities will be specifically annotated.

#### Programming Note

When a bit in a system register is made unavailable by the PCR, *mt spr* operations performed on the register in problem state have no effect on the value of the bit regardless of the privilege state in which the register may subsequently be read.

A PCR bit may also determine how an instruction field value is interpreted or may define other behavior as specified in the bit definitions below.

As described in more detail below, the value 1 in a defined bit in the PCR makes the affected resources unavailable and the value 0 makes them available.

The initial state of the PCR is all 0s. In this state, all instructions and facilities supported by the processor are available in all privilege states.

#### Programming Note

Hypervisors written for a given version of the architecture generally cannot support facilities that are defined in a subsequent version of the architecture if those facilities have new state that would need to be preserved across context switches. (In the absence of such state, support may or may not be possible.) Therefore, hypervisors will set to 1 all PCR bits that are reserved in the given version of the architecture.

The PCR has no effect on the setting of the MSR and [H]SRR1 by interrupts (and of the Count Register by the System Call Vectored interrupt), and by the *rfscv*, *[h]r fid* and *mtmsr[d]* instructions, except as specified elsewhere in this section.

When facilities that have enable bits in the MSR, FSCR, HFSCR, or MMCR0 are made unavailable by the value in the PCR, they become unavailable in problem state as specified above regardless of whether they are enabled by the corresponding MSR, FSCR, HFSCR, or MMCR0 bit; facility availability interrupts (e.g. [Hypervisor] Facility Available, Vector Unavailable, etc.) do not occur as a result of problem state accesses even if the corresponding field in the MSR, [H]FSCR, or MMCR0 makes them unavailable in problem state.

#### Programming Note

Facilities that can be disabled in problem state by the PCR that also have enable bits in either the MSR or [H]FSCR include the BHRB instructions, event-based branch instructions, TAR, DSCR at SPR 3, SIER, MMCR2, the event-based branch instructions, and certain Floating-Point, Vector, and VSX instructions. When any of these facilities are made unavailable in problem state by the PCR, the corresponding [Hypervisor] Facility Unavailable, Floating-Point Unavailable, Vector, or VSX unavailable interrupts do not occur when the facility is accessed in problem state. Note, however, that the PCR does not affect privileged accesses, and thus any Hypervisor Facility Unavailable, Floating-Point Unavailable, Vector unavailable, or VSX unavailable interrupts that are specified to occur as a result of privileged accesses occur regardless of the PCR value.

**Programming Note**

Because the PCR has no effect on privileged instructions except as specified above, privileged instructions that are available on newer implementations but not available on older implementations will behave differently when the thread is in problem state. On older implementations, a Hypervisor Emulation Assistance interrupt will occur because the instruction is undefined; on newer implementations, a Privileged Instruction type Program interrupt will occur because the instruction is implemented.

In future versions of the architecture, in general the lowest-order reserved bit of the PCR will be used to control the availability of the instructions and related resources that are new in that version of the architecture; the name of the bit will correspond to the previous version of the architecture (i.e., the newest version in which the instructions and related resources were not available).

In these future versions of the architecture, there will be a requirement that if any bit of the low-order defined bits is set to 1 then all higher-order bits of the defined low-order bits must also be set to 1, and the architecture version with which the implementation appears to comply, in problem state, will be the version corresponding to the name of the lowest-order 1 bit in the set of defined low-order PCR bits, or the current architecture version if none of these bits are 1. Also, in general the highest-order reserved bits will be used to control the availability of sets of instructions and related resources having the requirement that their availability be independent of versions of the architecture.

The bit definitions for the PCR are shown below.

Bit	Description
0:2	Reserved
3	<p><b>Matrix-Multiply Assist (MMA)</b></p> <p>This bit controls the availability of the instructions listed in Table 1 on page 1140 for all privilege states.</p> <p>0 The instructions listed in Table 1 are available if the v3.0 bit is also set to 0.</p> <p>1 The instructions listed in Table 1 are not available.</p>
4:58	Reserved
59	<p><b>Version 3.0 (v3.0)</b></p> <p>When <math>MSR_{PR}=1</math> (i.e., problem state), this bit controls the availability of the following instructions, facilities, and behaviors that were newly available in problem state in the version of the architecture subsequent to Version 3.0.</p> <ul style="list-style-type: none"> <li>– The instructions listed in Table 2 on page 1141</li> <li>– The value 0 in bit 10 of the <i>paste</i>. instruction. When this value is unavailable, attempt to execute a <i>paste</i>. instruction with bit 10 set to 0 causes a Hypervisor Emulation Assistance interrupt in all privilege levels. (Although the L field is new, it has behavior more like a new value of a field because its pre-existing value was 1 instead of 0, and there is a need to treat the new value as causing an illegal instruction behavior instead of being ignored.)</li> <li>– The ability to perform a data transfer from one storage location to another or to another system. When this function is unavailable, attempting to use it in any privilege state causes a DSI or HDSI on the <i>paste</i>. instruction, setting <math>[H]DSISR_{60}</math>, as would occur under Version 3.0 of the architecture. See the latest revision of Version 3.0 of the architecture for details.</li> <li>– SIER2, SIER3 and MMCR3</li> <li>– DEXCR and HDEXCR</li> </ul> <p>0 The instructions, behaviors, and facilities listed above are available.</p> <p>Any word in storage fetched as an instruction having a primary opcode of 0b000001 is treated as the prefix of a prefixed instruction and the next sequential word in storage is treated as the suffix of that prefixed instruction.</p>

Instructions with primary opcode 31 and extended opcodes 658, 690, 722 and 754 are treated as *hashstp*, *hashchkp*, *hashst* and *hashchk* instructions respectively. (Attempt to execute either of the first two instructions causes a Privileged Instruction type Program interrupt.)

1 The instructions, behaviors, and facilities listed above are unavailable.

Any word in storage fetched as an instruction having a primary opcode of 0b000001 is treated as an illegal word instruction.

Instructions with primary opcode 31 and extended opcodes 658, 690, 722 and 754 are treated as no-op instructions.

Because this bit affects whether prefixed instructions are treated as illegal word instructions, it may affect how the Hypervisor Emulation Assist interrupt sets  $HSRR1_{34}$  and HEIR.

If this bit is set to 1, then the MMA bit must also be set to 1.

When  $MSR_{PR}=1$  and  $MMCR0_{PMCC}=0b00$ , this bit controls whether read permission on Group B Performance Monitor registers (i.e., SIER, SIAR, SDAR, and MMCR1 at SPR numbers 768, 780, 781 and 782, respectively) specified in Version 3.0 of the architecture is further conditional on  $MMCR0_{PMCCEXT}$  bit or not.

0 *mfspr* availability on the mentioned registers is conditional on  $MMCR0_{PMCCEXT}$  bit.

1 *mfspr* on the mentioned registers is available in problem state without further conditions.

When  $MSR_{PR}=0$  (i.e., privileged state), this bit controls the behavior of instructions with primary opcode 31 and extended opcodes 658, 690, 722 and 754.

0 Instructions with primary opcode 31 and extended opcodes 658, 690, 722 and 754 are treated as *hashstp*, *hashchkp*, *hashst* and *hashchk* instructions respectively.

1 Instructions with primary opcode 31 and extended opcodes 658, 690, 722 and 754 are treated as no-op instructions.

#### 60 **Version 2.07 (v2.07)**

When  $MSR_{PR}=1$  (i.e., problem state), this bit controls the availability of the following instructions, facilities, and behaviors that were newly available in problem state in the version of the architecture subsequent to Version 2.07.

- The instructions listed in Table 3 on page 1144
  - **scv**
  - 0 The instructions, behaviors, and facilities listed above are available.  
*mfixer* reads the contents of the “OV32-CA32” bit pair for XER bits 44:45.
  - 1 The instructions, behaviors, and facilities listed above are unavailable.  
*mfixer* reads the contents of the “reserved” bit pair for XER bits 44:45.
- When  $MSR_{pp}=0$  (i.e., privileged or hypervisor-privileged state), this bit controls the availability of the *mcrxrx* instruction and which bit pair is read by *mfixer* for XER bits 44:45.
- 0 *mcrxrx* is available.  
*mfixer* reads the contents of the “OV32-CA32” bit pair for XER bits 44:45.
  - 1 *mcrxrx* is unavailable.  
*mfixer* reads the contents of the “reserved” bit pair for XER bits 44:45.

If this bit is set to 1, then the v3.0 bit must also be set to 1.

61:63 Reserved

## 2.6 Other Hypervisor Resources

In addition to the resources described in the preceding sections, all hypervisor privileged instructions as well as the following resources are hypervisor resources, accessible to software only when the thread is in hypervisor state except as noted below.

- All implementation-specific resources except for privileged non-hypervisor implementation-specific SPRs. (See Section 5.4.4 for the list of the implementation-specific SPRs that are allowed to be

privileged non-hypervisor SPRs.) Implementation-specific registers include registers (e.g., “HID” registers) that control hardware functions or affect the results of instruction execution. Examples include resources that disable caches, disable hardware error detection, set breakpoints, control power management, or significantly affect performance.

- ME bit of the MSR
- SPRs defined as hypervisor-privileged in Section 5.4.4. (Note: Although the Time Base, the PURR, and the SPURR can be altered only by a hypervisor program, the Time Base can be read by all programs and the PURR and SPURR can be read when the thread is in privileged state.)

The contents of a hypervisor resource can be modified by the execution of an instruction (e.g., *mtspr*) only in hypervisor state ( $MSR_{HV\_PR} = 0b10$ ). An attempt to modify the contents of a given hypervisor resource, other than  $MSR_{ME}$ , in privileged but non-hypervisor state ( $MSR_{HV\_PR} = 0b00$ ) causes a Privileged Instruction type Program Interrupt when  $LPCR_{EVIRT}=0$  and a Hypervisor Emulation Assistance interrupt when  $LPCR_{EVIRT}=1$ . An attempt to modify  $MSR_{ME}$  in privileged but non-hypervisor state is ignored (i.e., the bit is not changed).

#### Programming Note

Because the SPRs listed above are privileged for writing, an attempt to modify the contents of any of these SPRs in problem state ( $MSR_{PR}=1$ ) using *mtspr* causes a Privileged Instruction type Program exception, and similarly for  $MSR_{ME}$ .

## 2.7 Sharing Hypervisor and Ultravisor Resources

Shared SPRs are SPRs that are accessible to multiple threads. Changes to shared SPRs made by one thread are immediately readable (using *mfspir*) by all other threads sharing the SPR.

The LPIDR and DPDES must appear to software to be shared among threads of a sub-processor (see Section 2.8). If the implementation does not support sub-processors, the LPIDR and DPDES must be shared among all threads of the multi-threaded processor.

Certain additional hypervisor and ultravisor resources, and the PVR, may be shared among threads. Programs that modify these resources must be aware of this sharing, and must allow for the fact that changes to these resources may affect more than one thread.

The following additional resources may be shared among threads.

- HRMOR (see Section 2.3)
- LPIDR (see Section 2.4)

- PCR (see Section 2.5)
- URMOR (see Section 3.2)
- PVR (see Section 5.3.1)
- RPR (see Section 5.3.7)
- PTCR (see Section 6.7.6.1)
- AMOR (see Section 6.7.13.1)
- HMEER (see Section 7.2.11)
- Time Base (see Section 8.2)
- Virtual Time Base (see Section 8.3)
- Hypervisor Decrementer (see Section 8.5)
- certain implementation-specific registers or implementation-specific fields in architected registers

The set of resources that are shared is implementation-dependent.

Threads that share any of the resources listed above, with the exception of the PTCR, the PVR, the URMOR, and the HRMOR, must be in the same partition.

For each field of the LPCR, except the AIL, EVIRT, ONL, HDICE, MER,PECE, HEIC, and HVICE fields, software must ensure that the contents of the field are identical among all threads that are in the same partition and are not in hypervisor state.

Software must ensure that the contents of UILE and  $SMFCTRL_E$  are identical among all threads in the system that have completed ultravisor initialization. The contents of the D and UDEE fields of  $SMFCTRL$  may differ among threads.

## 2.8 Sub-Processors

Hardware is allowed to sub-divide a multi-threaded processor into “sub-processors” that appear to privileged programs as multi-threaded processors with fewer threads. Such a multi-threaded processor appears to the hypervisor as a processor with a number of threads equal to the sum of all sub-processor threads, and in which the LPIDR for each sub-processor must appear to be shared among all threads of that sub-processor.

## 2.9 Thread Identification Register (TIR)

The TIR is a 64-bit read-only register that contains the thread number, which is a binary number corresponding to the thread.

For implementations that do not support sub-processors, the thread number of a thread is unique among all thread numbers of threads on the multi-threaded processor.

For implementations that support sub-processors, the value of this register depends on whether it is read in hypervisor or privileged, non-hypervisor state as follows.

- When this register is read in privileged, non-hypervisor state, the thread number is unique among all thread numbers of threads on the sub-processor.
- When this register is read in hypervisor state, the thread number is unique among all thread numbers of threads on the multi-threaded processor.

Threads are numbered sequentially, with valid values ranging from 0 to  $t-1$ , where  $t$  is the number of threads implemented. A thread for which  $TIR = n$  is referred to as “thread  $n$ .”

The layout of the TIR is shown below.

**Figure 4. Thread Identification Register**

Access to the TIR is privileged.

Since the thread number contained in this register is different if it is read in hypervisor state from when it is read in privileged, non-hypervisor state in implementations that support sub-processors, the following conventions are used.

- The value returned in privileged, non-hypervisor state is referred to as the “privileged thread number.”
- The value returned in hypervisor state is referred to as the “hypervisor thread number.”

## 2.10 Hypervisor Interrupt Little-Endian (HILE) Bit

The Hypervisor Interrupt Little-Endian (HILE) bit is a bit in an implementation-dependent register or similar mechanism. The contents of the HILE bit are copied into  $MSR_{LE}$  by interrupts that result in  $MSR_{S_{HV}}$  being equal to 0b01 (see Section 7.5), to establish the Endian mode for the interrupt handler. The HILE bit is set, by an implementation-dependent method, only during system initialization.

The contents of the HILE bit must be the same for all threads under the control of a given instance of the hypervisor; otherwise all results are undefined.

## Chapter 3. Ultravisor and Secure Memory Facility (SMF)

### 3.1 Overview

The Secure Memory Facility (SMF) provides secure isolation of partitions from one another and from higher privilege system software. SMF functionality is implemented using a combination of hardware facilities and firmware that runs at a privilege level above the hypervisor. SMF targets a threat model in which the hypervisor can be compromised such that its inherent isolation capabilities can no longer be counted on. Maintaining the security of data is the sole objective of the ultravisor. It has no role in platform management and is not expected to deal with denial of service attacks. References elsewhere in the Books to “secure systems” apply more generally, and do not necessarily imply that the system uses SMF.

The SMF protection mechanism is based on the assignment of partitions to security domains. The hypervisor is in one security domain, along with all processes that run directly under the hypervisor and all partitions that do not take advantage of the SMF security capabilities. Each of the secure partitions is assigned to its own security domain so that its data and instructions can be protected from access by other security domains. A partition is identified as secure when  $MSR_S=1$ . Each location in main storage has an associated Secure Memory property,  $mem_{SM}$ . Memory with  $mem_{SM}=1$  may be referred to as “secure memory.” Memory with  $mem_{SM}=0$  may be referred to as “ordinary memory.” The granularity and method with which main storage is mapped for the Secure Memory property is implementation specific. The Secure Memory property is commonly cached in the TLB and in implementation-specific lookaside buffers. When secure data are to be shared with untrusted software, the standard synchronization associated with PTE updates is used to regulate access. For example, prior to sharing secure data, the PTEs used to access the data are marked invalid and the corresponding TLB entries invalidated by the ultravisor using the standard invalidation sequence. (See Section 6.10.1.2.) The data are then encrypted and made available in ordinary memory (either  $mem_{SM}$  is turned off or the data are moved to ordinary memory). Finally the PTEs that will be used to access the data in ordinary memory are marked valid.

(The last step may be done lazily.) Software running with  $MSR_S=0$  is prohibited from accessing secure memory. Software running with  $MSR_S=1$  may access both secure and ordinary memory.

#### Programming Note

The ultravisor will commonly use a no-execute protection setting to prevent a secure partition from executing instructions from any ordinary memory mapped into its address space.

SMF firmware runs in ultravisor state, a privilege level above that of the hypervisor. That firmware, along with the SMF hardware, is responsible for maintaining isolation of secure partitions from each other and from the hypervisor. This is accomplished by direct ultravisor management of the partition-scoped translation tables in secure memory for secure partitions. The ultravisor itself runs only in (ultravisor) real addressing mode. Security is the result of proper management of the partition-scoped translation together with the hardware enforcement of the access restriction for secure memory. With this hybrid approach, firmware has the ability to enable secure memory sharing between secure partitions and ordinary memory sharing between a given secure partition and the hypervisor, e.g. for system calls. The ultravisor can access any architecture resource or facility.

The hypervisor is expected to cooperate in the management of secure partitions by using ultravisor calls to dispatch them and to manage their storage allocations. To protect against programming errors and malicious hypervisor behavior, *mtmsr[d]*, *rfd*, *hrfid*, and *rfscv* preserve  $MSR_S$  and hypervisor interrupts from secure partitions are always received in ultravisor state.

The purpose of intercepting hypervisor interrupts is to protect the state of the secure partition from the hypervisor. The ultravisor’s interrupt handler provides a ‘shim’ that saves and clears the processing state, and then transfers control to the hypervisor to handle the exception condition itself. The ultravisor will restore the secure partition state when it services the ultravisor call to (re-) dispatch the secure partition. Note that the ultravisor’s goal is merely to protect the security of

data, and not to provide broader system management oversight.

## 3.2 Ultravisor Real Mode Offset Register (URMOR)

The layout of the Ultravisor Real Mode Offset Register (URMOR) is shown in Figure 5 below..

Bit(s)	Name	Description
4:63	URMO	Real Mode Offset

**Figure 5. Ultravisor Real Mode Offset Register**

All other fields are reserved.

The supported URMO values are the non-negative multiples of  $2^r$ , where  $r$  is the same implementation-dependent value that constrains the HRMO field of the HRMOR.

The contents of the URMOR affect how some storage accesses are performed as described in Sections 6.7.3 and 6.7.5.

## 3.3 Ultravisor Interrupt Little-Endian (UILE) Bit

The Ultravisor Interrupt Little-Endian (UILE) bit is a bit in an implementation-dependent register or similar mechanism. The contents of the UILE bit are copied into  $MSR_{LE}$  by interrupts that result in  $MSR_{S_{HV}}$  being equal to 0b11 (see Section 7.5), to establish the Endian mode for the interrupt handler. The UILE bit is set, by an implementation-dependent method, only during system initialization.

The contents of the UILE bit must be the same for all threads in the system; otherwise all results are undefined.

## 3.4 Secure Memory Facility Control Register (SMFCTRL)

The Secure Memory Facility Control Register (SMFCTRL) is shown in Figure 6 below.

**Figure 6. Secure Memory Facility Control Register (SMFCTRL)**

Bit	Description
0	<p><b>SMF Enable (E)</b></p> <p>0 SMF functionality including secure memory checking is disabled.</p> <p>1 SMF functionality including secure memory checking is enabled.</p> <p>When <math>SMFCTRL_E=1</math>, writing the PTCR is ultravisor privileged.</p>
1	<p><b>Debug enable (D)</b></p> <p>0 Ultravisor debug mode is disabled.</p> <p>1 Ultravisor debug mode is enabled.</p> <p>In ultravisor debug mode, CIABR, DAWR<sub>n</sub>, and DAWRX<sub>n</sub> are ultravisor privileged. See Chapter 10 for a description of how instruction and data address tracing work in ultravisor debug mode.</p>
2	<p><b>Ultravisor Doorbell Exit Enable (UDEE)</b></p> <p>0 When the <b>stop</b> instruction is executed with <math>PSSCR_{EC}=1</math>, Directed Ultravisor Doorbell exceptions are not enabled to cause exit from power-saving mode</p> <p>1 When the <b>stop</b> instruction is executed with <math>PSSCR_{EC}=1</math>, Directed Ultravisor Doorbell exceptions are enabled to cause exit from power-saving mode.</p>
3:61	Reserved
62:63	Implementation-specific use

$SMFCTRL_E$  must be set to 1 prior to exiting ultravisor state if the system will use the SMF facilities. (When  $SMFCTRL_E=0$  and  $MSR_S=0$ , there is no way to achieve  $MSR_S=1$  without a reboot.)

### Programming Note

The two useful runtime states with respect to SMF operation are (1)  $MSR_S=0$  and  $SMFCTRL_E=0$  (SMF permanently disabled) and (2)  $SMFCTRL_E=1$  (SMF enabled). Very limited verification may be performed on the state with  $MSR_S=1$  and  $SMFCTRL_E=0$  and around state changes of  $SMFCTRL_E$ . Therefore, software should change the value of  $SMFCTRL_E$  at most once, making the change prior to the first dispatch of a partition, and spending as little time as possible in the state with  $MSR_S=1$  and  $SMFCTRL_E=0$ .

If  $SMFCTRL_E=0$ ,  $SMFCTRL_D$  and  $SMFCTRL_{UDEE}$  must be set to zero. References to  $SMFCTRL_D=1$  or  $SMFCTRL_{UDEE}=1$  elsewhere in the architecture assume  $SMFCTRL_E=1$  unless otherwise stated or obvious from context.

### 3.4.1 Enabling SMF and Secure Memory Enforcement

The  $SMFCTRL_E$  bit enables SMF functionality. When  $SMFCTRL_E=1$ , certain facilities are ultravisor resources instead of hypervisor resources and secure memory checking is enabled.

Independent of the basic feature enablement above, SMF has state transition rules that facilitate the protection of security domains. (While these rules are nominally independent of the value of  $SMFCTRL_E$ , some transitions cannot happen when  $SMFCTRL_E=0$ . Specifically, ultravisor interrupts cannot occur when  $SMFCTRL_E=0$ .)

- All interrupts that are not ultravisor interrupts preserve  $MSR_S$ . (Ultravisor interrupts necessarily set  $MSR_S$  to 1.)
- *mtmsr[d]*, *rfid*, *hrfid*, and *rfscv* are not permitted to change  $MSR_S$

Table 4 summarizes the effect of the  $SMFCTRL_E$  bit and the  $MSR_S_{HVPR}$  bits on various facilities.

facility	MSR <sub>S HV PR</sub>	SMFCTRL <sub>E</sub>	LPCR <sub>E VIRT</sub>	behavior
<i>mtspr</i> or <i>mfspr</i> specifying URMOR, USRR0, USRR1, USPRG0, USPRG1, or SMFCTRL; <i>urfid</i> , <i>msgsndu</i> , <i>msgclru</i>	110	dc	dc	execution allowed
	all xxx except 110**	dc	dc	Privileged Instruction type Program interrupt to xx0
<i>mtspr</i> specifying PTCR	110	dc	dc	execution allowed

<i>mtspr</i> or <i>mfspr</i> specifying DAWR <sub>n</sub> , DAWRX <sub>n</sub> or CIABR when SMFCTRL <sub>D</sub> =1	110	1	dc	execution allowed
	010	1	dc	HEAI to 010
			0	Privileged Instruction type Program interrupt to x00
	xx1**	1	1	HEAI to x10
dc			Privileged Instruction type Program interrupt to xx0	
sc 2 instruction	dc**	0	dc	hypervisor call, but with SRR1 showing LEV=2
	dc**	1	dc	ultravisor call
mem <sub>SM</sub> evaluation and match	dc**	0	dc	disabled
	dc**	1	dc	enabled*
* mem <sub>SM</sub> evaluation may be avoided when MSR <sub>S</sub> =1, depending on translation cache design dc = don't care ** The encoding MSR <sub>S HV PR</sub> =0b111 is reserved and must not be used.				

Table 4: Ultravisor Resource Behavior

**Programming Note**

Access to memory by mechanisms outside the core must also enforce secure memory access restrictions. Facilities that translate addresses or otherwise use real addresses to access memory must check mem<sub>SM</sub> against PATE<sub>S</sub> for the partition on behalf of which they access memory.

Such mechanisms will require a means to evaluate mem<sub>SM</sub> and a proxy for SMFCTRL<sub>E</sub> to provide the same enablement function for secure memory access enforcement as in the core.

In addition or as an alternative, TCE tables may be managed by the ultravisor and used to identify regions of memory that I/O devices may access.

## Chapter 4. Branch Facility

### 4.1 Branch Facility Overview

This chapter describes the details concerning the registers and the privileged instructions implemented in the Branch Facility that are not covered in Book I.

### 4.2 Branch Facility Registers

#### 4.2.1 Machine State Register

The Machine State Register (MSR) is a 64-bit register. This register defines the state of the thread. On interrupt, the MSR bits are altered in accordance with Figure 69 on page 1275. The MSR can also be modified by the *mtmsr[d]*, *rfscv*, *rfid*, *hrfid*, and *urfid* instructions. It can be read by the *mfmsr* instruction.

**Figure 7. Machine State Register**

Below are shown the bit definitions for the Machine State Register.

Bit	Description
0	<b>Sixty-Four-Bit Mode</b> (SF) 0 The thread is in 32-bit mode. 1 The thread is in 64-bit mode. Software must ensure that SF=1 whenever the thread is in ultravisor state.
1:2	Reserved
3	<b>Hypervisor State</b> (HV) 0 The thread is not in hypervisor state. 1 If MSR <sub>PR</sub> =0, the thread is in hypervisor state; otherwise the thread is not in hypervisor state.
4	Reserved
5	Software must ensure that this bit contains 0; otherwise the results of executing all instructions are boundedly undefined.

#### Programming Note

The privilege state of the thread is determined by MSR<sub>S</sub>, MSR<sub>HV</sub>, and MSR<sub>PR</sub>, as follows.

S	HVPR	Privilege State
0	x1	problem
1	01	problem
x	x0	privileged
x	10	hypervisor
1	10	ultravisor
1	11	reserved

Hypervisor state is also a privileged state (MSR<sub>PR</sub> = 0). All references to “privileged state” in the Books include hypervisor state unless otherwise stated or obvious from context. Ultravisor state is also a hypervisor state (MSR<sub>HV PR</sub> = 0b10). All references to “hypervisor state” in the Books include ultravisor state unless otherwise stated or obvious from context.

MSR<sub>HV</sub> can be set to 1 only by the *System Call* instruction and some interrupts. It can be set to 0 only by *rfid*, *hrfid*, and *urfid*.

It is possible to run an operating system in an environment that lacks a hypervisor, by always having MSR<sub>HV</sub> = 1 and using MSR<sub>HV PR</sub> = 0b10 for the operating system (effectively, the OS runs in hypervisor state) and MSR<sub>HV PR</sub> = 0b11 for applications. In this use, MSR<sub>S</sub> would be 0, and the environment would also lack an ultravisor.

Reserved

Software must ensure that this bit contains 0; otherwise the results of executing all instructions are boundedly undefined.

**Programming Note**

This bit is initialized to 0 by hardware at system bringup. The handling of this bit by interrupts and by the *rfid*, *hrfid*, *urfid*, and *rfscv* instructions is such that, unless software deliberately sets the bit to 1, the bit will continue to contain 0.

6:37 Reserved

38 **Vector Available** (VEC)

- 0 The thread cannot execute any vector instructions, including vector loads, stores, and moves.
- 1 The thread can execute vector instructions unless they have been made unavailable by some other register.

39 Reserved

40 **VSX Available** (VSX)

- 0 The thread cannot execute any VSX instructions, including VSX loads, stores, and moves.
- 1 The thread can execute VSX instructions unless they have been made unavailable by some other register.

**Programming Note**

An application binary interface defined to support Vector-Scalar operations should also specify a requirement that  $MSR_{FP}$  and  $MSR_{VEC}$  be set to 1 whenever  $MSR_{VSX}$  is set to 1.

41 **Secure** (S)

- 0 The thread is not in Secure state. It may not access Secure memory. The thread is not in ultravisor state.
- 1 The thread is in Secure state. If  $MSR_{HV}=1$  and  $MSR_{PR}=0$ , the thread is in ultravisor state; otherwise the value does not affect privilege. The state with  $MSR_{HV}=1$  and  $MSR_{PR}=1$  is reserved. Software must not set  $MSR_{S\ HV\ PR} = 0b111$ . References elsewhere in this document to  $MSR_{HV\ PR}=0b11$  assume  $MSR_S=0$  unless otherwise stated or obvious from context.

**Programming Note**

$MSR_S$  can be set to 1 only by the *System Call* instruction and some interrupts. It can be set to 0 only by *urfid*.

Any instruction or event that causes  $MSR_{S\ HV\ PR}$  to be set to 0b110 also causes  $MSR_{IR}$  and  $MSR_{DR}$  to be set to 0.

42:47 Reserved

48 **External Interrupt Enable** (EE)

- 0 External, Decrementer, Performance Monitor, and Privileged Doorbell interrupts are disabled.
- 1 External, Decrementer, Performance Monitor, and Privileged Doorbell interrupts are enabled.

This bit also affects whether Hypervisor Decrementer, Hypervisor Maintenance, Directed Hypervisor Doorbell, and Directed Ultravisor Doorbell interrupts are enabled; see Section 7.5.12 on page 1290, Section 7.5.19 on page 1300, Section 7.5.20 on page 1300, and Section 7.5.28 on page 1304.

49 **Problem State** (PR)

- 0 The thread is in privileged state.
- 1 If  $MSR_{S\ HV} \neq 0b11$ , the thread is in problem state.

**Programming Note**

Any instruction that sets  $MSR_{PR}$  to 1 also sets  $MSR_{EE}$ ,  $MSR_{IR}$ , and  $MSR_{DR}$  to 1.

The state with  $MSR_{S\ HV\ PR}=0b111$  is reserved.

50 **Floating-Point Available** (FP)

- 0 The thread cannot execute any floating-point instructions, including floating-point loads, stores, and moves.
- 1 The thread can execute floating-point instructions unless they have been made unavailable by some other register.

51 **Machine Check Interrupt Enable** (ME)

- 0 Machine Check interrupts are disabled.
- 1 Machine Check interrupts are enabled.

This bit is a hypervisor resource; see Chapter 2., “Logical Partitioning (LPAR) and Thread Control”, on page 1131.

**Programming Note**

The only instructions that can alter  $MSR_{ME}$  are *rfid*, *hrfid*, and *urfid*.

52 **Floating-Point Exception Mode 0** (FE0)

See below.

53:54 **Trace Enable** (TE)

- 00 Trace Disabled: The thread executes instructions normally.

01 Branch Trace: The thread generates a Branch type Trace interrupt after completing the execution of a branch instruction, whether or not the branch is taken.

10 Single Step Trace: The thread generates a Single-Step type Trace interrupt after successfully completing the execution of the next instruction, unless that instruction is a *urfid*, *hrfid*, *ruid*, *rfscv*, or a *Power-Saving Mode* instruction, all of which are never traced. Successful completion means that the instruction caused no other interrupt.

11 Reserved.

Branch tracing need not be supported. If the function is not implemented, the 0b01 bit encoding is treated as reserved.

55 **Floating-Point Exception Mode 1 (FE1)**

See below.

56:57 Reserved

58 **Instruction Relocate (IR)**

0 Instruction address translation is disabled.

1 Instruction address translation is enabled.

#### Programming Note

See the Programming Note in the definition of MSR<sub>S</sub> and in the definition of MSR<sub>PR</sub>.

#### Programming Note

Before hypervisor support was added to the architecture, “translation is disabled” for MSR<sub>IR</sub>=0 truly meant that no translation was performed for instruction addresses, and correspondingly for MSR<sub>DR</sub>=0 for data addresses. The architecture continues to use “translation is disabled” to refer to MSR<sub>IR</sub>=0 and MSR<sub>DR</sub>=0 despite that the behavior today is more complicated. When MSR<sub>HV IR</sub>=0b10, it is still true that no translation is performed for instruction addresses, and correspondingly for data addresses if MSR<sub>HV DR</sub>=0b10. But in privileged non-hypervisor state when MSR<sub>IR</sub>=0 or MSR<sub>DR</sub>=0, limited translation is performed under control of the hypervisor. For an HPT translation guest, translation is performed as described in Section 6.7.3.3, with storage exceptions directed to the hypervisor. For a Radix Tree Translation guest, only partition-scoped translation is performed, with storage exceptions directed to the hypervisor.

59 **Data Relocate (DR)**

0 Data address translation is disabled. Effective Address Overflow (EAO) (see Book I) does not occur.

1 Data address translation is enabled. EAO causes a Data Storage interrupt.

#### Programming Note

See the second Programming Note in the definition of MSR<sub>IR</sub> and the Programming Notes in the definition of MSR<sub>S</sub> and in the definition of MSR<sub>PR</sub>.

60 Reserved

61 **Performance Monitor Mark (PMM)**

This bit is used by software in conjunction with the Performance Monitor, as described in Chapter 11.

**Programming Note**

Software can use this bit as a process-specific marker which, in conjunction with  $MMCR0_{FCM0}$   $FCM1$  (see Section 11.4.4) and  $MMCR2$  (see Section 11.4.6), permits events to be counted on a process-specific basis. (The bit is saved by interrupts and restored by *rfid*.)

Common uses of the PMM bit include the following.

- All counters count events for a few selected processes. This use requires the following bit settings.
  - $MSR_{PMM}=1$  for the selected processes,  $MSR_{PMM}=0$  for all other processes
  - $MMCR0_{FCM0}=1$
  - $MMCR0_{FCM1}=0$
  - $MMCR2 = 0x0000$
- All counters count events for all but a few selected processes. This use requires the following bit settings.
  - $MSR_{PMM}=1$  for the selected processes,  $MSR_{PMM}=0$  for all other processes
  - $MMCR0_{FCM0}=0$
  - $MMCR0_{FCM1}=1$
  - $MMCR2 = 0x0000$

Notice that for both of these uses a mark value of 1 identifies the “few” processes and a mark value of 0 identifies the remaining “many” processes. Because the PMM bit is set to 0 when an interrupt occurs (see Figure 69 on page 1275), interrupt handlers are treated as one of the “many”. If it is desired to treat interrupt handlers as one of the “few”, the mark value convention just described would be reversed.

If only a specific counter *n* is to be frozen,  $MMCR0_{FCM0}$   $FCM1$  is set to 0b00, and  $MMCR2_{FCnM0}$  and  $MMCR2_{FCnM1}$  instead of  $MMCR0_{FCM0}$  and  $MMCR0_{FCM1}$  are set to the values described above.

- 0 The thread is in Big-Endian mode.
- 1 The thread is in Little-Endian mode.

**Programming Note**

The only instructions that can alter  $MSR_{LE}$  are *rfid*, *hrfid*, *urfid*, and *rfscv*.

The Floating-Point Exception Mode bits FE0 and FE1 are interpreted as shown below. For further details see Book I.

FE0	FE1	Mode
0	0	Ignore Exceptions
0	1	Imprecise Nonrecoverable
1	0	Imprecise Recoverable
1	1	Precise

62 **Recoverable Interrupt (RI)**

- 0 Interrupt is not recoverable.
- 1 Interrupt is recoverable.

Additional information about the use of this bit is given in Sections 7.4.3, “Interrupt Processing” on page 1270, 7.5.1, “System Reset Interrupt” on page 1276, and 7.5.2, “Machine Check Interrupt” on page 1278.

63 **Little-Endian Mode (LE)**

## 4.2.2 Processor Stop Status and Control Register (PSSCR)

The layout of the PSSCR is shown below.

**Figure 8. Processor stop Status and Control Register**

The contents of the PSSCR control the operation of the **stop** instruction and provide status indicating the level of power saving that was entered while in power-saving mode.

All fields of this register can be read and written by the hypervisor using either hypervisor SPR 855 or privileged SPR 823. A subset of the fields of this register can be read and written in privileged non-hypervisor state using privileged SPR 823, as specified below. Fields that can only be read or written by the hypervisor are indicated below; all other fields can be read or written in either privileged non-hypervisor or hypervisor states. When a field that is accessible only to the hypervisor is accessed in privileged non-hypervisor state, writes have no effect and reads return 0s regardless of the value of the field.

The bits and their meanings are as follows.

### 0:3 Power-Saving Level Status (PLS)

Hardware sets this field to the highest power-saving level that the thread entered between the time when the **stop** instruction is executed and when the thread exits power-saving mode. See the description of the SD field for the value returned in this field when the PSSCR is read.

#### Programming Note

Since the power-saving level entered during power-saving mode may vary with time, the PLS field may not indicate the power-saving level that existed at exit from power-saving mode.

4:40 Reserved

### 41 Status Disable (SD)

This field is accessible only to the hypervisor.

- 0 The current value of the PLS field is returned in the PLS field when reading the PSSCR (using *mf spr*).
- 1 0's are returned in the PLS field when reading the PSSCR (using *mf spr*).

#### Programming Note

Before dispatching an OS, the hypervisor may initialize this field to 1 in order to prevent the OS from reading the Power-Saving Level Status (PLS) field. This may be necessary in secure systems since an OS may be capable of detecting the presence of another OS on the same processor by observing the state of the PLS field after exiting power-saving mode.

42

### Enable State Loss (ESL)

This field is accessible only to the hypervisor.

- 0 State loss while in power-saving mode is controlled by the RL, MTL, and PSLL fields.
- 1 Non-hypervisor state loss is allowed while in power-saving mode in addition to state loss controlled by the RL, MTL, and PSLL fields.

If this field is set to 1 when the **stop** instruction is executed in privileged non-hypervisor state, a Hypervisor Facility Unavailable interrupt occurs. See Section 7.5.26.

For power-saving levels that allow loss of the LPCR, implementations must provide the means to exit power-saving mode upon the occurrence of a System Reset exception and any of the exceptions that were enabled by the PECE field when the **stop** instruction was executed. For this case, the implementation is also allowed to exit on the occurrence of any exceptions that were disabled by the PECE as well.

For power-saving levels that allow loss of SMFCTRL, implementations must provide the means to exit power-saving mode upon the occurrence of a Directed Ultravisor Doorbell exception if SMFCTRL<sub>UDEE</sub> was set to 1 when **stop** was executed. For this case, the implementation is also allowed to exit on the occurrence of a Directed Ultravisor Doorbell

exception if SMFCTRL<sub>UDEE</sub> was set to 0 when **stop** was executed.

**Programming Note**

When state loss occurs, thread resources such as SPRs, GPRs, address translation resources, etc. may be powered off or allocated to other threads during power-saving mode. The amount of state loss for various combinations of ESL, RL, and MTL values is implementation dependent, subject to the restrictions specified in Section 4.3.2.

43 **Exit Criterion (EC)**

This field is accessible only to the hypervisor.

- 0 Hardware will exit power-saving mode when the exception corresponding to any system-caused interrupt occurs. Power-saving mode is exited either at the instruction following the stop (if MSR<sub>EE</sub>=0) or in the corresponding interrupt handler (if MSR<sub>EE</sub>=1).
- 1 If SMFCTRL<sub>UDEE</sub> was set to 1 when **stop** was executed and SMFCTRL<sub>UDEE</sub> was not lost, hardware will exit power-saving mode when a Directed Ultravisor Doorbell exception occurs. If LPCR<sub>PECE</sub> is not lost, hardware will exit power-saving mode when a System Reset exception or one of the events specified in LPCR<sub>PECE</sub> occurs. If the event is a Machine Check exception, then a Machine Check interrupt occurs; otherwise a System Reset interrupt occurs, and the contents of SRR1 indicate the event that caused exit from power-saving mode.

When the **stop** instruction is executed in hypervisor state, the hypervisor must set the ESL field to the same value as this field. Also, if the RL or MTL fields are set to values that allow state loss, then fields ESL and EC must both be set to 1. Other combinations of the values of the ESL, EC, RL, and MTL fields are reserved for future use.

**Architecture Note**

Other combinations of the values of the ESL, EC, RL, and MTL fields may be allowed in a future version of the architecture in order to provide additional functionality.

If this field is set to 1 when the **stop** instruction is executed in privileged non-hypervisor state, a Hypervisor Facility Unavailable interrupt occurs. See Section 7.5.26.

**Programming Note**

In order to enable an OS to enter power-saving mode without hypervisor involvement, both the EC and ESL bits must be set to 0s. When this is done, OS execution of the **stop** instruction will not cause hypervisor involvement provided that bits RL and and MTL are less than or equal to PSL. See Section 7.5.26 for details.

44:47 **Power-Saving Level Limit (PSLL)**

This field is accessible only to the hypervisor.

This field limits the power-saving level that may be entered or transitioned into when the **stop** instruction is executed in privileged non-hypervisor state; when the **stop** instruction is executed in hypervisor state, this field is ignored.

48:53 Reserved

54:55 **Transition Rate (TR)**

This field is used to specify the relative rate at which the power-saving level increases during power-saving mode. The rate of power-saving level increase corresponding to each value is implementation-dependent, and monotonically increasing with the value specified.

56:59 **Maximum Transition Level (MTL)**

If the value of this field is greater than the value of the Power-Saving Level Limit (PSLL) field when **stop** is executed in privileged non-hypervisor state, a Hypervisor Facility Unavailable interrupt occurs. See Section 7.5.26 of Book III.

Otherwise, if the value of this field is greater than the value of the RL field, the power-saving level is allowed to increase from the value in the RL field up to the value of this field during power-saving mode.

If this field is less than or equal to the value of the PSLL field when **stop** is executed in privileged non-hypervisor state, this field is used to specify the maximum power-saving level that can be reached during power-saving mode provided that the value of this field is greater than the value of the RL field. If this field is less than the Requested Level (RL) field when **stop** is executed hardware is not allowed to increase the power-saving level during power-saving mode beyond the value indicated in the RL field.

60:63 **Requested Level (RL)**

This field is used to specify the power-saving level that is to be entered when the **stop** instruction is executed.

If the value of this field is greater than the value of the Power-Saving Level Limit (PSLL) field when **stop** is executed in privileged non-hypervisor state, a Hypervisor Facility Unavailable interrupt occurs.

**Programming Note**

The Hypervisor Facility Unavailable interrupt occurs when a privileged non-hypervisor program executes **stop** when  $PSSCR_{RL} > PSSCR_{PSLL}$  so that the Hypervisor may decide whether or not to allow the requested loss of state to occur.

If the hypervisor decides that some loss of state is acceptable, it may choose to re-execute **stop** after either setting  $PSSCR_{MTL}$  to a value that causes state loss, or setting both  $PSSCR_{RL}$  and  $PSSCR_{MTL}$  to values that cause state loss. When the thread exits power-saving mode, the hypervisor can quickly determine whether any resources were actually lost and need to be restored.

## 4.3 Branch Facility Instructions

### 4.3.1 System Linkage Instructions

These instructions provide the means by which a program can call upon the system to perform a service, and by which the system can return from performing a service or from processing an interrupt.

The *System Call* instruction is described in Book I, but only at the level required by an application programmer. A complete description of this instruction appears below.

#### System Call

#### SC-form

sc            LEV

17	///	///	//	LEV	//	1	/
0	6	11	16	20	27	30	31

$SRR0 \leftarrow_{iea} CIA + 4$   
 $SRR1_{33:36\ 42:47} \leftarrow 0$   
 $SRR1_{0:32\ 37:41\ 48:63} \leftarrow MSR_{0:32\ 37:41\ 48:63}$   
 $MSR \leftarrow new\_value$  (see below)  
 $NIA \leftarrow 0x0000\_0000\_0000\_0C00$

The effective address of the instruction following the *System Call* instruction is placed into SRR0. Bits 0:32, 37:41, and 48:63 of the MSR are placed into the corresponding bits of SRR1, and bits 33:36 and 42:47 of SRR1 are set to zero.

Then a System Call interrupt is generated. The interrupt causes the MSR to be set as described in Section 7.5, “Interrupt Definitions” on page 1274. The setting of the MSR is affected by the contents of the LEV field. LEV values greater than 2 are reserved. Bits 0:4 of the LEV field (instruction bits 20:24) are treated as a reserved field.

The interrupt causes the next instruction to be fetched from effective address 0x0000\_0000\_0000\_0C00.

This instruction is context synchronizing.

#### Special Registers Altered:

SRR0 SRR1 MSR

#### Programming Note

If LEV=1, the hypervisor is invoked.

If LEV=2 and SMFCTRL<sub>E</sub> = 1, the ultravisor is invoked.

If LEV=2 and SMFCTRL<sub>E</sub> = 0, the hypervisor is invoked. However, such invocation should be considered a programming error.

Executing this instruction with LEV=1 or LEV=2 is the only way that executing an instruction can cause a transition from non-hypervisor state to hypervisor state on the thread that executed the instruction. Executing this instruction with LEV=2 when SMFCTRL<sub>E</sub>=1 is the only way that executing an instruction can cause a transition from non-ultravisor state to ultravisor state on the thread that executed the instruction.

In correct use, this instruction is used to “call up” one privilege level (application program calls operating system, operating system calls hypervisor, hypervisor calls ultravisor). However, it is possible for a program to call up more than one level (e.g., for an application program to call the hypervisor). An attempt to call up more than one level should be considered a programming error.

#### Programming Note

**sc** serves as both a basic and an extended mnemonic. The Assembler will recognize an **sc** mnemonic with one operand as the basic form, and an **sc** mnemonic with no operand as the extended form. In the extended form the LEV operand is omitted and assumed to be 0.

**System Call Vectored****SC-form**

scv LEV

17	///	///	//	LEV	//	0	1
0	6	11	16	20	27	30	31

LR ← CIA + 4

CTR<sub>33:36 42:47</sub> ← undefinedCTR<sub>0:32 37:41 48:63</sub> ← MSR<sub>0:32 37:41 48:63</sub>

MSR ← new\_value (see below)

NIA ← (see below)

The effective address of the instruction following the *System Call Vectored* instruction is placed into the Link Register. Bits 0:32, 37:41, and 48:63 of the MSR are placed into the corresponding bits of Count Register, and bits 33:36 and 42:47 of Count Register are set to undefined values.

Then a System Call Vectored interrupt is generated. The interrupt causes the MSR to be altered as described in Section 7.5.

The interrupt causes the next instruction to be fetched as specified in LPCR<sub>AIL</sub> or LPCR<sub>HAIL</sub> as appropriate (see Section 2.2).

The SRRs are not affected.

This instruction is context synchronizing.

**Special Registers Altered:**

& ¬(MSR<sub>41</sub> & MSR<sub>3</sub> & (¬CTR<sub>49</sub>))MSR<sub>0:2 4:32 37:40 49:50 52:57 60:63</sub> ← CTR<sub>0:2 4:32 37:40 49:50 52:57 60:63</sub>NIA ←<sub>iea</sub> LR<sub>0:61</sub> || 0b00

The result of ORing bits 48 and 49 of the Count Register is placed into MSR<sub>48</sub>. The result of ANDing bit 41 of the MSR with bit 3 of the MSR and with the complement of bit 49 of the Count Register is complemented and then ANDed with the result of ORing bits 58 and 49

of the Count Register and placed into MSR<sub>58</sub>. The result of ANDing bit 41 of the MSR with bit 3 of the MSR and with the complement of bit 49 of the Count Register is complemented and then ANDed with the result of ORing bits 59 and 49 of the Count Register and placed into MSR<sub>59</sub>. Bits 0:2, 4:32, 37:40, 49:50, 52:57, and 60:63 of the Count Register are placed into the corresponding bits of the MSR.

If the new MSR value does not enable any pending exceptions, then the next instruction is fetched, under control of the new MSR value, from the address LR<sub>0:61</sub> || 0b00 (when SF=1 in the new MSR value) or <sup>32</sup>0 || LR<sub>32:61</sub> || 0b00 (when SF=0 in the new MSR value). If the new MSR value enables one or more pending exceptions, the interrupt associated with the highest priority pending exception is generated; in this case the value placed into SRR0, HSRR0, or USRR0 by the interrupt processing mechanism (see Section 7.4.3) is the address of the instruction that would have been executed next had the interrupt not occurred.

This instruction is privileged and context synchronizing.

**Special Registers Altered:**

MSR

**Programming Note**

If this instruction sets MSR<sub>PR</sub> to 1, it also sets MSR<sub>EE</sub>, MSR<sub>IR</sub>, and MSR<sub>DR</sub> to 1. If this instruction results in MSR<sub>S HV PR</sub> being equal to 0b110, it also sets MSR<sub>IR</sub> and MSR<sub>DR</sub> to 0.

This instruction does not alter MSR<sub>HV</sub>, MSR<sub>S</sub>, or MSR<sub>ME</sub>.

## Return From Interrupt Doubleword XL-form

rfid

19	///	///	///	18	/
0	6	11	16	21	31

$$\begin{aligned} \text{MSR}_{51} &\leftarrow (\text{MSR}_3 \ \& \ \text{SRR1}_{51}) \mid ((\neg \text{MSR}_3) \ \& \ \text{MSR}_{51}) \\ \text{MSR}_3 &\leftarrow \text{MSR}_3 \ \& \ \text{SRR1}_3 \\ \text{MSR}_{48} &\leftarrow \text{SRR1}_{48} \mid \text{SRR1}_{49} \\ \text{MSR}_{58} &\leftarrow (\text{SRR1}_{58} \mid \text{SRR1}_{49}) \\ &\quad \& \ \neg(\text{MSR}_{41} \ \& \ \text{MSR}_3 \ \& \ (\neg \text{SRR1}_{49})) \\ \text{MSR}_{59} &\leftarrow (\text{SRR1}_{59} \mid \text{SRR1}_{49}) \\ &\quad \& \ \neg(\text{MSR}_{41} \ \& \ \text{MSR}_3 \ \& \ (\neg \text{SRR1}_{49})) \\ \text{MSR}_{0:2 \ 4:32 \ 37:40 \ 49:50 \ 52:57 \ 60:63} &\leftarrow \text{SRR1}_{0:2 \ 4:32 \ 37:40 \ 49:50 \ 52:57 \ 60:63} \\ \text{NIA} &\leftarrow_{\text{iea}} \text{SRR0}_{0:61} \mid \mid \text{0b00} \end{aligned}$$

If  $\text{MSR}_3=1$  then bits 3 and 51 of SRR1 are placed into the corresponding bits of the MSR. The result of ORing bits 48 and 49 of SRR1 is placed into  $\text{MSR}_{48}$ . The result of ANDing bit 41 of the MSR with bit 3 of the MSR and with the complement of bit 49 of SRR1 is complemented and then ANDed with the result of ORing bits 58 and 49 of SRR1 and placed into  $\text{MSR}_{58}$ . The result of ANDing bit 41 of the MSR with bit 3 of the MSR and with the complement of bit 49 of SRR1 is complemented and then ANDed with the result of ORing bits 59 and 49 of SRR1 and placed into  $\text{MSR}_{59}$ . Bits 0:2, 4:32, 37:40, 49:50, 52:57, and 60:63 of SRR1 are placed into the corresponding bits of the MSR.

If the new MSR value does not enable any pending exceptions, then the next instruction is fetched, under control of the new MSR value, from the address  $\text{SRR0}_{0:61} \mid \mid \text{0b00}$  (when  $\text{SF}=1$  in the new MSR value) or  $^{32}0 \mid \mid \text{SRR0}_{32:61} \mid \mid \text{0b00}$  (when  $\text{SF}=0$  in the new MSR value). If the new MSR value enables one or more pending exceptions, the interrupt associated with the highest priority pending exception is generated; in this case the value placed into SRR0, HSRR0, or USRR0 by the interrupt processing mechanism (see Section 7.4.3) is the address of the instruction that would have been executed next had the interrupt not occurred.

This instruction is privileged and context synchronizing.

### Special Registers Altered:

MSR

#### Programming Note

If this instruction sets  $\text{MSR}_{\text{PR}}$  to 1, it also sets  $\text{MSR}_{\text{EE}}$ ,  $\text{MSR}_{\text{IR}}$ , and  $\text{MSR}_{\text{DR}}$  to 1. If this instruction results in  $\text{MSR}_{\text{S HV PR}}$  being equal to 0b110, it also sets  $\text{MSR}_{\text{IR}}$  and  $\text{MSR}_{\text{DR}}$  to 0.

```

The result of ORing bits 48 and 49 of USRR1 is placed into MSR<sub>48</sub>. The result of ANDing bit 41 of USRR1 with bit 3 of USRR1 and with the complement of bit 49 of USRR1 is complemented and then ANDed with the result of ORing bits 58 and 49 of USRR1 and placed into MSR<sub>58</sub>. The result of ANDing bit 41 of USRR1 with bit 3 of USRR1 and with the complement of bit 49 of USRR1 is complemented and then ANDed with the result of ORing bits 59 and 49 of USRR1 and placed into MSR<sub>59</sub>. Bits 0:32, 37:41, 49:57, and 60:63 of USRR1 are placed into the corresponding bits of the MSR.

If the new MSR value does not enable any pending exceptions, then the next instruction is fetched, under control of the new MSR value, from the address USRR0<sub>0:61</sub> || 0b00 (when SF=1 in the new MSR value) or <sup>32</sup>0 || USRR0<sub>32:61</sub> || 0b00 (when SF=0 in the new MSR value). If the new MSR value enables one or more pending exceptions, the interrupt associated with the highest priority pending exception is generated; in this case the value placed into SRR0, HSRR0, or USRR0 by the interrupt processing mechanism (see Section 7.4.3) is the address of the instruction that would have been executed next had the interrupt not occurred.

This instruction is ultravisor privileged and context synchronizing.

Special Registers Altered:  
MSR

### Programming Note

If this instruction sets MSR<sub>PR</sub> to 1, it also sets MSR<sub>EE</sub>, MSR<sub>IR</sub>, and MSR<sub>DR</sub> to 1. If this instruction sets MSR<sub>S HV PR</sub> to 0b110, it also sets MSR<sub>IR</sub> and MSR<sub>DR</sub> to 0.

### 4.3.2 Power-Saving Mode

*Power-Saving Mode* is a mode in which the thread does not execute instructions and may consume less power than it would if it were not in power-saving mode.

There are 16 levels of power savings, designated as levels 0-15. For each power-saving level, the power consumed may be less than or equal to the power consumed in the next-lower level, and the time required for the thread to exit power-saving mode and resume execution may be greater than or equal that of the next-lower level.

When the thread is in power-saving mode, some resource state may be lost. The state that may be lost while in each power-saving level is implementation dependent, with the following restrictions.

- For  $PSSCR_{ESL} = 0$  and power-saving level 0000, no thread state is lost.
- There must be a power-saving level in which the Decrementer and all hypervisor resources are maintained as if the thread was not in power-saving mode, and in which sufficient information is maintained to allow the hypervisor to resume execution.
- The amount of state loss in a given level is less than or equal to the amount of state loss in the next higher level.
- The state of all read-only resources,  $SMFCTRL_E$ , and the URMOR in an SMF-enabled system or the HRMOR in an SMF-disabled system is always maintained.

#### Programming Note

For the power-saving level corresponding to the second item above, if the state of the Decrementer were not maintained and updated as if the thread was not in power-saving mode, Decrementer exceptions would not reliably cause exit from this power-saving level even if Decrementer exceptions were enabled to cause exit.

### 4.3.2.1 Power-Saving Mode Instruction

The **stop** instruction is used to stop instruction fetching and execution and put the thread into power-saving mode. The thread remains in power-saving mode until

a system reset exception or an event that is enabled to cause exit from power-saving mode occurs. (See the definition of  $PSSCR_{EC}$  in Section 4.2.2.)

#### **stop**

#### ***XL-form***

stop

19	///	///	///	370	/
0	6	11	16	21	31

The thread is placed into power-saving mode and execution is stopped.

The power-saving level that is entered is determined by the contents of the PSSCR (see Section 4.2.2). The thread state that is maintained depends on the power-saving level that is entered. The thread state that is maintained at each power-saving level is implementation-dependent, subject to the restrictions specified in Section 4.3.2.MSR<sub>EE</sub>=0) or in the corresponding interrupt handler (if MSR<sub>EE</sub>=1).

The thread remains in power-saving mode until either a System Reset exception or certain other events occur. The events that may cause exit from power-saving mode are specified by PSSCR<sub>EC</sub>, LPCR<sub>PECE</sub>, and SMFCTRL<sub>UDEE</sub>. If the event that causes the exit is a System Reset, Machine Check, or Hypervisor Maintenance exception, resource state that would be lost if the exception occurred when the thread was not in power-saving mode may be lost.

This instruction should not be executed in ultravisor state because that scenario may not be thoroughly verified.

This instruction is privileged and context synchronizing.

#### **Special Registers Altered:**

None

### 4.3.2.2 Entering and Exiting Power-Saving Mode

Before software executes the **stop** instruction, the PSSCR is initialized. If the **stop** instruction is to be used by the OS, the hypervisor initializes the fields that are accessible only to the hypervisor before dispatching the OS. These fields include the SD, ESL, EC, and PSL fields. See the Programming Notes for these fields in Section 4.2.2 for additional information.

If the **stop** instruction is to be executed by the hypervisor when PSSCR<sub>EC</sub>=1, LPCR<sub>PECE</sub> and SMFCTRL<sub>UDEE</sub> must be set to the desired value (see Sections 2.2 and 3.4). Depending on the implementation and the

power-saving level to be entered, it may also be necessary to save the state of certain resources and perform synchronization procedures to ensure that all stores have been performed with respect to other threads or mechanisms that use the storage areas before executing the **stop**. See the the User's Manual for the implementation for details.

Software must also specify the requested and maximum power-saving level limit fields (i.e RL and MTL fields), and the Transition Rate (TR) field in the PSSCR in order to bound the range of power-saving modes that can be entered. If the value of the RL field is greater than or equal to the value of the MTL field, the power-saving level will not increase from the initial level during power-saving mode.

#### **Programming Note**

If MSR<sub>EE</sub>=1 when the **stop** instruction is executed, then the interrupt corresponding to the exception that was expected to cause exit from power-saving mode may occur immediately prior to execution of the **stop** instruction. If this occurs, the result may be a software hang condition since the exception that was expected to cause exit from power-saving mode has already occurred.

The above software hang condition can be prevented by setting MSR<sub>EE</sub>=0 prior to executing **stop**.

After the thread has entered power-saving mode with PSSCR<sub>EC</sub>=0, any exception may cause exit from power-saving mode. When an exception occurs, power-saving mode is exited either at the instruction following the stop (if MSR<sub>EE</sub>=0) or in the corresponding interrupt handler (if MSR<sub>EE</sub>=1).

#### **Programming Note**

If **stop** was executed when PSSCR<sub>EC</sub>=0, then PSSCR<sub>ESL</sub> must also be set to 0 and PSSCR<sub>RL</sub> MTL must be set to values that do not allow state loss. (See the definition of the EC bit description in Section 4.3.2.) This guarantees that the state of MSR<sub>EE</sub> is not lost.

**Programming Note**

If **stop** was executed when  $PSSCR_{EC}=0$  and  $MSR_{EE}=0$  (in order to avoid the hang condition described in a preceding Programming Note),  $MSR_{EE}$  should be set to 1 after power-saving mode is exited in order to take the interrupt corresponding to the exception that caused exit from power-saving mode.

After the thread has entered power-saving mode with  $PSSCR_{EC}=1$ , only the System Reset exception and the exceptions enabled in  $LPCR_{PECE}$  and  $SMFCTRL_{UDEE}$  will cause exit. If the event that causes exit is a Machine Check exception, then a Machine Check interrupt occurs; otherwise a System Reset interrupt occurs, and the contents of  $SRR1$  indicate the exception that caused exit from power-saving mode. If state loss has occurred in an SMF-enabled system, the interrupt is taken in ultravisor state.

If the hypervisor has set  $PSSCR_{SD}=0$  prior to when the **stop** instruction is executed, the instruction following the **stop** may typically be a **mfspr** in order to read the contents of  $PSSCR_{PLS}$  to determine the maximum power-saving level that was entered during power-saving mode.

**Programming Note**

The ultravisor does not initiate power-saving.

If a secure partition attempts to execute **stop** with parameters that allow state loss, the ultravisor gets control via the Hypervisor Facility Unavailable interrupt. It saves secure state and gives control to the hypervisor's Hypervisor Facility Unavailable interrupt handler.

Upon exit from a state-losing power-saving mode in an SMF-enabled system, the ultravisor gets control at its Machine Check or System Reset interrupt handler. It restores any ultravisor state that was lost, and then services the Directed Ultravisor Doorbell exception if that caused the wakeup. It then restores the HRMOR and transfers control to the hypervisor at the hypervisor's Machine Check interrupt handler if the ultravisor got control at the ultravisor's Machine Check interrupt handler, and to the hypervisor's System Reset interrupt handler otherwise. The hypervisor restores any lost hypervisor state, and then handles the exception (other than Directed Ultravisor Doorbell exception) that caused the wakeup. For this process to work, the ultravisor must have stored a record of its state in some known location prior to transferring control to the hypervisor to execute **stop**. The hypervisor in turn must have stored its HRMOR value in a location known to the ultravisor. It must also have stored a record of its state in some known location.

The only other function the ultravisor may need to perform for a given power-saving mode transition is to be a proxy accessing hypervisor state in the platform that is mixed with ultravisor state and lacking independent access control.

## 4.4 Event-Based Branch Facility and Instruction

The Event-Based Branch facility is described in Chapter 6 of Book II, but only at the level required by the application program.

Event-based branches can only occur in problem state and when event-based branches and exceptions have been enabled in the FSCR and HFSCR, and  $BESCR_{GE}=1$ . Additionally, the following additional bits must be set to one in order to enable EBB exceptions specific to a given function to occur.

- $MMCR0_{EBE}$  and  $BESCR_{PME}$  must be set to 1 to enable Performance Monitor event-based exceptions.
- $BESCR_{EE}$  must be set to 1 to enable External event-based exceptions.

If an event-based exception exists (as indicated by  $BESCR_{PME0}=1$  or  $BESCR_{EE0}=1$ ) when  $MSR_{PR}=0$ , the corresponding event-based branch will occur when  $MSR_{PR}=1$ ,  $FSCR_{EBB}=1$ ,  $HFSCR_{EBB}=1$ , and  $BESCR_{GE}=1$ .

### Programming Note

Software EBB handlers should ensure that previous exceptions have been cleared (by setting  $BESCR_{PME0}$  and/or  $BESCR_{EE0}$  to 0) before re-enabling event-based branches (by setting  $BESCR_{GE}$  to 1 or executing `rfebb 1`) in order to prevent earlier exceptions from causing additional EBBs.

## Chapter 5. Fixed-Point Facility

### 5.1 Fixed-Point Facility Overview

This chapter describes the details concerning the registers and the privileged instructions implemented in the Fixed-Point Facility that are not covered in Book I.

### 5.2 Special Purpose Registers

Special Purpose Registers (SPRs) are read and written using the *mfspr* (page 1184) and *mtspr* (page 1182) instructions. Most SPRs are defined in other chapters of this book; see the index to locate those definitions.

### 5.3 Fixed-Point Facility Registers

#### 5.3.1 Processor Version Register

The Processor Version Register (PVR) is a 32-bit read-only register that contains a value identifying the version and revision level of the implementation. The contents of the PVR can be copied to a GPR by the *mfspr* instruction. Read access to the PVR is privileged; write access is not provided.

**Figure 9. Processor Version Register**

The PVR distinguishes between implementations that differ in attributes that may affect software. It contains two fields.

**Version** A 16-bit number that identifies the version of the implementation. Different version numbers indicate major differences between implementations.

**Revision** A 16-bit number that distinguishes between implementations of the version. Different revision numbers indicate minor differences between implementations having the same

version number, such as clock rate and Engineering Change level.

Version numbers are assigned by the Power ISA process. Revision numbers are assigned by an implementation-defined process.

#### 5.3.2 Processor Identification Register

The Processor Identification Register (PIR) is a 32-bit register that contains a 20-bit PROCID field that can be used to distinguish the thread from other threads in the system. The contents of the PIR can be copied to a GPR by the *mfspr* instruction. Read access to the PIR is privileged; write access is not provided.

Bits	Name	Description
32:43		Reserved
44:63	PROCID	Thread ID

**Figure 10. Processor Identification Register**

The means by which the PIR is initialized are implementation-dependent.

The PIR is a hypervisor resource; see Chapter 2.

### 5.3.3 Process Identification Register

The layout of the Process Identification Register (PIDR) is shown in Figure 11 below.

Bit(s)	Name	Description
32:63	PID	Process Identifier

**Figure 11. Process Identification Register**

The contents of the PIDR identify the process to which the thread is assigned. The value is used to perform translation and manage the caching of translations. The number of PIDR bits supported is implementation-dependent.

Access to the PIDR is privileged.

#### Programming Note

Radix tree translation assigns special meaning to  $PID=0$ , specifically indicating the operating system's kernel process. When  $GR=1$ , PIDR should not be set to zero except when  $MSR_{PR}=0$ .

### 5.3.4 Control Register

The Control Register (CTRL) is a 32-bit register as shown below.

**Figure 12. Control Register**

The field definitions for the CTRL are shown below.

Bit(s)	Description
32:47	Reserved
48:55	<b>Thread State (TS)</b>
	Problem State Access
	Reserved
	Privileged Non-hypervisor State Access
	Bits 0:7 of this field are read-only bits that indicate the state of $CTRL_{RUN}$ for threads with privileged thread numbers 0 through 7, respectively; bits corresponding to privileged thread numbers higher than the maximum privileged thread number supported are set to 0s.
	Hypervisor State Access
	Bits 0:7 of this field are read-only bits that indicate the state of $CTRL_{RUN}$ for threads with

hypervisor thread numbers 0 through 7, respectively; bits corresponding to hypervisor thread numbers higher than the maximum hypervisor thread number supported are set to 0s.

56:62	Reserved
63	RUN

This bit controls an external I/O pin. This signal may be used for the following:

- driving the RUN Light on a system operator panel
- Direct External exception routing
- Performance Monitor Counter incrementing (see Chapter 11)

The RUN bit can be used by the operating system to indicate when the thread is doing useful work.

Write access to the CTRL is privileged. Reads can be performed in privileged or problem state.

### 5.3.5 Program Priority Register

Privileged programs may set a wider range of program priorities in the PRI field of PPR and PPR32 than may be set by problem state programs (see Chapter 3 of Book II). Problem state programs may only set values in the range of 0b001 to 0b100 unless the Problem State Priority Boost register (see Section 5.3.6) allows the value 0b101. Privileged programs may set values in the range of 0b001 to 0b110. Hypervisor software may also set 0b111. For all priorities except 0b101, if a program attempts to set a value that is not allowed for its privilege level, the PRI field remains unchanged. If a problem state program attempts to set its priority value to 0b101 when this priority value is not allowed for problem state programs, the priority is set to 0b100. The values and their corresponding meanings are as follows.

Bit(s)	Description
11:13	<b>Program Priority (PRI)</b>
001	very low
010	low
011	medium low
100	medium
101	medium high
110	high
111	very high

### 5.3.6 Problem State Priority Boost Register

The Problem State Priority Boost (PSPB) register is a 32-bit register that controls whether problem state pro-

grams have access to program priority medium high. (See Section 3.1 of Book II.)

**Figure 13. Problem State Priority Boost Register**

A problem state program is able to set the program priority to medium high only when the PSPB of the thread contains a non-zero value.

The maximum value to which the PSPB can be set must be a power of 2 minus 1. Bits that are not required to represent this maximum value must return 0s when read regardless of what was written to them.

When the PSPB is set to a value less than its maximum value but greater than 0, its contents decrease monotonically at the same rate as the SPURR until its contents minus the amount it is to be decreased are 0 or less when a problem state program is executing on the thread at a priority of medium high. When the contents of the PSPB minus the amount it is to be decreased are 0 or less, its contents are replaced by 0.

When the PSPB is set to its maximum value or 0, its contents do not change until it is set to a different value.

Whenever the priority of a thread is medium high and either of the following conditions exist, hardware changes the priority to medium:

- the PSPB counts down to 0, or
- PSPB=0 and the privilege state of the thread is changed to problem state ( $MSR_{PR}=1$ ).

### 5.3.7 Relative Priority Register

The Relative Priority Register (RPR) is a 64-bit register that allows the hypervisor to control the relative priorities corresponding to each valid value of  $PPR_{PRI}$ .

**Figure 14. Relative Priority Register**

Each  $RP_n$  field is defined as follows.

Bits	Meaning
0:1	Reserved
2:7	<b>Relative priority of priority level n:</b> Specifies the relative priority that corresponds to the priority corresponding to $PPR_{PRI}=n$ , where a value of 0 indicates the lowest relative priority and a value of 0b111111 indicates the highest relative priority.

#### Programming Note

The hypervisor must ensure that the values of the  $RP_n$  fields increase monotonically for each  $n$  and are of different enough magnitudes to ensure that each priority level provides a meaningful difference in priority.

### 5.3.8 Hash Key Registers

The Hash Key Register (HASHKEYR) is a 64-bit register which contains the key for the hash computation done by the non-privileged *Hash* instructions, namely *hashst* and *hashchk* (see Section 3.3.17 of Book I). Similarly, the Hash Privileged Key Register (HASHPKEYR) is a 64-bit register which contains the key for the hash computation done by the privileged *Hash* instructions, namely *hashstp* and *hashchkp* (see Section 5.4.2 of Book III).

**Figure 15. Hash Key Register**

**Figure 16. Hash Privileged Key Register**

HASHKEYR is a privileged register. HASHPKEYR is a hypervisor privileged register.

#### Programming Note

Normally any indication of privilege in the name and mnemonic of an SPR appears at the beginning -- e.g., Hypervisor Decrementer (HDEC), Ultravisor Real Mode Offset Register (URMOR). The Hash Privileged Key Register (HASHPKEYR) seems to violate this convention, because the privilege indication is in the middle of the name and mnemonic. But "Privileged (P)" for this SPR indicates the privilege not of the SPR -- which is hypervisor privileged -- but of the instructions (*hashstp* and *hashchkp*) that use the SPR. So the seeming violation of the convention is appropriate.

### 5.3.9 Software-use SPRs

Software-use SPRs are 64-bit registers provided for use by software.

**Figure 17. Software-use SPRs**

SPRG0, SPRG1, and SPRG2 are privileged registers. SPRG3 is a privileged register except that the contents may be copied to a GPR in Problem state when accessed using the *mfspr* instruction.

**Programming Note**

Neither the contents of the SPRGs, nor accessing them using *mtspr* or *mfspr*, has a side effect on the operation of the thread. One or more of the registers is likely to be needed by interrupt handlers that run in privileged non-hypervisor state (e.g., as scratch registers and/or pointers to per thread save areas).

Operating systems must ensure that no sensitive data are left in SPRG3 when a problem state program is dispatched, and operating systems for secure systems must ensure that SPRG3 cannot be used to implement a “covert channel” between problem state programs. These requirements can be satisfied by clearing SPRG3 before passing control to a program that will run in problem state.

HSPRG0 and HSPRG1 are 64-bit registers provided for use by hypervisor programs.

**Figure 18. SPRs for use by hypervisor programs**

**Programming Note**

Neither the contents of the HSPRGs, nor accessing them using *mtspr* or *mfspr*, has a side effect on the operation of the thread. One or both of the registers is likely to be needed by interrupt handlers that run in hypervisor non-ultravisor state (e.g., as scratch registers and/or pointers to per thread save areas).

USPRG0 and USPRG1 are 64-bit registers provided for use by ultravisor programs.

**Figure 19. SPRs for use by ultravisor programs**

**Programming Note**

Neither the contents of the USPRGs, nor accessing them using *mtspr* or *mfspr*, has a side effect on the operation of the thread. One or both of the registers is likely to be needed by interrupt handlers that run in ultravisor state (e.g., as scratch registers and/or pointers to per thread save areas).

## 5.4 Fixed-Point Facility Instructions

### 5.4.1 Fixed-Point Load and Store Caching Inhibited Instructions

The storage accesses caused by the instructions described in this section are performed as though the specified storage location is Caching Inhibited and Guarded. The instructions can be executed only in hypervisor state. Software must ensure that the specified storage location is not in the caches. If the specified storage location is in a cache, the results are undefined.

The *Fixed-Point Load and Store Caching Inhibited* instructions must be executed only when  $MSR_{DR}=0$ . The storage location specified by the instructions must not be in storage specified by the Hypervisor Real Mode Storage Control facility to be treated as

non-Guarded. If either of these conditions is violated, the result is a Data Storage interrupt.

#### Programming Note

The instructions described in this section can be used to permit a control register on an I/O device to be accessed without permitting the corresponding storage location to be copied into the caches.

The *Fixed-Point Load and Store Caching Inhibited* instructions are fixed-point *Storage Access* instructions; see Section 3.3.1 of Book I.

**Load Byte and Zero Caching Inhibited Indexed X-form**

lbzcx RT,RA,RB

0	31	RT	RA	RB	853	/
	6	11	16	21		31

```

if RA = 0 then b ← 0
else      b ← (RA)
EA ← b + (RB)
RT ← 560 || MEM(EA, 1)

```

Let the effective address (EA) be the sum (RA|0)+(RB). The byte in storage addressed by EA is loaded into RT<sub>56:63</sub>. RT<sub>0:55</sub> are set to 0.

The storage access caused by this instruction is performed as though the specified storage location is Caching Inhibited and Guarded.

This instruction is hypervisor privileged.

**Special Registers Altered:**

None

**Load Word and Zero Caching Inhibited Indexed X-form**

lwzcx RT,RA,RB

0	31	RT	RA	RB	789	/
	6	11	16	21		31

```

if RA = 0 then b ← 0
else      b ← (RA)
EA ← b + (RB)
RT ← 320 || MEM(EA, 4)

```

Let the effective address (EA) be the sum (RA|0)+(RB). The word in storage addressed by EA is loaded into RT<sub>32:63</sub>. RT<sub>0:31</sub> are set to 0.

The storage access caused by this instruction is performed as though the specified storage location is Caching Inhibited and Guarded.

This instruction is hypervisor privileged.

**Special Registers Altered:**

None

**Load Halfword and Zero Caching Inhibited Indexed X-form**

lhzcix RT,RA,RB

0	31	RT	RA	RB	821	/
	6	11	16	21		31

```

if RA = 0 then b ← 0
else      b ← (RA)
EA ← b + (RB)
RT ← 480 || MEM(EA, 2)

```

Let the effective address (EA) be the sum (RA|0)+(RB). The halfword in storage addressed by EA is loaded into RT<sub>48:63</sub>. RT<sub>0:47</sub> are set to 0.

The storage access caused by this instruction is performed as though the specified storage location is Caching Inhibited and Guarded.

This instruction is hypervisor privileged.

**Special Registers Altered:**

None

**Load Doubleword Caching Inhibited Indexed X-form**

ldcix RT,RA,RB

0	31	RT	RA	RB	885	/
	6	11	16	21		31

```

if RA = 0 then b ← 0
else      b ← (RA)
EA ← b + (RB)
RT ← MEM(EA, 8)

```

Let the effective address (EA) be the sum (RA|0)+(RB). The doubleword in storage addressed by EA is loaded into RT.

The storage access caused by this instruction is performed as though the specified storage location is Caching Inhibited and Guarded.

This instruction is hypervisor privileged.

**Special Registers Altered:**

None

### Store Byte Caching Inhibited Indexed X-form

stbcix RS,RA,RB

```

if RA = 0 then b ← 0
else      b ← (RA)
EA ← b + (RB)
MEM(EA, 8) ← (RS)

```

Let the effective address (EA) be the sum (RA|0)+(RB). (RS) is stored into the doubleword in storage addressed by EA.

The storage access caused by this instruction is performed as though the specified storage location is Caching Inhibited and Guarded.

This instruction is hypervisor privileged.

#### Special Registers Altered:

None

## 5.4.2 Fixed-Point Hash Instructions

Privileged instructions analogous to the *Hash* instructions described in Section 3.3.17 of Book I are defined

in this section. The HashDigest function, used below, is defined in Section 3.3.17.1 of Book I.

**Hash Store Privileged****X-form**

hashstp RB,offset(RA)

31	D	RA	RB	658	DX
0	6	11	16	21	31

```

DW ← 32×DX + D
d ← EXTS(0b111_1111 || DW || 0b000)
EA ← (RA) + d
temp ← HashDigest((RA),(RB),(HASHKEYR))
MEM(EA, 8) ← temp

```

Let DW be the value  $32 \times DX + D$ . The offset is  $(0b111\_1111 \parallel DW \parallel 0b000)$  sign extended to 64 bits. Let the effective address (EA) be the sum  $(RA) + \text{offset}$ . The doubleword hash value computed from the contents of RA, RB, and the hypervisor privileged SPR HASHKEYR, as specified by the HashDigest function described in Section 3.3.17.1 of Book I, is stored into the doubleword in storage addressed by EA.

This instruction is privileged.

EA must be a multiple of 8. If it is not, either an Alignment interrupt occurs or the results are boundedly undefined.

If RA=0, the instruction form is invalid.

**Special Registers Altered:**

None

**Hash Check Privileged****X-form**

hashchkp RB,offset(RA)

31	D	RA	RB	690	DX
0	6	11	16	21	31

```

DW ← 32×DX + D
d ← EXTS(0b111_1111 || DW || 0b000)
EA ← (RA) + d
temp ← HashDigest((RA),(RB),(HASHKEYR))
temp1 ← MEM(EA, 8)
if (temp ≠ temp1)then TRAP

```

Let DW be the value  $32 \times DX + D$ . The offset is  $(0b111\_1111 \parallel DW \parallel 0b000)$  sign extended to 64 bits. Let the effective address (EA) be the sum  $(RA) + \text{offset}$ . The doubleword in storage addressed by EA is read and compared with the doubleword hash value computed from the contents of RA, RB, and the hypervisor privileged SPR HASHKEYR, as specified by the HashDigest function described in Section 3.3.17.1 of Book I. If the values are unequal, the system trap handler is invoked.

This instruction is treated as a *Load*; see Section 4.3 of Book II.

This instruction is privileged.

If the values are unequal, this instruction is context synchronizing (see Book III).

EA must be a multiple of 8. If it is not, either an Alignment interrupt occurs or the results are boundedly undefined.

If RA=0, the instruction form is invalid.

**Special Registers Altered:**

None

**Programming Note**

See the Programming Notes that appear in the description of **hashst** and **hashchk** in Section 3.3.17.2 of Book I.

### 5.4.3 OR Instruction

or  $Rx, Rx, Rx$  can be used to set  $PPR_{PRI}$  (see Section 5.3.5) as shown in Figure 20. For all priorities except medium high,  $PPR_{PRI}$  remains unchanged if the privilege state of the thread executing the instruction is lower than the privilege indicated in the figure. For priority medium high,  $PPR_{PRI}$  is set to medium if the thread executing the instruction is in problem state and medium high priority is not allowed for problem state programs. (The encodings available to problem state programs, as well as encodings for additional shared resource hints not shown here, are described in Chapter 3 of Book II.)

Rx	$PPR_{PRI}$	Priority	Privileged
31	001	very low	no
1	010	low	no
6	011	medium low	no
2	100	medium	no
5	101	medium high	no/yes <sup>1</sup>
3	110	high	yes
7	111	very high	hypv

<sup>1</sup>This value is privileged unless the Problem State Priority Boost register allows the priority value 0b101 (See Section 5.3.6.)

Figure 20. Priority levels for or  $Rx, Rx, Rx$

SPR numbers that are not shown in Figure 21 and are in the ranges shown below are reserved for implementation-specific uses.

848 - 863  
880 - 895  
976 - 991  
1008 - 1023

Implementation-specific registers must be privileged. SPR numbers for implementation-specific SPRs should be registered in advance with the Power ISA architects.

### 5.4.4 Move To/From System Register Instructions

The *Move To Special Purpose Register* and *Move From Special Purpose Register* instructions are described in Book I, but only at the level available to an application programmer. For example, no mention is made there of registers that can be accessed only in privileged state. The descriptions of these instructions given below extend the descriptions given in Book I, but do not list Special Purpose Registers that are implementation-dependent. In the descriptions of these instructions given in below, the “defined” SPR numbers are the SPR numbers shown in the Figure 21 for the instruction and the implementation-specific SPR numbers that are implemented, and similarly for “defined” registers. All other SPR numbers are undefined for the instruction. (Implementation-specific SPR numbers that are not implemented are considered to be undefined.) When an SPR is defined for *mtspr* and undefined for *mfspr*, or vice versa, a hyphen appears in the column for the instruction for which the SPR number is undefined.

Figure 21. SPR encodings (Sheet 1 of 4)

Figure 21. SPR encodings (Sheet 4 of 4)

decimal	SPR <sup>1</sup>		Register Name	Privileged		Length (bits)	Extended Mnemonics*	
	spr <sub>5:9</sub>	spr <sub>0:4</sub>		mtspr	mfspir		mtspr	mfspir
-	This register is not defined for this instruction.							
1	Note that the order of the two 5-bit halves of the SPR number is reversed.							
2	This register is a hypervisor resource, and can be accessed by this instruction only in hypervisor state (see Chapter 2).							
3	This register cannot be directly written. Instead, bits in the register corresponding to 0 bits in (RS) can be cleared using <i>mtspr SPR,RS</i> .							
4	The value specified in register RS may be masked by the contents of the [U]AMOR before being placed into the AMR; see the <i>mtspr</i> instruction description.							
5	The value specified in register RS may be ANDed with the contents of the AMOR before being placed into the UAMOR; see the <i>mtspr</i> instruction description.							
6	MMCR0 <sub>PMCC</sub> and MMCR0 <sub>PMCCEXT</sub> controls the availability of this SPR, and its contents depend on the privilege state in which it is accessed. See Section 11.4.4 for details.							
7	The value specified in Register RS may be masked by the contents of the AMOR before being placed into the IAMR; see the <i>mtspr</i> instruction description.							
8	Accesses to these SPRs are no-ops; see Section 1.3.3, “Reserved Fields, Reserved Values, and Reserved SPRs” in Book I.							
9	SPR numbers 777-778, 783, 793-794, and 799 are reserved for the Performance Monitor. All other SPR numbers that are not shown above and are not implementation-specific are reserved.							
10	The <i>mftb</i> instruction is Phased-Out. Assemblers targeting Version 2.03 or later of the architecture should generate an <i>mfspir</i> instruction for the <i>mftb</i> and <i>mftbu</i> extended mnemonics; see the corresponding Assembler Note in the <i>mftb</i> instruction description (see Section 5.1 of Book II).							
11	No extended mnemonic is provided because previous versions of the architecture defined the obvious extended mnemonic as resolving to the non-privileged SPR number, and because there is no software benefit in using the privileged SPR number, rather than the non-privileged SPR number, for this function.							
12	<i>mtspr</i> specifying this register is ultravisor privileged when SMFCTRL <sub>E</sub> =1; otherwise it is hypervisor privileged.							
13	This register is ultravisor privileged when SMFCTRL <sub>D</sub> =1; otherwise it is hypervisor privileged.							
14	“udexcr” in the extended mnemonic refers to the non-privileged SPR number for DEXCR. It is not to be confused with “UDEXCR”, which is the ultravisor equivalent of HDEXCR and cannot be read using <i>mfspir</i> instruction. See Section 9.3.3 of Book III.							
*This figure also defines extended mnemonics for the <i>mtspr</i> and <i>mfspir</i> instructions, including the Special Purpose Registers (SPRs) defined in Book I and for the <i>Move From Time Base</i> instruction defined in Book II.								
The <i>mtspr</i> and <i>mfspir</i> instructions specify an SPR as a numeric operand; extended mnemonics are provided that represent the SPR in the mnemonic rather than requiring it to be coded as an operand. Similar extended mnemonics are provided for the <i>Move From Time Base</i> instruction, which specifies the portion of the Time Base as a numeric operand.								
<b>Note:</b> <i>mftb</i> serves as both a basic and an extended mnemonic. The Assembler will recognize an <i>mftb</i> mnemonic with two operands as the basic form, and an <i>mftb</i> mnemonic with one operand as the extended form. In the extended form the TBR operand is omitted and assumed to be 268 (the value that corresponds to TB)								

## Move To Special Purpose Register XFX-form

mtspr SPR,RS

0	31	RS	spr	467	/
	6	11	21	31	

```

n ← spr5:9 || spr0:4

  case (336): SPR(336) ← (SPR(336)) & (RS)
  case (158, 808, 809, 810, 811):
  default: if length(SPR(n)) = 64 then
    SPR(n) ← (RS)
  else
    SPR(n) ← (RS)32:63

```

The SPR field denotes a Special Purpose Register, encoded as shown in Figure 21. If the SPR field contains the value 158, the instruction is treated as a privileged no-op. If the SPR field contains a value from 808 through 811, the instruction specifies a reserved SPR, and is treated as a no-op; see Section 1.3.3, “Reserved Fields, Reserved Values, and Reserved SPRs” in Book I. Otherwise, the contents of register RS are placed into the designated Special Purpose Register, except as described in the next five paragraphs. For Special Purpose Registers that are 32 bits long, the low-order 32 bits of RS are placed into the SPR.

When the designated SPR is the Authority Mask Register (AMR), (using SPR 13 or SPR 29), or the designated SPR is the Instruction Authority Mask Register (IAMR), and MSR<sub>HV PR</sub>=0b00, the contents of bit positions of register RS corresponding to 1 bits in the Authority Mask Override Register (AMOR) are placed into the corresponding bits of the AMR or IAMR, respectively; the other AMR or IAMR bits are not modified.

When the designated SPR is the AMR, using SPR 13, and MSR<sub>PR</sub>=1, the contents of bit positions of register RS corresponding to 1 bits in the User Authority Mask

Override Register (UAMOR) are placed into the corresponding bits of the AMR; the other AMR bits are not modified.

When the designated SPR is the UAMOR and MSR<sub>HV PR</sub>=0b00, the contents of register RS are ANDed with the contents of the AMOR and the result is placed into the UAMOR.

When the designated SPR is the Hypervisor Maintenance Exception Register (HMER), the contents of register RS are ANDed with the contents of the HMER and the result is placed into the HMER.

For this instruction, SPRs TBL and TBU are treated as separate 32-bit registers; setting one leaves the other unaltered.

spr<sub>0</sub>=1 if and only if writing the register is privileged. Execution of this instruction specifying an SPR number with spr<sub>0</sub>=1 when the privilege state of the thread does not permit the access causes one of the following.

- MSR<sub>PR</sub>=1: Privileged Instruction type Program interrupt
- MSR<sub>HV PR</sub>=0b00 or MSR<sub>S HV PR</sub>=0b010 and the SPR is always an ultravisor resource (independent of the contents of SMFCTRL): Privileged Instruction type Program interrupt
- MSR<sub>HV PR</sub>=0b00 and the SPR is a hypervisor resource (see Figure 21) or is PTCR, DAWR<sub>n</sub>, DAWRX<sub>n</sub>, or CIABR when they are ultravisor privileged for the operation:
  - LPCR<sub>EVRT</sub>=0: Privileged Instruction type Program interrupt
  - LPCR<sub>EVRT</sub>=1: Hypervisor Emulation Assistance interrupt
- MSR<sub>S HV PR</sub>=0b010 and the SPR is PTCR, DAWR<sub>n</sub>, DAWRX<sub>n</sub>, or CIABR when they are ultravisor privileged for the operation: Hypervisor Emulation Assistance interrupt

Execution of this instruction specifying an SPR number that is undefined for the implementation causes one of the following.

- if spr<sub>0</sub>=0:
  - if MSR<sub>PR</sub>=1: Hypervisor Emulation Assistance interrupt
  - if MSR<sub>PR</sub>=0: Hypervisor Emulation Assistance interrupt for SPR 0,4,5, and 6, and no operation (i.e., the instruction is treated as a no-op) when LPCR<sub>EVRT</sub>=0 and Hypervisor Emulation Assistance interrupt when LPCR<sub>EVRT</sub>=1 for all other SPRs
- if spr<sub>0</sub>=1:
  - if MSR<sub>PR</sub>=1: Privileged Instruction type Program interrupt
  - if MSR<sub>PR</sub>=0: no operation (i.e., the instruction is treated as a no-op) when LPCR<sub>EVRT</sub>=0 and Hypervisor Emulation Assistance interrupt when LPCR<sub>EVRT</sub>=1

**Special Registers Altered:**

See Figure 21

**Programming Note**

For a discussion of software synchronization requirements when altering certain Special Purpose Registers, see Chapter 13. “Synchronization Requirements for Context Alterations” on page 1353.

**Programming Note**

Requiring that an attempt to execute an *mtspr* or *mfspir* instruction with SPR=0 or an attempt to execute an *mfspir* instruction with SPR=4, 5, or 6 cause a Hypervisor Emulation Assistance interrupt permits efficient emulation of *mt/fspir* specifying the corresponding SPRs as defined in the POWER Architecture.

Requiring that an attempt to execute an *mtspir* instruction with SPR=4, 5, or 6 cause a Hypervisor Emulation Assistance interrupt, even in privileged state, makes the behavior be the same for both instructions for all four SPR numbers, thereby simplifying the architecture. (SPRs 4, 5, and 6 were not defined for *mtspir* in the POWER Architecture. The corresponding SPRs were privileged for writing, and *mtspir* to those SPRs used the corresponding privileged SPR number.)

## Move From Special Purpose Register XFX-form

mfspr RT,SPR

0	31	RT	6	11	spr	21	339	/	31
---	----	----	---	----	-----	----	-----	---	----

```
n ← spr5:9 || spr0:4
switch (n)
```

```
case(808, 809, 810, 811):
default:
  if length(SPR(n)) = 64 then
    RT ← SPR(n)
  else
    RT ← 320 || SPR(n)
```

The SPR field denotes a Special Purpose Register, encoded as shown in Figure 21. If the SPR field contains a value from 808 through 811, the instruction specifies a reserved SPR, and is treated as a no-op; see Section 1.3.3, “Reserved Fields, Reserved Values, and Reserved SPRs” in Book I. Otherwise, the contents of the designated Special Purpose Register are placed into register RT. For Special Purpose Registers that are 32 bits long, the low-order 32 bits of RT receive the contents of the Special Purpose Register and the high-order 32 bits of RT are set to zero.

spr<sub>0</sub>=1 if and only if reading the register is privileged. Execution of this instruction specifying an SPR number with spr<sub>0</sub>=1 when the privilege state of the thread does not permit the access causes one of the following.

- MSR<sub>PR</sub>=1: Privileged Instruction type Program interrupt
- MSR<sub>HV PR</sub>=0b00 or MSR<sub>S HV PR</sub>=0b010 and the SPR is always an ultravisor resource (independent of the contents of SMFCTRL): Privileged Instruction type Program interrupt
- MSR<sub>HV PR</sub>=0b00 and the SPR is a hypervisor resource (see Figure 21) or is DAWR<sub>n</sub>, DAWR<sub>Xn</sub>, or CIABR when they are ultravisor privileged for the operation:
  - LPCR<sub>EVRT</sub>=0: Privileged Instruction type Program interrupt
  - LPCR<sub>EVRT</sub>=1: Hypervisor Emulation Assistance interrupt
- MSR<sub>S HV PR</sub>=0b010 and the SPR is DAWR<sub>n</sub>, DAWR<sub>Xn</sub>, or CIABR when they are ultravisor privileged for the operation: Hypervisor Emulation Assistance interrupt

Execution of this instruction specifying an SPR number that is not defined for the implementation causes one of the following.

- if spr<sub>0</sub>=0:
  - if MSR<sub>PR</sub>=1: Hypervisor Emulation Assistance interrupt

- if MSR<sub>PR</sub>=0: Hypervisor Emulation Assistance interrupt for SPRs 0, 4, 5, and 6, and no operation (i.e., the instruction is treated as a no-op) when LPCR<sub>EVRT</sub>=0 and Hypervisor Emulation Assistance interrupt when LPCR<sub>EVRT</sub>=1 for all other SPRs

- if spr<sub>0</sub>=1:
  - if MSR<sub>PR</sub>=1: Privileged Instruction type Program interrupt
  - if MSR<sub>PR</sub>=0: no operation (i.e., the instruction is treated as a no-op) when LPCR<sub>EVRT</sub>=0 and Hypervisor Emulation Assistance interrupt when LPCR<sub>EVRT</sub>=1

### Special Registers Altered:

None

### Note

See the Notes that appear with *mtspr*.

## Move To Machine State Register X-form

mtmsr      RS,L

31	RS	///	L	///	146	/
0	6	11	15	16	21	31

```

if L = 0 then
    MSR48 ← (RS)48 | (RS)49
    MSR58 ← ((RS)58 | (RS)49)
        & ¬(MSR41 & MSR3 & (¬(RS)49))
    MSR59 ← ((RS)59 | (RS)49)
        & ¬(MSR41 & MSR3 & (¬(RS)49))
    MSR32:40 42:47 49:50 52:57 60:62
        ← (RS)32:40 42:47 49:50 52:57 60:62
else
    MSR48 62 ← (RS)48 62

```

The MSR is set based on the contents of register RS and of the L field.

L=0:

The result of ORing bits 48 and 49 of register RS is placed into MSR<sub>48</sub>. The result of ANDing bit 41 of the MSR with bit 3 of the MSR and with the complement of bit 49 of register RS is complemented and then ANDed with the result of ORing bits 58 and 49 of register RS and placed into MSR<sub>58</sub>. The result of ANDing bit 41 of the MSR with bit 3 of the MSR and with the complement of bit 49 of register RS is complemented and then ANDed with the result of ORing bits 59 and 49 of register RS and placed into MSR<sub>59</sub>. Bits 32:40, 42:47, 49:50, 52:57, and 60:62 of register RS are placed into the corresponding bits of the MSR.

L=1:

Bits 48 and 62 of register RS are placed into the corresponding bits of the MSR. The remaining bits of the MSR are unchanged.

This instruction is privileged.

If L=0 this instruction is context synchronizing. If L=1 this instruction is execution synchronizing; in addition, the alterations of the EE and RI bits take effect as soon as the instruction completes.

### Special Registers Altered:

MSR

Except in the *mtmsr* instruction description in this section, references to “*mtmsr*” in this document imply either L value unless otherwise stated or obvious from context (e.g., a reference to an *mtmsr* instruction that modifies an MSR bit other than the EE or RI bit implies L=0).

### Programming Note

If this instruction sets MSR<sub>PR</sub> to 1, it also sets MSR<sub>EE</sub>, MSR<sub>IR</sub>, and MSR<sub>DR</sub> to 1. If this instruction results in MSR<sub>S HV PR</sub> being equal to 0b110, it also sets MSR<sub>IR</sub> and MSR<sub>DR</sub> to 0.

This instruction does not alter MSR<sub>S</sub>, MSR<sub>ME</sub>, or MSR<sub>LE</sub>. (This instruction does not alter MSR<sub>HV</sub> because it does not alter any of the high-order 32 bits of the MSR.)

If the only MSR bits to be altered are MSR<sub>EE RI</sub>, to obtain the best performance L=1 should be used.

### Programming Note

If MSR<sub>EE</sub>=0 and an External, Decrementer, or Performance Monitor exception is pending, executing an *mtmsrd* instruction that sets MSR<sub>EE</sub> to 1 will cause the interrupt to occur before the next instruction is executed, if no higher priority exception exists (see Section 7.9, “Interrupt Priorities” on page 1306). Similarly, if a Hypervisor Decrementer interrupt is pending, execution of the instruction by the hypervisor causes a Hypervisor Decrementer interrupt to occur if HDICE=1.

For a discussion of software synchronization requirements when altering certain MSR bits, see Chapter 13.

### Programming Note

*mtmsr* serves as both a basic and an extended mnemonic. The Assembler will recognize an *mtmsr* mnemonic with two operands as the basic form, and an *mtmsr* mnemonic with one operand as the extended form. In the extended form the L operand is omitted and assumed to be 0.

### Programming Note

There is no need for an analogous version of the *mfmsr* instruction, because the existing instruction copies the entire contents of the MSR to the selected GPR.

## Move To Machine State Register Doubleword X-form

mtmsrd      RS,L

31	RS	///	L	///	178	/
0	6	11	15	16	21	31

```

if L = 0 then
  MSR48 ← (RS)48 | (RS)49
  MSR58 ← ((RS)58 | (RS)49)
    & ¬(MSR41 & MSR3 & (¬(RS)49))
  MSR59 ← ((RS)59 | (RS)49)
    & ¬(MSR41 & MSR3 & (¬(RS)49))
  MSR0:2 4:40 42:47 49:50 52:57 60:62
    ← (RS)0:2 4 6:40 42:47 49:50 52:57 60:62

```

```

else
  MSR48 62 ← (RS)48 62

```

The MSR is set based on the contents of register RS and of the L field.

L=0:

The result of ORing bits 48 and 49 of register RS is placed into MSR<sub>48</sub>. The result of ANDing bit 41 of the MSR with bit 3 of the MSR and with the complement of bit 49 of register RS is complemented and then ANDed with the result of ORing bits 58 and 49 of register RS and placed into MSR<sub>58</sub>. The result of ANDing bit 41 of the MSR with bit 3 of the MSR and with the complement of bit 49 of register RS is complemented and then ANDed with the result of ORing bits 59 and 49 of register RS and placed into MSR<sub>59</sub>. Bits 0:2, 4:40 42:47, 49:50, 52:57, and 60:62 of register RS are placed into the corresponding bits of the MSR.

L=1:

Bits 48 and 62 of register RS are placed into the corresponding bits of the MSR. The remaining bits of the MSR are unchanged.

This instruction is privileged.

If L=0 this instruction is context synchronizing. If L=1 this instruction is execution synchronizing; in addition, the alterations of the EE and RI bits take effect as soon as the instruction completes.

### Special Registers Altered:

MSR

Except in the *mtmsrd* instruction description in this section, references to "*mtmsrd*" in this document imply either L value unless otherwise stated or obvious from context (e.g., a reference to an *mtmsrd* instruction that modifies an MSR bit other than the EE or RI bit implies L=0).

### Programming Note

If this instruction sets MSR<sub>PR</sub> to 1, it also sets MSR<sub>EE</sub>, MSR<sub>IR</sub>, and MSR<sub>DR</sub> to 1. If this instruction results in MSR<sub>S HV PR</sub> being equal to 0b110, it also sets MSR<sub>IR</sub> and MSR<sub>DR</sub> to 0.

This instruction does not alter MSR<sub>HV</sub>, MSR<sub>S</sub>, MSR<sub>ME</sub>, or MSR<sub>LE</sub>.

If the only MSR bits to be altered are MSR<sub>EE RI</sub>, to obtain the best performance L=1 should be used.

### Programming Note

If MSR<sub>EE</sub>=0 and an External, Decrementer, or Performance Monitor exception is pending, executing an *mtmsrd* instruction that sets MSR<sub>EE</sub> to 1 will cause the interrupt to occur before the next instruction is executed, if no higher priority exception exists (see Section 7.9, "Interrupt Priorities" on page 1306). Similarly, if a Hypervisor Decrementer interrupt is pending, execution of the instruction by the hypervisor causes a Hypervisor Decrementer interrupt to occur if HDICE=1.

For a discussion of software synchronization requirements when altering certain MSR bits, see Chapter 13.

### Programming Note

*mtmsrd* serves as both a basic and an extended mnemonic. The Assembler will recognize an *mtmsrd* mnemonic with two operands as the basic form, and an *mtmsrd* mnemonic with one operand as the extended form. In the extended form the L operand is omitted and assumed to be 0.

## ***Move From Machine State Register*** ***X-form***

mfmsr      RT

31	RT	///	///	83	/
0	6	11	16	21	31

RT ← MSR

The contents of the MSR are placed into register RT.

This instruction is privileged.

**Special Registers Altered:**

None

## Chapter 6. Storage Control

---

### 6.1 Overview

A program references storage using the effective address computed by the hardware when it executes a *Load*, *Store*, *Branch*, or *Cache Management* instruction, or when it fetches the next sequential instruction. The effective address is translated to a real address according to procedures described in Section 6.7.3, in Section 6.7.7 and in the following sections. The real address is what is presented to the storage subsystem.

For a complete discussion of storage addressing and effective address calculation, see Section 1.10 of Book I.

### 6.2 Storage Exceptions

A *storage exception* results when the sequential execution model requires that a storage access be performed but the access is not permitted (e.g., is not permitted by the storage protection mechanism), the access cannot be performed because the effective address cannot be translated to a real address, or the access matches some tracking mechanism criteria (e.g., Data Address Watchpoint).

In certain cases a storage exception may result in the “restart” of (re-execution of at least part of) a *Load* or *Store* instruction. See Section of Book II, and Section 7.6 in this Book.

### 6.3 Instruction Fetch

Instructions are fetched under control of  $MSR_{IR}$ .

#### $MSR_{IR}=0$

The effective address of the instruction is interpreted as described in Section 6.7.3.

#### $MSR_{IR}=1$

The effective address of the instruction is translated by the Address Translation mechanism described beginning in Section 6.7.7.

### 6.3.1 Implicit Branch

Explicitly altering certain MSR bits (using  $mtmsr[d]$ ), or explicitly altering SLB entries, Page Table Entries, or certain System Registers (including the HRMOR, URMOR, and possibly other implementation-dependent registers), may have the side effect of changing the addresses, effective or real, from which the current instruction stream is being fetched. This side effect is called an *implicit branch*. For example, an  $mtmsrd$  instruction that changes the value of  $MSR_{SF}$  may change the effective addresses from which the current instruction stream is being fetched. The MSR bits and System Registers (excluding implementation-dependent registers) for which alteration can cause an implicit branch are indicated as such in Chapter 13. “Synchronization Requirements for Context Alterations” on page 1353. Implicit branches are not supported by the Power ISA. If an implicit branch occurs, the results are boundedly undefined.

### 6.3.2 Address Wrapping Combined with Changing MSR Bit SF

If the current instruction is at effective address  $2^{32} - 4$  and is an  $mtmsrd$  instruction that changes the contents of  $MSR_{SF}$ , the effective address of the next sequential instruction is undefined.

#### Programming Note

If the thread is in 32-bit mode, the current instruction is a word instruction at effective address  $2^{32}-4$  or a prefixed instruction at effective address  $2^{32}-8$ , and an interrupt occurs that is defined to set  $SRR0$  or  $HSRR0$  (or  $LR$ , for the System Call Vectored interrupt) to the effective address of the next sequential instruction, the contents of  $SRR0$  or  $HSRR0$  (or  $LR$ ), as appropriate to the interrupt, are undefined.

## 6.4 Data Access

Data accesses are controlled by  $MSR_{DR}$ .

### $MSR_{DR}=0$

The effective address of the data is interpreted as described in Section 6.7.3.

### $MSR_{DR}=1$

The effective address of the data is translated by the Address Translation mechanism described in Section 6.7.7.

## 6.5 Performing Operations Out-of-Order

An operation is said to be performed “in-order” if, at the time that it is performed, it is known to be required by the sequential execution model. An operation is said to be performed “out-of-order” if, at the time that it is performed, it is not known to be required by the sequential execution model.

Operations are performed out-of-order on the expectation that the results will be needed by an instruction that will be required by the sequential execution model. Whether the results are really needed is contingent on everything that might divert the control flow away from the instruction, such as *Branch*, *Trap*, *System Call*, and *Return From Interrupt* instructions, and interrupts, and on everything that might change the context in which the instruction is executed.

Typically, operations are performed out-of-order when resources are available that would otherwise be idle, so the operation incurs little or no cost. If subsequent events such as branches or interrupts indicate that the operation would not have been performed in the sequential execution model, any results of the operation are abandoned (except as described below).

In the remainder of this section, including its subsections, “*Load* instruction” includes the *Cache Management* and other instructions that are stated in the instruction descriptions to be “treated as a *Load*”, and similarly for “*Store* instruction”.

A data access that is performed out-of-order may correspond to an arbitrary *Load* or *Store* instruction (e.g., a *Load* or *Store* instruction that is not in the instruction stream being executed). Similarly, an instruction fetch that is performed out-of-order may be for an arbitrary instruction (e.g., the aligned word at an arbitrary location in instruction storage).

Most operations can be performed out-of-order, as long as the machine appears to follow the sequential execution model. Certain out-of-order operations are restricted, as follows.

- Stores

Stores are not performed out-of-order (even if the *Store* instructions that caused them were executed out-of-order).

- Accessing Guarded Storage  
The restrictions for this case are given in Section 6.8.1.1.
- Executing instructions subsequent to an *ori R31,R31,0* instruction  
The restrictions for this case are given in Section 9.2.1.

The only permitted side effects of performing an operation out-of-order are the following.

- A Machine Check or Checkstop that could be caused by in-order execution may occur out-of-order.
- Reference and Change bits may be set as described in Section 6.7.12.
- Non-Guarded storage locations that could be fetched into a cache by in-order fetching or execution of an arbitrary instruction may be fetched out-of-order into that cache.

## 6.6 Invalid Real Address

A storage access (including an access that is performed out-of-order; see Section 6.5) may cause a Machine Check if the accessed storage location contains an uncorrectable error or does not exist.

In the case that the accessed storage location does not exist, the Checkstop state may be entered. See Section 7.5.2 on page 1278.

### Programming Note

In configurations supporting multiple partitions, hypervisor software must ensure that a storage access by a program in one partition will not cause a Checkstop or other system-wide event that could affect the integrity of other partitions (see Chapter 2). For example, such an event could occur if a real address placed in a Page Table Entry does not exist.

## 6.7 Storage Addressing

### Storage Control Overview

- Host real address space size is  $2^m$  bytes,  $m \leq 60$ ; see Note 1.
- Guest real address space size is  $2^m$  bytes,  $m \leq 60$ ; see Notes 1 and 2.
- Real page size is  $2^{12}$  bytes (4 KB).
- Effective address space size is  $2^{64}$  bytes.
- For HPT translation, an effective address is translated to a virtual address via a segment descriptor that was either bolted into the Segment Lookaside Buffer (SLB) by software or found and installed into the SLB via a hardware walk of the Segment Table. After that, the virtual address is translated to a host real address via a hardware walk of the Page Table.
  - Virtual address space size is  $2^n$  bytes,  $65 \leq n \leq 78$ ; see Note 3.
  - Segment size is  $2^s$  bytes,  $s = 28$  or  $40$ .
  - $2^{n-40} \leq$  number of virtual segments  $\leq 2^{n-28}$ ; see Note 3.
  - Virtual page size is  $2^p$  bytes, where  $12 \leq p$ , and  $2^p$  is no larger than either the size of the biggest segment or the real address space; a size of 4 KB, 64 KB, and an implementation-dependent number of other sizes are supported; see Note 4. The Page Table specifies the virtual page size. The SLB specifies the base virtual page size, which is the smallest virtual page size that the segment can contain. The base virtual page size is  $2^b$  bytes.
  - Segments contain pages of a single size, a mixture of 4 KB and 64 KB pages, or a mixture of page sizes that include implementation-dependent page sizes.
  -
- For Radix Tree translation, an effective address is translated to a (guest or host) real address via a hardware walk of the Page Table..
  - Virtual page size is  $2^p$  bytes, where  $12 \leq p$ , and  $2^p$  is no larger than the size of the real address space; a size of 4 KB, 64 KB, 2MB, and an implementation-dependent number of other sizes are supported; see Note 4. The virtual page size is determined by the location of the Page Table Entry in the Radix Tree.

#### Notes:

1. The value of  $m$  is implementation-dependent (subject to the maximum given above). When used to address storage or to represent a guest real address, the high-order 60- $m$  bits of the “60-bit” real address must be zeros.
2. The hypervisor may assign a guest real address space size for each partition that uses Radix Tree translation. Accesses to guest real storage outside this range but still mappable by the second level Radix Tree will cause an HISI or HDSI. Accesses to storage outside the mappable range will have boundedly undefined results.
3. The value of  $n$  is implementation-dependent (subject to the range given above). In references to 78-bit virtual addresses elsewhere in this Book, the high-order 78- $n$  bits of the “78-bit” virtual address are assumed to be zeros.
4. The supported values of  $p$  for the larger virtual page sizes are implementation-dependent (subject to the limitations given above).

#### Programming Note

Note that without some of the reserved bits in the Radix PTE, the RPN field cannot address the full 60-bit real address space. Similarly without some of the reserved bits in the HPT PTE, the ARPN field cannot address the full 60-bit real address space.

Note that without some of the reserved bits in the HPT PTE, the AVA field cannot resolve the full 78-bit virtual address.

### 6.7.1 32-Bit Mode

The computation of the 64-bit effective address is independent of whether the thread is in 32-bit mode or 64-bit mode. In 32-bit mode ( $MSR_{SE}=0$ ), the high-order 32 bits of the 64-bit effective address are treated as zeros for the purpose of addressing storage. This applies to both data accesses and instruction fetches. It applies independent of whether address translation is enabled or disabled. This truncation of the effective address is the only respect in which storage accesses in 32-bit mode differ from those in 64-bit mode.

#### Programming Note

Treating the high-order 32 bits of the effective address as zeros effectively truncates the 64-bit effective address to a 32-bit effective address such as would have been generated on a 32-bit implementation of the Power ISA. Thus, for example, the ESID in 32-bit mode is the high-order four bits of this truncated effective address; the ESID thus lies in the range 0-15. When address translation is enabled, these four bits would select a Segment Register on a 32-bit implementation of the Power ISA. The SLB entries that translate these 16 ESIDs can be used to emulate these Segment Registers.

## 6.7.2 Virtualized Partition Memory (VPM) Mode

VPM mode enables the hypervisor to reassign all or part of a partition's memory transparently so that the reassignment is not visible to the partition. When this is done, the partition's memory is said to be "virtualized." This mode is only available within Paravirtualized HPT translation mode. Radix Tree translation mode provides equivalent function by providing two levels of translation with separate Page Tables for the operating system and the hypervisor. (See Section 6.7.7 for a more complete overview of the translation modes.) The VPM field in the LPCR enables VPM mode when address translation is enabled. VPM is always enabled when address translation is disabled.

If the thread is not in hypervisor state, and either address translation is enabled and VPM=1, or address translation is disabled, conditions that would have caused a Data Storage or an Instruction Storage interrupt if the affected memory were not virtualized instead cause a Hypervisor Data Storage or a Hypervisor Instruction Storage interrupt respectively. Because the Hypervisor Data Storage and Hypervisor Instruction Storage interrupts always put the thread in hypervisor state, they permit the hypervisor to handle the condition if appropriate (e.g., to restore the contents of a page that was reassigned), and to reflect it to the operating system's Data Storage or Instruction Storage interrupt handler otherwise.

When address translation is enabled, VPM mode has no effect on address translation. When address translation is disabled, addressing is controlled as specified in Section 6.7.3.

## 6.7.3 Ultravisor Real, Hypervisor Real, and Virtual Real Addressing Modes

If a storage access is an instruction fetch performed when instruction address translation is disabled, or if the access is a data access performed when data address translation is disabled, it is said to be performed in "ultravisor real addressing mode" if the thread is in ultravisor state, in "hypervisor real addressing mode" if the thread is in hypervisor non-ultravisor state, and in "virtual real addressing mode" if the thread is in privileged non-hypervisor state. Storage accesses in ultravisor real, hypervisor real, and virtual real addressing modes are performed in a manner that depends on the contents of  $MSR_S_{HV}$ ,  $PATE_{HR}$ ,  $PATE_{PS}$ ,  $URMOR$  (see Chapter 3),  $HRMOR$  (see Chapter 2), bit 0 of the effective address ( $EA_0$ ), and the state of the Real Mode Storage Control Facility as described below. Bits 1:3 of the effective address are ignored.

### $MSR_S_{HV}=0b11$

- If  $EA_0=0$ , the Ultravisor Offset Real Mode Address mechanism, described in Section 6.7.3.1, controls the access.
- If  $EA_0=1$ , bits 4:63 of the effective address are used as the real address for the access.

### $MSR_S_{HV}=0b01$

- If  $EA_0=0$ , the Hypervisor Offset Real Mode Address mechanism, described in Section 6.7.3.1, controls the access.
- If  $EA_0=1$ , bits 4:63 of the effective address are used as the real address for the access.

### $MSR_{HV}=0$

- If  $PATE_{HR}=0$ , the Virtual Real Mode Addressing mechanism, described in Section 6.7.3.3, controls the access.
- If  $PATE_{HR}=1$ , partition-scoped translation is performed on the effective address. (See Section 6.7.11.3, "Obtaining Host Real Address, Radix on Radix".)

### 6.7.3.1 Ultravisor/Hypervisor Offset Real Mode Address

If  $MSR_{HV} = 1$  and  $EA_0 = 0$ , the access is controlled by the contents of the Ultravisor Real Mode Offset Register or the Hypervisor Real Mode Offset Register, depending on the value of  $MSR_S$ , as follows.

#### Ultravisor Real Mode Offset Register (URMOR)

When  $MSR_S=1$ , bits 4:63 of the effective address for the access are ORed with the 60-bit offset represented by the contents of the URMOR, and the 60-bit result is used as the real address for the access.

#### Hypervisor Real Mode Offset Register (HRMOR)

When  $MSR_S=0$ , bits 4:63 of the effective address for the access are ORed with the 60-bit offset represented by the contents of the HRMOR, and the 60-bit result is used as the real address for the access.

For each of the two registers, the supported offset values are all values of the form  $i \times 2^r$ , where  $0 \leq i < 2^j$ , and  $j$  and  $r$  are implementation-dependent values having the properties that  $12 \leq r \leq 26$  (i.e., the minimum offset granularity is 4 KB and the maximum offset granularity is 64 MB) and  $j+r = m$ , where the real address size supported by the implementation is  $m$  bits.

**Programming Note**

$EA_{4:63-r}$  should equal  $60-r0$ . If this condition is satisfied, ORing the effective address with the offset produces a result that is equivalent to adding the effective address and the offset.

If  $m < 60$ ,  $EA_{4:63-m}$ ,  $URMOR_{4:63-m}$ , and  $HRMOR_{4:63-m}$  must be zeros.

### 6.7.3.2 Storage Control Attributes for Accesses in Ultravisor and Hypervisor Real Addressing Modes

Storage accesses in ultravisor and hypervisor real addressing modes are performed as though all of storage had the following storage control attributes, except as modified by the Hypervisor Real Mode Storage Control facility (see Section 6.7.3.2.1). (The storage control attributes are defined in Book II.)

- not Write Through Required
- not Caching Inhibited, for instruction fetches
- not Caching Inhibited, for data accesses except those caused by the *Load/Store Caching Inhibited* instructions; Caching Inhibited, for data accesses caused by the *Load/Store Caching Inhibited* instructions
- Memory Coherence Required, for data accesses
- Guarded
- 

Additionally, storage accesses in ultravisor and hypervisor real addressing modes are performed as though all storage was not No-execute.

**Programming Note**

Because storage accesses in ultravisor and hypervisor real addressing modes do not use the SLB or the Page Table, accesses in these modes bypass all checking and recording of information contained therein (e.g., storage protection checks that use information contained therein are not performed, and reference and change information is not recorded).

#### 6.7.3.2.1 Hypervisor Real Mode Storage Control

The Hypervisor Real Mode Storage Control facility provides a means of specifying portions of real storage that are treated as neither Caching Inhibited nor Guarded in ultravisor and hypervisor real addressing modes ( $MSR_{HVPR}=0b10$ , and  $MSR_{IR}=0$  or  $MSR_{DR}=0$ , as appropriate for the type of access). The remaining portions are treated as Caching Inhibited and Guarded in ultravisor and hypervisor real addressing modes.

The means is a hypervisor resource (see Chapter 2), and may also be system-specific.

The facility divides real storage into history blocks, in implementation-specific sizes. The history for instruction fetches is tracked separately from that for data accesses. If there is no instruction fetch history for a block and it is the target of an instruction fetch, the access is performed as though the block is Guarded, but the block is treated as not Guarded for subsequent instruction fetches on a best effort basis, limited by the amount of history that the facility can maintain. If there is no data access history for a block and it is accessed using a *Load/Store Caching Inhibited* instruction, the access is performed as though the block is Guarded, and the block is treated as Guarded for subsequent accesses on a best effort basis, limited by the amount of history that the facility can maintain. If there is no data access history for a block and it is accessed using any other *Load* or *Store* instruction, the access is performed as though the block is Guarded, but the block is treated as not Guarded for subsequent accesses on a best effort basis, limited by the amount of history that the facility can maintain. If the history causes a block to be treated as Guarded, the block is also treated as Caching Inhibited; if the history causes a block to be treated as not Guarded, the block is also treated as not Caching Inhibited.

If the storage location specified by a *Load/Store Caching Inhibited* instruction is in storage that is specified by the Hypervisor Real Mode Storage Control facility to be treated as not Guarded, a Data Storage interrupt occurs. ("specified by the Hypervisor Real Mode Storage Control facility" means "specified in a history block".) The history can be erased using an *slbia* instruction; see Section 6.9.3.2.

**Programming Note**

There are two cautions about mixing different types of accesses (i.e. *Load/Store Caching Inhibited* instructions vs. any other *Load* or *Store* instruction vs. instruction fetches). The first is that if a *Load* or *Store* instruction specifies a location in a block for which history exists and was established by the other type of *Load/Store*, the data access will perform less well than it otherwise would (another type of *Load/Store* and history was established by *Load/Store Caching Inhibited*) or will cause a Data Storage interrupt (*Load/Store Caching Inhibited* and history was established by another type of *Load/Store*). The granularity for concern is the history block. For this caution, instruction fetches are irrelevant because they have their own history mechanism and are always intended to be treated as neither *Caching Inhibited* nor *Guarded*.

The second caution is to avoid storage paradoxes that result from a *Caching Inhibited* access to a location that is held in a cache. The nature of this caution and its solution are described in Section 6.8.2.2, “Altering the Storage Control Bits”. The minimum granularity for concern is the history block, but may be larger, depending on extant translations to the storage in question. Since the consistency of instruction storage is managed by software and ultravisor and hypervisor real mode instruction fetches are always not *Caching Inhibited*, instruction fetches are also irrelevant to this caution.

The facility does not apply to implicit accesses to the Page Table performed during address translation or in recording reference and change information. These accesses are performed as described in Section 6.7.3.4.

**Programming Note**

The preceding capability can be used to improve the performance of software that runs in ultravisor and hypervisor real addressing modes, by causing accesses to instructions and data that occupy well-behaved storage to be treated as neither *Caching Inhibited* nor *Guarded*.

**6.7.3.3 Virtual Real Mode Addressing Mechanism**

If  $MSR_{HV}=0$ , the partition is using Paravirtualized HPT translation ( $PATE_{HR}=0$ ), and  $MSR_{DR}=0$  or  $MSR_{IR}=0$  as appropriate for the type of access, the access is said to be made in virtual real addressing mode and is controlled by the mechanism specified below. The set of storage locations accessible by code is referred to as the Virtualized Real Mode Area (VRMA).

In virtual real addressing mode, address translation, storage protection, and reference and change recording are handled as follows.

- Address translation and storage protection are handled as if address translation were enabled, except that translation of effective addresses to virtual addresses use the SLBE values in Figure 22 instead of the entry in the SLB corresponding to the ESID. In this translation, bits 0:23 of the effective address are ignored (i.e., treated as if they were 0s), bits 24:63-m may be ignored if  $m < 40$ , and the Virtual Page Class Key Protection mechanism does not apply.

**Programming Note**

The Virtual Page Class Key Protection mechanism does not apply because the authority mask that an OS has set for application programs executing with address translation enabled may not be the same as the authority mask required by the OS when address translation is disabled, such as when first entering an interrupt handler.

- Reference and change recording are handled as if address translation were enabled.

Field	Value
ESID	<sup>36</sup> 0
V	1
B	0b01 - 1 TB
VSID	0b00    0x0_01FF_FFFF
K <sub>s</sub>	0
K <sub>p</sub>	undefined
N	0
L	PATE <sub>PS[0]</sub>
C	0
LP	PATE <sub>PS[1:2]</sub>

**Figure 22. SLBE for VRMA**

**Programming Note**

The C bit in Figure 22 is set to 0 because the implementation-specific lookaside information associated with the VRMA is expected to be long-lived. See the Programming Note about Class in Section 6.7.8.1.

**Programming Note**

The 1 TB VSID 0x0\_01FF\_FFFF should not be used by the operating system for purposes other than mapping the VRMA when address translation is enabled.

**Programming Note**

Software should specify  $PTE_B = 0b01$  for all Page Table Entries that map the VRMA in order to be consistent with the values in Figure 22.

### 6.7.3.4 Storage Control Attributes for Implicit Storage Accesses

Implicit accesses to the Partition Table and to a partition-scoped Page Table during address translation and in recording reference and change information are performed as though the storage occupied by the tables had the following storage control attributes.

- not Write Through Required
- not Caching Inhibited
- Memory Coherence Required
- not Guarded
- 

Implicit accesses to a Process Table, Segment table, or process-scoped Page Table during address translation and in recording reference and change information are performed using the storage control attributes in the partition-scoped Page Table Entry that maps the other In-Memory Table Entry or the process-scoped Page Table Entry that is being accessed. The storage control attributes must be those described above.

## 6.7.4 Definitions

**translation mode:** Refers to either HPT translation or Radix Tree translation. The translation mode is specified by the HR field in the Partition Table Entry corresponding to the contents of the LPIDR.

**process-scoped:** Refers to translation performed using tables pointed to by Process Table Entries: guest Radix Tree translation, host Radix Tree translation for quadrants 0 and 3 when  $MSR_{HV}=1$ , or Segment translation.

**partition-scoped:** Refers to translation performed using table(s) found using the first doubleword of Partition Table Entries, either host Radix Tree translation or HPT translation.

**fully-qualified address:** Refers to the address to be translated, when qualified by the effective LPID and effective PID.

**guest real address:** Refers to the input to the partition-scoped translation process when using nested Radix Tree translation.

**virtual address:** Refers to the output of Segment translation and input to HPT translation.

**host real address:** Refers to the output of the partition-scoped translation process in nested Radix Tree

translation or the output of the process-scoped translation in nested Radix Tree translation for quadrants 0 and 3 when  $MSR_{HV}=1$ . The simpler “real address” may be used interchangeably.

**Page Directory:** A table within the Radix Tree translation structure that contains elements (“Page Directory Entries”) that point to other tables, instead of containing just Page Table Entries. The Page Directory that is at the root of the Radix Tree is called the “Root Page Directory.”

**effLPID, effPID:** This is shorthand for effective LPID and effective PID. In certain circumstances, the value used for the LPID and/or the PID is specified to be zero instead of the actual register contents. “Effective” or “eff” is used to indicate the possibility of such a substitution. This value substitution happens only in Radix Tree translation, and is based on the value of  $EA_{0:1}$  (see Section 6.7.5.1, “Effective Address Space Structure for Radix-using Partitions”). Value substitution does not happen in HPT translation. When a guest uses Radix Tree translation, PID substitution may take place. When a host uses Radix Tree translation, both PID and LPID substitution may take place. When a host uses HPT translation, the only special significance associated with  $LPIDR=0$  is with regard to Segment Table walk when  $MSR_{HV}=1$ , as described later.

**adjunct:** An adjunct is a software entity that resides in a partition along with an operating system and its applications in order to efficiently provide services (e.g. device drivers) for the partition. The adjunct is managed by the hypervisor. It runs in problem state with  $MSR_{S_{HV}}_{PR}=0b011$ , thereby restricting the resources it can modify ( $MSR_{PR}=1$ ) and causing its interrupts to go to the hypervisor ( $MSR_{S_{HV}}=0b01$ ). It shares an HPT with the partition it serves. The adjunct’s storage is kept separate from the client partition’s storage using Virtual Page Class Key protection. (The adjunct’s lightness of weight derives from not requiring a full partition context switch (SLB flush, TLB flush, LPID/PID change, etc.) when the client partition invokes the services of the adjunct.) Each hardware thread may have its own unique translations for an adjunct. As a result, adjunct segment descriptors cannot exist in the process’s Segment Table and must instead be bolted in the SLB manually. The adjunct construct exists only with an  $HR=0$  hypervisor and only for  $LPID \neq 0$ . The adjunct has its own 64-bit EA space. Entry to an adjunct is only possible from hypervisor state. Prior to dispatching the adjunct, the hypervisor must invalidate SLB entries that map the effective address range that will be used by the adjunct. Similarly, on exit from the adjunct, the hypervisor must invalidate its SLB entries

## 6.7.5 Address Ranges Having Defined Uses

The address ranges described below have uses that are defined by the architecture.

- Fixed interrupt vectors

Except for the first 256 bytes, which are reserved for software use, the real page beginning at real address 0x0000\_0000\_0000\_0000 is either used for interrupt vectors or reserved for future interrupt vectors.

- Implementation-specific use

The two contiguous real pages beginning at real address 0x0000\_0000\_0000\_1000 are reserved for implementation-specific purposes.

- Offset Real Mode interrupt vectors

The real pages beginning at the real addresses specified by the URMOR and the HRMOR are used similarly to the page for the fixed interrupt vectors.

- Relocated interrupt vectors

Depending on the values of MSR<sub>S HV IR DR</sub> when the interrupt occurs and on the value of LPCR<sub>AIL</sub> or LPCR<sub>HAIL</sub> as appropriate, the virtual page containing the byte addressed by effective address 0xC000\_0000\_0000\_4000 may be used similarly to the page for the fixed interrupt vectors. (See Section 2.2.)

- *System Call Vectored* interrupt vectors

Depending on the values of MSR<sub>S HV IR DR</sub> when the interrupt occurs and on the value of LPCR<sub>AIL</sub> or LPCR<sub>HAIL</sub> as appropriate, the virtual page containing the effective address 0x0000\_0000\_0001\_7000 or 0xc000\_0000\_0000\_3000 contains the interrupt vectors that are invoked by the *System Call Vectored* instruction. (See Section 2.2.)

- Partition Table

A contiguous sequence of real pages beginning at the real address specified by the PTCR contains the Partition Table.

- Page Table

A contiguous sequence of real pages beginning at the real address specified by the first doubleword of the Partition Table Entry when HR=0 contains the Page Table.

### 6.7.5.1 Effective Address Space Structure for Radix-using Partitions

When Radix Tree translation is in use but translation is disabled (MSR<sub>IR</sub>=0 or MSR<sub>DR</sub>=0, as appropriate for the

type of access), MSR<sub>HV</sub> selects between partition-scoped translation of the real mode guest real address, formed by treating EA<sub>0:1</sub> as 0b00, and hypervisor or ultravisor real mode (see Section 6.7.3). When Radix Tree translation is in use and translation is enabled, EA<sub>0:1</sub> together with MSR<sub>HV</sub> are used to select one of as many as three distinct Radix Trees with which to perform process-scoped translation, as a technique to make system calls and interrupts more efficient by avoiding the need to immediately change the contents of the PIDR and LPIDR. (See Figure 23 for an illustration of the mappings.) Since there's nothing to prevent a process from generating any address in the 64b EA space, the exceptional cases are defined as follows. When a quadrant of the EA space has no associated Radix Tree, access to it results in an Instruction Segment exception or Data Segment exception, as appropriate for the type of access. Similarly, reference to any portion of these quadrants or the real mode guest real address described above that is not mapped by a Radix Tree (versus mapped by an invalid entry) will cause an Instruction or Data Segment exception.

#### Programming Note

Note that the quadrant structure is only available to software running in 64b mode with address translation enabled. 32b software will only be able to access storage mapped by its own Radix Tree. When address translation is disabled and HV||PR=0b00, the EA accesses storage mapped into the guest real address space.

#### Programming Note

**Warning:** The functionality described in this section, e.g. directing most hypervisor interrupts to the LPID=0 translation tables, places great importance on the correctness of the format of and mappings in Partition Table Entry 0 and the tables it anchors. An error in any of these structures could have severe consequences including system checkstops and hangs.

#### Programming Note

The intent is that the PIDR and LPIDR contents indicate the process and partition on behalf of which execution is taking place. For example, when a guest process interrupts to the hypervisor, execution to service the interrupt will generally be on behalf of the guest partition. When execution changes to be purely managing hypervisor resources that are not directly tied to any partition, the hypervisor should set LPIDR to 0.

For guest and host applications, quadrant 0 (EA<sub>0:1</sub>=0b00) is mapped by the Radix Tree for the application. For guest operating systems and the hypervisor acting as an operating system (LPIDR=0), quadrant 0 is mapped by the Radix Tree for the appli-

ication and quadrant 3 (EA<sub>0:1</sub>=0b11) is mapped by the Radix Tree for the direct supervisor of the application. Quadrants 1 and 2 have no associated Radix Tree for guest and host applications and guest operating systems, but hold echoes of quadrants 0 and 3 for the hypervisor acting as an operating system.

**Programming Note**

Outboard accelerators may commonly be limited to accessing quadrant 0 as a matter of platform architecture. In such platforms, references to other quadrants may be regarded as errors.

For the hypervisor acting as a hypervisor (LPIDR≠0), quadrant 3 is as described above. Quadrant 1 (EA<sub>0:1</sub>=0b01) is mapped by the Radix Tree for the guest application and quadrant 2 (EA<sub>0:1</sub>=0b10) is mapped by the Radix Tree for the guest operating system, one of which experienced a hypervisor interrupt or performed a system call to the hypervisor. Quadrant 0 has no associated Radix Tree.

When MSR<sub>HV</sub>=1 and EA<sub>0:1</sub>=0b00 or 0b11 (and the quadrant is mapped by a Radix Tree), only process-scoped translation is performed. When MSR<sub>HV</sub>=0 and MSR<sub>IR/DR</sub>=0, only partition-scoped translation is performed. Otherwise, nested process- and partition-scoped translations are performed.

Guest/Host App	Guest OS	Hypervisor
	EA <sub>0:1</sub> =0b11 effPID=0 effLPID=LPIDR	EA <sub>0:1</sub> =0b11 effPID=0 effLPID=0
		EA <sub>0:1</sub> =0b10 effPID=0 effLPID=LPIDR
		EA <sub>0:1</sub> =0b01 effPID=PIDR effLPID=LPIDR
EA <sub>0:1</sub> =0b00 effPID=PIDR effLPID=LPIDR	EA <sub>0:1</sub> =0b00 effPID=PIDR effLPID=LPIDR	EA <sub>0:1</sub> =0b00 effPID=PIDR effLPID=LPIDR (when LPIDR=0)

**Figure 23. Effective address space structure when using Radix Tree translation**

## 6.7.6 In-Memory Tables

The In-Memory Tables are used to find the tables that are used in the actual translation process for the partition and process that are executing. They enable hardware, including accelerator hardware separate and distinct from the Power ISA processors in the platform, to perform the translation process largely without software intervention. Description of the In-Memory Table structure follows. Hardware may cache the contents of the In-Memory Tables. Variants of *tlbie[]* may be used to manage the caching even though the In-Memory Table contents are not cached in the TLB. When “thread” is used in descriptions of the ordering of accesses and operations (e.g. invalidations) related to translation cache management, it should be understood to include execution streams in accelerators unless otherwise stated or obvious from context.

When an address in the In-Memory Table structure is specified to be a virtual or guest real address, the access to that address is considered to be performed with translation on. For a host using HPT translation, a base page size is specified for each such access to be used in the HPT search. The hypervisor can override the Segment Table Page Size in the Process Table Entry (PRTE<sub>STPS</sub>, see Figure 26) using LPCR<sub>ISL</sub>. The base page size for the Process Table (PATE<sub>PRTPS</sub>) can be safely altered by the hypervisor since the OS does not have direct access to the Partition Table Entry. All accesses to the In-Memory Tables, the Segment Tables, and the guest Radix Tables that are performed with translation on, including for instruction address translation, are data accesses performed as if MSR<sub>PR</sub>=0 for the purpose of determining storage protection, although instruction side translation exceptions cause [H]ISI. (A specific example of the implications of this is that tables used to translate instruction fetches may be located in guarded or no-execute storage.)

**Programming Note**

The descriptors in the entries in this section and its subsections contain addresses that are properly aligned so that no shifting is required. For example, the minimum size of the Partition Table is 4KB, so PATB has the thirteenth least significant address bit as its least significant bit. To construct the real address for a 4KB table, 12 zeros are appended on the right, and an appropriate number of address bits are removed from the left to match the real address size (m) supported by the implementation. For an aligned 8K table, bit 51 of the PTCR would be disregarded, and 13 zeros would be appended.

### 6.7.6.1 Partition Table

The Partition Table Control Register (PTCR) is a 64-bit register that contains the host real address of the base

of the Partition Table and specifies its size. Software must ensure that the contents of the PTCR are the same for all processors in the system prior to enabling translation or transferring control to a partition.

///	PATB	//	PATS
0 3	51	58	63

#### Partition Descriptor

Bit(s)	Name	Description
4:51	PATB	Partition Table Base
59:63	PATS	Partition Table Size= $2^{12+PATS}$ PATS $\leq 24$

All other fields are reserved.

**Figure 24. Partition Table Control Register**

#### Programming Note

If it becomes necessary to shrink the Partition Table or to change PATB to point to a table that is not identical to the existing one, it is necessary to issue *tlbie* with RIC=2 to invalidate caching of outdated In-Memory Table Entries.

The Partition Table is composed of a pair of doublewords per partition. The first doubleword indicates whether the partition uses HPT or Radix Tree translation and whether the partition is secure, and contains the base of the host's translation table structure in host real memory. The first doubleword also contains the size of the table structure and the size of the Root Page Directory for a hypervisor using Radix Tree translation, or the base page size for the VRMA for Paravirtualized HPT translation. Additional details about the parameters for HPT translation follow.

The HTABORG field contains the high-order 42 bits of the 60-bit real address of the Page Table. The Page Table is thus constrained to lie on a  $2^{18}$  byte (256 KB) boundary. At least 11 bits from the hash function (see Figure 33) are used to index into the Page Table. The minimum size Page Table is 256 KB ( $2^{11}$  PTEGs of 128 bytes each).

The Page Table can be any size  $2^n$  bytes where  $18 \leq n \leq 46$ . As the table size is increased, more bits are used from the hash to index into the table.

The HTABSIZE field contains an integer giving the number of bits (in addition to the minimum of 11 bits) from the hash that are used in the Page Table index. This number must not exceed 28. HTABSIZE is used to generate a mask of the form 0b00...011...1, which is a string of 28 - HTABSIZE 0-bits followed by a string of HTABSIZE 1-bits. The 1-bits determine which additional bits (beyond the minimum of 11) from the hash are used in the index (see Figure 33).

On implementations that support a real address size of only  $m$  bits,  $m < 60$ , bits 0:59- $m$  of the HTABORG field

are treated as reserved bits, and software must set them to zeros.

#### Programming Note

Let  $n$  equal the virtual address size (in bits) supported by the implementation. If  $n < 67$ , software should set the HTABSIZE field to a value that does not exceed  $n-39$ . Because the high-order 78- $n$  bits of the VSID are assumed to be zeros, the hash value used in the Page Table search will have the high-order  $67-n$  bits either all 0s (primary hash; see Section 6.7.9.2) or all 1s (secondary hash). If  $HTABSIZE > n-39$ , some of these hash value bits will be used to index into the Page Table, with the result that certain PTEGs will not be searched.

#### Example:

Suppose that the Page Table is 16,384 ( $2^{14}$ ) 128-byte PTEGs, for a total size of  $2^{21}$  bytes (2 MB). A 14-bit index is required. Eleven bits are provided from the hash to start with, so 3 additional bits from the hash must be selected. Thus the value in HTABSIZE must be 3. The HPT may begin on any 256KB boundary.

### Paravirtualized HPT Partition Table Entry

Bit(s)	Name	Description
0	HR	Host Radix 0b0- hypervisor uses HPT translation for this partition 0b1- hypervisor uses Radix Tree translation for this partition
3	S	Partition is Secure
4:45	HTABORG	Hashed Page Table Base
56:58	PS	Page Size (uses L  LP encoding as in SLBE)
59:63	HTABSIZE	HPT size = $2^{\text{HTABSIZE}+18}$ $\text{HTABSIZE} \leq 28$
1:38	PRTB	Process Table Base (when UPRT=1)
56:58	PRTPS	Process Table Page Size (when UPRT=1) (uses L  LP encoding as in SLBE)
59:63	PRTS	Process Table Size = $2^{12+\text{PRTS}}$ $\text{PRTS} \leq 24$ (when UPRT=1)

### Radix on Radix Partition Table Entry

Bit(s)	Name	Description
0	HR	Host Radix 0b0- hypervisor uses HPT translation for this partition 0b1- hypervisor uses Radix Tree translation for this partition
1:2	RTS1	Radix Tree Size[0:1]
3	S	Partition is Secure
4:55	RPDB	Root Page Directory Base
56:58	RTS2	Radix Tree Size[2:4] (number of address bits mapped), $\text{size} = 2^{\text{RTS}+31}$
59:63	RPDS	Root Page Directory Size $= 2^{\text{RPDS}+3}$ , $\text{RPDS} \geq 5$
4:51	PRTB	Process Table Base
59:63	PRTS	Process Table Size = $2^{12+\text{PRTS}}$ $\text{PRTS} \leq 24$ (when UPRT=1)

All other fields are reserved.

### Figure 25. Partition Table Entry Variants

The second doubleword of the Partition Table Entry contains the base of the partition's Process Table, which is a guest real address (or effective address when effective LPID=0) for a radix partition and a virtual

address for an HPT partition, and the size of the Process Table. The Process Table is assumed to be aligned. Software that uses Radix Tree translation must set the low order PRTS bits of PRTB to 0s. For an HPT partition, the Process Table base address is specified as a VSID with the assumption that the Process Table is located at zero offset in the segment. The second doubleword also includes the base page size used for the HPT search. Address translation and storage protection for the Process Table Entry are handled as if address translation were enabled using an implied segment descriptor with base page size as just described,  $B=0b01$  (1TB segment),  $K_s=K_p=0$ ,  $N=0$ , and  $C=0$ , and the Virtual Page Class Key Protection mechanism does not apply. The Partition Table Entry variants are illustrated in Figure 25. Note that a configuration with  $HR=1$  for a non-zero LPID and  $HR=0$  for  $LPID=0$  is considered an unsupported MMU configuration because it would attempt to perform HPT translation in quadrants 0 and 3 when  $MSR_{HV}=1$ . In addition,  $LPID=0$  with Radix Tree translation is an unsupported MMU configuration when  $MSR_{HV}=0$ . These two unsupported MMU configurations, plus the case of UPRT being 0 when  $HR=1$ , constitute translation mode mismatches.

### Programming Note

The S bit in Partition Table Entries is provided for use by outboard mechanisms that access storage. The processor uses  $MSR_S$ , not  $PATE_S$ , to determine partition security.

The size of the Process Table is provided to simplify hardware design and testing. The size enables the hardware to mask address bits instead of providing an adder. No size checking is provided. (An out-of-range PID will not produce an exception simply because of its size.) Hypervisor software may protect against such errors by the OS by not providing a translation for virtual / guest real addresses beyond the end of the Process Table.

Similarly, no size checking is provided for the Partition Table. (An out-of-range LPID will not produce an exception simply because of its size.)

### 6.7.6.2 Process Table

The Process Table is composed of a quadword Process Table Entry per process in the partition. For partitions that use HPT translation, the Process Table Entry contains a Segment Table descriptor, which is composed of the origin of the Segment Table in virtual address space, the segment size and base page size for the segment that holds the table, the size of the table, and a Valid bit that is turned off while changes are made to the entry and Segment Table. Address translation and storage protection for the Segment

Table Entry Group are handled as if address translation were enabled using an implied segment descriptor with segment size and base page size as just described,  $K_s=K_p=0$ ,  $N=0$ , and  $C=0$ , and the Virtual Page Class Key Protection mechanism does not apply. For partitions that use Radix Tree translation, the Process Table Entry contains a Radix Tree root descriptor. When running on a host that uses Radix Tree translation, there are two cases. When  $effLPID=0$ , the RPDB is a host real address. Otherwise, the address is a guest real address and must undergo translation using the hypervisor's Radix Tree for the partition (i.e. the "partition-scoped" tables, as defined later).

DW	Bit(s)	Name	Description
0	0:1	B	Segment Table Segment Size
	2:63	STABORGU	Segment Table Origin Upper ( $VA_{0:61}$ )
1	0:3	STABORGL	Segment Table Origin Lower ( $VA_{62:65}$ )
	56:59	STABSIZE	Segment Table Size $= 2^{12+STABSIZE}$ , $STABSIZE \leq 12$
	60:62	STPS	Segment Table Page Size (uses L  LP encoding as in SLBE)
	63	V	Valid

DW	Bit(s)	Name	Description
0	1:2	RTS1	Radix Tree Size[0:1]
	3	/	Reserved
	4:55	RPDB	Root Page Directory Base
	56:58	RTS2	Radix Tree Size[2:4] (number of address bits mapped), $size=2^{RTS+31}$
	59:63	RPDS	Root Page Directory Size $= 2^{RPDS+3}$ , $RPDS \geq 5$

All other fields are reserved.

**Figure 26. Process Table Entry Variants**

## 6.7.7 Address Translation Overview

The effective address (EA) is the address generated by the hardware for an instruction fetch or for a data access. If address translation is enabled, this address is passed to the Address Translation mechanism, which attempts to convert the address to a real address which is then used to access storage. If the effective address cannot be translated, a storage exception (see Section 6.2) occurs.

The architecture defines segment translation and two types of page translation. Segment translation is paired with HPT translation. The other supported "pairing" is two level Radix Tree translation. Either of these pairings can be used to translate an effective address into a host real address. The In-Memory Tables described above determine the translation mode used by a partition, as well as the locations of the Page Tables and Segment Tables, and the base page size for the Segment Tables. When  $MSR_{HV}=1$  and/or  $MSR_{IR}=0$  or  $MSR_{DR}=0$  (as appropriate for the type of access), the steps taken for a given mode vary. See Sections 6.7.11.3 and 6.7.11.4 for details.

The pairing of Segment translation and Hashed Page Table (HPT) translation applies Segment translation to an effective address to produce a virtual address as described in Section 6.7.8, and HPT translation to the virtual address to produce a host real address as described in Section 6.7.9. Segment translations can be established by both the guest and the hypervisor, but the HPT translation is always managed by the hypervisor with the guest typically giving direction via system calls to the hypervisor in a paravirtualization relationship. This mode is commonly referred to as Paravirtualized HPT translation. The segment translation is managed on a per-process ("process-scoped") basis, mapping a smaller effective address space into a large "partition-scoped" virtual address space, where the segment can be used as a shared memory object. There is also the possibility of thread-unique mappings. In the basic version of HPT translation, storage exceptions are directed to the operating system, which in turn issues system calls to the hypervisor. When Virtualized Partition Memory is enabled, storage exceptions are directed to the hypervisor, enabling a higher degree of memory overcommitment as the hypervisor transparently steals pages from the partition. Figure 27 gives an overview of the address translation process.

**Figure 27. Address translation overview**

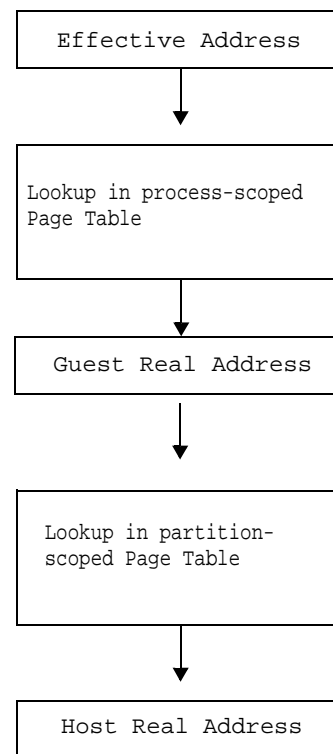

In Paravirtualized HPT mode, the hypervisor also uses the segment/HPT pairing, and can create a process called an “adjunct”. To do so, it eliminates any potentially conflicting guest segment mappings and creates adjunct mappings prior to dispatching the adjunct.

In the other pairing, Radix Tree translation is used for both the process-scoped and partition-scoped mappings. This mode is sometimes referred to as nested Radix or Radix on Radix translation. Figure 28 gives an overview of the address translation process for Radix on Radix translation. Note that each level of the guest Radix Tree produces a guest real address that must itself undergo partition-scoped translation. See Figure 39 for a detailed illustration of the entire process.

Storage exceptions for process-scoped translation are directed to the operating system, and storage exceptions for partition-scoped translation are directed to the hypervisor. (In this categorization, single level translation is considered process-scoped translation except when VPM is active, in which case it is treated like partition-scoped translation.) As a result, for Radix on Radix translation, the hypervisor can use the partition-scoped mapping to limit the size of the guest real address space, and Virtualized Partition Memory is not

necessary to enable a higher degree of memory over-commitment. If in Radix on Radix mode the guest real address is outside the range covered by the partition-scoped Radix Tree, the results are boundedly undefined.

The address specified in ASDR is the guest real address or VSID for which translation has most immediately failed except when the translation fails too early to produce that value. HDAR will generally contain the EA or lower VA bits for which translation has most immediately failed. For example, in the case of a Page Directory being paged out, the ASDR will contain the guest real address of the Page Directory Entry (down to bit 51), rather than the GRA of the datum being accessed. Exceptions may be manifest in unexpected ways. For example, an instruction fetch can fail to set a Change bit in the host PTE mapping the guest PTE. Similarly, the Reference bit update might fail for lack of write authority on the PTE.

**Figure 28. Address translation overview, Radix on Radix**

## Translation Lookaside Buffer

Conceptually, the Page Table is searched by the address relocation hardware to translate every reference. For performance reasons, the hardware usually

keeps a Translation Lookaside Buffer (TLB) that holds PTEs that have recently been used. (Page-size-related information in TLB entries and its use in match checks may differ from that in PTEs; see Section 6.7.9.2 and Section 6.7.10.3.) The TLB is searched prior to searching the Page Table and, for Radix Tree Translation, prior to searching the Page Walk Cache. As a consequence, when software makes changes to the Page Table it must perform the appropriate TLB invalidate operations to maintain the consistency of the TLB with the Page Table (see Section 6.10). An implementation may associate each of its TLB entries with the partition for which the TLB entry was created, so that the entries can be retained while other partitions are executing.

Hardware generally will not create more than one TLB entry to translate a given address. Multiple matching TLB entries may be created only if the Page Table contains PTEs that map different-sized virtual pages that overlap in the virtual address space (HPT translation) or when software fails to invalidate the corresponding TLB entry when changing a page size. If a TLB search during address translation finds multiple matching TLB entries created from such PTEs, one of the matching TLB entries is used as if it were the only matching entry, or a Machine Check occurs. Software should scrupulously avoid creating such mappings.

#### Programming Notes

1. Page Directory Entries may or may not be cached in a PWC.
2. It is possible that the hardware implements more than one PWC, such as one for data and one for instructions. In this case the size and shape of the PWCs may differ, as may the values contained therein.
3. Use the *tlbie* instruction to ensure that the PWC no longer contains information describing a particular portion of a Radix Tree.

#### Programming Notes

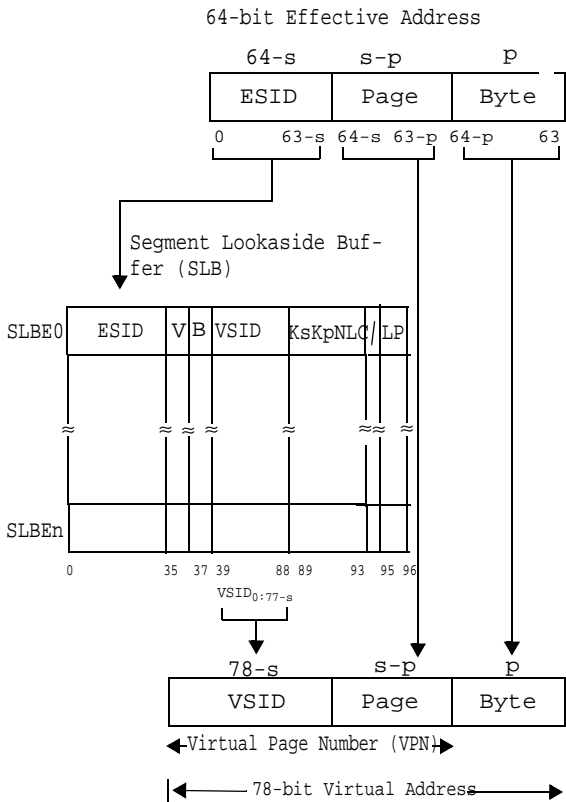

1. Page Table Entries may or may not be cached in a TLB.
2. It is possible that the hardware implements more than one TLB, such as one for data and one for instructions. In this case the size and shape of the TLBs may differ, as may the values contained therein.
3. Use the *tlbie* instruction to ensure that the TLB no longer contains a mapping for a particular page.

## Page Walk Cache

For performance reasons, the hardware usually keeps a Page Walk Cache (PWC) that holds Page Directory Entries that represent partial tree traversals (one or more levels) from recent Radix Tree translations. The PWC is searched (perhaps iteratively, depending on the design) with the goal of skipping some of the storage accesses that would otherwise be needed to traverse the Radix Tree. The internal structures of the Radix Trees are considered to be managed separately from the final translations. When software changes this structure, it must perform appropriate invalidations to the PWC to maintain the consistency of the PWC with the Radix Tree (see Section 6.10). An implementation may associate each of its PWC entries with the partition for which the PWC entry was created, so that the entries can be retained while other partitions are executing.

## 6.7.8 Segment Translation

Conversion of a 64-bit effective address to a virtual address is done by searching the Segment Lookaside Buffer (SLB) as shown in Figure 29. If no matching translation is found in the SLB,  $LPCR_{UPRT}=1$ , and either  $MSR_{HV}=0$  or  $LPID=0$ , the Segment Table is searched. For implicit accesses, implicit segment descriptors are provided, as described elsewhere in this chapter.

**Figure 29. Translation of 64-bit effective address to 78 bit virtual address**

### 6.7.8.1 Segment Lookaside Buffer (SLB)

The Segment Lookaside Buffer (SLB) specifies the mapping between Effective Segment IDs (ESIDs) and Virtual Segment IDs (VSIDs). The number of SLB entries is implementation-dependent, except that all implementations provide at least 32 entries.

The first four entries, and when  $LPCR_{UPRT}=0$  all of the entries, of the SLB are managed by software, using the instructions described in Section 6.9.3.2. See Chapter 13. “Synchronization Requirements for Context Alterations” on page 1353 for the rules that software must follow when updating the SLB.

## SLB Entry

Each SLB entry (SLBE, sometimes referred to as a “segment descriptor”) maps one ESID to one VSID. Figure 30 shows the layout of an SLB entry

Bit(s)	Name	Description
0:35	ESID	Effective Segment ID
36	V	Entry valid (V=1) or invalid (V=0)
37:38	B	Segment Size Selector 0b00 - 256 MB (s=28) 0b01 - 1 TB (s=40) 0b10 - reserved 0b11 - reserved
39:88	VSID	Virtual Segment ID
89	$K_s$	Supervisor (privileged) state storage key (see Section 6.7.13.2)
90	$K_p$	Problem state storage key (See Section 6.7.13.2.)
91	N	No-execute segment if N=1
92	L	Virtual page size selector bit 0
93	C	Class
95:96	LP	Virtual page size selector bits 1:2

All other fields are reserved.  $B_0$  (SLBE<sub>37</sub>) is treated as a reserved field.

**Figure 30. SLB Entry**

Instructions cannot be executed from a No-execute (N=1) segment.

Segments may contain a mixture of page sizes. The L and LP bits specify the base virtual page size for the segment. The  $SLB_{L|LP}$  encodings are those shown in Figure 31. The base virtual page size (also referred to as the “base page size”) is the smallest virtual page size that can be used to map a given access, and in most cases is the smallest virtual page size for the segment. (The exception is that multiple base virtual page sizes can occur within the same segment when the base page size specified for a given implicit access (e.g. of one segment table) does not match the base page size specified for another implicit access (e.g. of a different segment table or the process table) or for explicit accesses. References to the base page size for a segment will be understood not to preclude or functionally conflict with this possibility.) The base virtual page size is  $2^b$  bytes. The actual virtual page size (also referred to as the “actual page size” or “virtual page size”) is specified by  $PTE_{L|LP}$ .

encoding	base page size
0b000	4 KB
0b101	64 KB
additional values <sup>1</sup>	2 <sup>b</sup> bytes, where b > 12 and b may differ among encoding values
<sup>1</sup> The “additional values” are implementation-dependent, as are the corresponding base virtual page sizes. Any values that are not supported by a given implementation are reserved in that implementation.	

**Figure 31. Page Size Encodings**

For each SLB entry, software must ensure the following requirements are satisfied.

- L||LP contains a value supported by the implementation.
- The base virtual page size selected by the L and LP fields does not exceed the segment size selected by the B field.
- If s=40, the following bits of the SLB entry contain 0s.
  - ESID<sub>24:35</sub>
  - VSID<sub>38:49</sub>

The bits in the above two items are ignored by the hardware.

The Class field of the SLBE is used in conjunction with the *slbie*, *slbieg*, and *slbia* instructions (see Section 6.9.3.2). “Class” refers to a grouping of SLB entries and implementation-specific lookaside information so that only entries in a certain group need be invalidated and others might be preserved. The Class value assigned to an implementation-specific lookaside entry derived from an SLB entry must match the Class value of that SLB entry. The Class value assigned to an implementation-specific lookaside entry derived from real mode address “translation,” SLS address translation, or translations required to access the Segment Table Entry Group is 0.

Software must ensure that the SLB contains at most one entry that translates a given effective address, and that if the SLB contains an entry that translates a given effective address, then any previously existing translation of that effective address has been invalidated. An attempt to create an SLB entry that violates this requirement may cause a Machine Check.

#### Programming Note

Class values should be assigned such that Class 0 is used for translations that are expected to be long-lived and Class 1 is used for translations that are expected to be short-lived. This assignment facilitates use of the *slbia* instruction, for which several IH values cause preferential invalidation of Class 1 SLB entries and lookaside information entries.

#### Programming Note

It is permissible for software to replace the contents of a valid SLB entry without invalidating the translation specified by that entry provided the specified restrictions are followed. See Chapter 13 Note 10.

### 6.7.8.2 SLB Search

When the hardware searches the SLB, all entries are tested for a match with the EA. For a match to exist, the following conditions must be satisfied for indicated fields in the SLBE.

- V=1
- ESID<sub>0:63-s</sub>=EA<sub>0:63-s</sub>, where the value of s is specified by the B field in the SLBE being tested

If no match is found, the search fails. If one match is found, the search succeeds. If more than one match is found, one of the matching entries is used as if it were the only matching entry, or a Machine Check occurs.

If the SLB search succeeds, the virtual address (VA) is formed from the EA and the matching SLB entry fields as follows.

$$VA = VSID_{0:77-s} \parallel EA_{64-s:63}$$

The Virtual Page Number (VPN) is bits 0:77-p of the virtual address. The value of p is the actual virtual page size specified by the PTE used to translate the virtual address (see Section 6.7.9.1). If SLBE<sub>N</sub> = 1, the N (No-execute) value used for the storage access is 1.

If the SLB search fails and the state is not such that a Segment Table search will be performed, a *segment fault* occurs. This is an Instruction Segment exception or a Data Segment exception, depending on whether the effective address is for an instruction fetch or for a data access.

### 6.7.8.3 Segment Table Description and Search

The Segment Table is an aligned structure composed of 16B segment descriptors organized into 128 byte Segment Table Entry Groups (STEGs). Let q = STAB-SIZE+12, log<sub>2</sub>(size of the Segment Table). The base of the Segment Table in virtual address space is

STABORG<sub>0:77-q</sub> || <sup>q</sup>0. Software must set the low order q-12 bits of STABORG to 0s. Primary and secondary hashes are defined for 256MB and 1TB segments, each mapping the ESID to an STEG. The appropriate number (for the size of the Segment Table) of low order ESID bits (their inverse, for the secondary hash) directly select the STEG. The order of STEG specification in the following subsections is the preferred order for a serial search. Implementations may search the STEGs in parallel. If no match is found, a segment fault occurs. If a serial search is done, the search may stop when a match has been found. If more than one match is found, one of the matching entries is used as if it were the only matching entry.

ESID	V	//	B	VSID	K <sub>s</sub> K <sub>p</sub> NLC	/	LP	SW	
0	35	36	63	65	115	120	121	123	127

Bit(s)	Name	Description
0:35	ESID	Effective Segment ID
36	V	Entry valid (V=1) or invalid (V=0)
64:65	B	Segment Size Selector 0b00 - 256 MB (s=28) 0b01 - 1 TB (s=40) 0b10 - reserved 0b11 - reserved
66:115	VSID	Virtual Segment ID
116	K <sub>s</sub>	Supervisor (privileged) state storage key (see Section 6.7.13.2)
117	K <sub>p</sub>	Problem state storage key (See Section 6.7.13.2.)
118	N	No-execute segment if N=1
119	L	Virtual page size selector bit 0
120	C	Class
122:123	LP	Virtual page size selector bits 1:2
124:127	SW	available for software use

All other fields are reserved.

**Figure 32. Segment Table Entry**

### 6.7.8.3.1 Primary Hash for 256MB Segment

The STEG is located at host VA STABORG<sub>0:77-q</sub> || EA<sub>43-q:35</sub> || 0b0000000. Each of the 8 STEs are searched to find a valid entry (V=1, B=0b00) that matches the ESID (STE<sub>ESID[0:35]</sub> = EA<sub>0:35</sub>) of the access being translated.

### 6.7.8.3.2 Primary Hash for 1TB Segment

The STEG is located at host VA STABORG<sub>0:77-q</sub> || EA<sub>31-q:23</sub> || 0b0000000. Each of the 8 STEs are searched to find a valid entry (V=1, B=0b01) that matches the ESID (STE<sub>ESID[0:23]</sub> = EA<sub>0:23</sub>) of the access being translated.

### 6.7.8.3.3 Secondary Hash for 256MB Segment

The STEG is located at host VA STABORG<sub>0:77-q</sub> || ¬EA<sub>43-q:35</sub> || 0b0000000.

Each of the 8 STEs are searched to find a valid entry (V=1, B=0b00) that matches the ESID (STE<sub>ESID[0:35]</sub> = EA<sub>0:35</sub>) of the access being translated.

### 6.7.8.3.4 Secondary Hash for 1TB Segment

The STEG is located at host VA STABORG<sub>0:77-q</sub> || ¬EA<sub>31-q:23</sub> || 0b0000000. Each of the 8 STEs are searched to find a valid entry (V=1, B=0b01) that matches the ESID (STE<sub>ESID[0:23]</sub> = EA<sub>0:23</sub>) of the access being translated.

## 6.7.9 Hashed Page Table Translation

In Paravirtualized HPT mode, conversion of a 78-bit virtual address to a real address is done by searching the Page Table as shown in Figure 33.

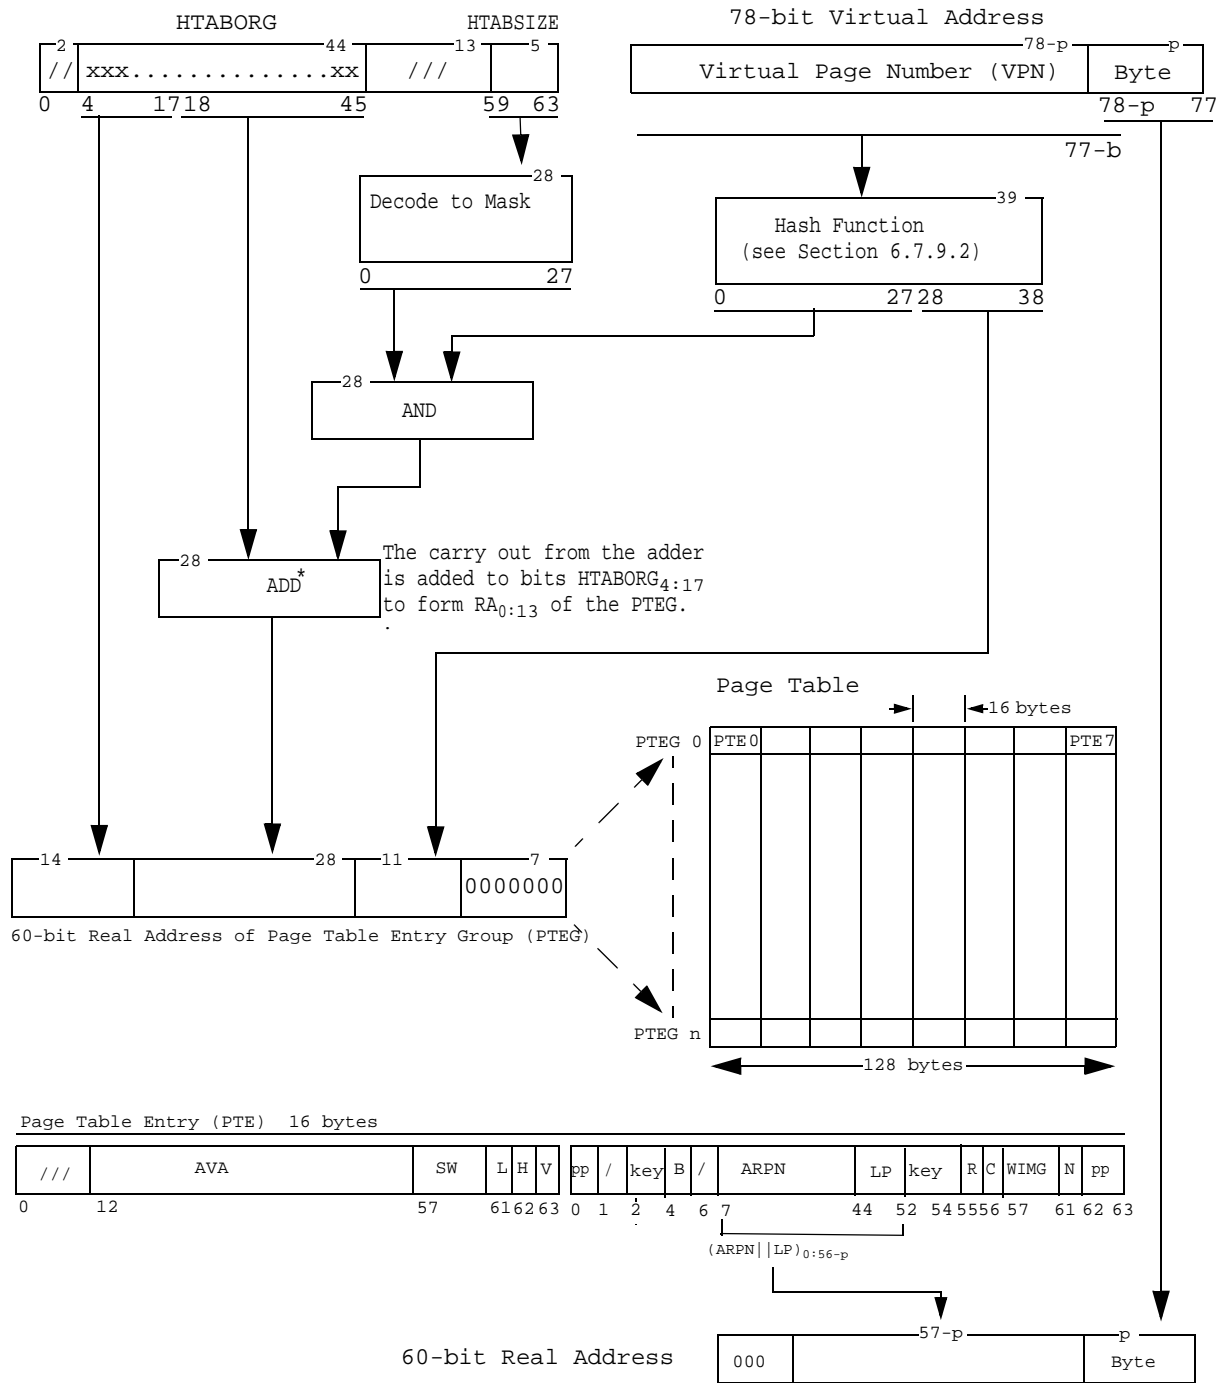

Figure 33. Translation of 78-bit virtual address to 60-bit real address

### 6.7.9.1 Hashed Page Table

The Hashed Page Table (HTAB) is a variable-sized data structure that specifies the mapping between virtual page numbers and real page numbers, where the real page number of a real page is bits 0:47 of the address of the first byte in the real page. The HTAB's size can be any size  $2^n$  bytes where  $18 \leq n \leq 46$ . The HTAB must be located in storage having the storage control attributes that are used for implicit accesses to it (see Section 6.7.3.4). The starting address must be a multiple of  $2^{18}$  bytes.

The HTAB contains Page Table Entry Groups (PTEGs). A PTEG contains 8 Page Table Entries (PTEs) of 16 bytes each; each PTEG is thus 128 bytes long. PTEGs are entry points for searches of the Page Table.

See Section 6.10 for the rules that software must follow when updating the Page Table.

#### Programming Note

The Page Table must be treated as a hypervisor resource (see Chapter 2), and therefore must be placed in real storage to which only the hypervisor has write access. Moreover, the contents of the Page Table must be such that non-hypervisor software cannot modify storage that contains hypervisor programs or data.

### Page Table Entry

Each Page Table Entry (PTE) maps one VPN to one RPN. Figure 34 shows the layout of a PTE. This layout is independent of the Endian mode of the thread.

Dword	Bit(s)	Name	Description
0	12:56	AVA	Abbreviated Virtual Address
	57:60	SW	Available for software use
	61	L	Virtual page size 0b0 - 4 KB 0b1 - greater than 4KB (large page)
	62	H	Hash function identifier
	63	V	Entry valid (V=1) or invalid (V=0)
1	0	pp	Page Protection bit 0
	2:3	key	KEY bits 0:1
	4:5	B	Segment Size 0b00 - 256 MB 0b01 - 1 TB 0b10 - reserved 0b11 - reserved

Dword	Bit(s)	Name	Description
7:43	ARNP	Abbreviated Real Page Number	
44:51	LP	Large page size selector	
52:54	key	KEY bits 2:4	
55	R	Reference bit	
56	C	Change bit	
57:60	WIMG	Storage control bits	
61	N	No-execute page if N=1	
62:63	pp	Page Protection bits 1:2	

All other fields are reserved.

Figure 34. Page Table Entry

#### Programming Note

The H bit in the Page Table Entry should not be set to one unless the secondary Page Table search has been enabled.

Because the length of the Abbreviated Virtual Address (AVA) field is only 45 bits, on implementations of this version of the architecture the virtual address size cannot exceed 68 bits ( $n \leq 68$ ). On implementations for which  $n < 68$ , bits 0:67-n of the AVA field must be zeros.

If  $b \leq 23$ , the AVA field contains bits 10:54 of the VA. Otherwise bits 0:67-b of the AVA field contain bits 10:77-b of the VA, and bits 68-b:44 of the AVA field must be zero.

#### Programming Note

The AVA field omits the low-order 23 bits of the VA. These bits are not needed in the PTE, because the low-order b of these bits are part of the byte offset into the virtual page and, if  $b < 23$ , the high-order 23-b of these bits are always used in selecting the PTEs to be searched (see Section 6.7.9.2).

A virtual page is mapped to a sequence of  $2^{p-12}$  contiguous real pages such that the low-order p-12 bits of the real page number of the first real page in the sequence are 0s.

$PTE_{L,LP}$  specify both a base virtual page size (henceforth referred to as the “base page size”) and an actual virtual page size (henceforth referred to as the “actual page size” or “virtual page size”). The actual page size is the size of the virtual page mapped by the PTE. The base page size is the smallest actual page size that a segment can contain for explicit accesses or for a given implicit access, and plays a role in the placement of the PTE in the HPT.

If  $PTE_L=0$ , the base virtual page size and actual virtual page size are 4KB, and ARPN concatenated with LP ( $ARNP||LP$ ) contains the page number of the real page that maps the virtual page described by the entry.

If  $PTE_L=1$ , the base page size and actual page size are specified by  $PTE_{LP}$ . In this case, the contents of  $PTE_{LP}$  have the format shown in Figure 35. Bits labelled “r” are bits of the real page number. Bits labelled “z” specify the base page size and actual page size. The values of the “z” bits used to specify each size are implementation-dependent. The values of the “z” bits used to specify each size, along with all possible values of “r” bits in the LP field, must result in LP values distinct from other LP values for other sizes. Actual page sizes 4KB and 64KB are always supported; other actual page sizes are implementation-dependent. If  $PTE_L=1$ , the actual page size must be greater than 4 KB. Which combinations of different base page size and actual page size are supported is implementation-dependent, except that the combination of a base page size of 4 KB with an actual page size of 64 KB is always supported.

$PTE_{LP}$	actual page size
rrrr_rrrz	≥8 KB
rrrr_rrzz	≥16 KB
rrrr_rzzz	≥32 KB
rrrr_zzzz	≥64 KB
rrrz_zzzz	≥128 KB
rrzz_zzzz	≥256 KB
rzzz_zzzz	≥512 KB
zzzz_zzzz	≥1 MB

**Figure 35. Format of  $PTE_{LP}$  when  $PTE_L=1$**

There are at least 2 formats of  $PTE_{LP}$  that specify a 64 KB page. One format is used with  $SLBE_{L|LP} = 0b000$  and one format is used with  $SLBE_{L|LP} = 0b101$ .

The actual page size selected by the LP field must not exceed the segment size selected by the B field. Forms of  $PTE_{LP}$  not supported by a given implementation are treated as reserved values for that implementation.

The concatenation of the ARPN field and bits labeled “r” in the LP field contain the high-order bits of the real page number of the real page that maps the first 4KB of the virtual page described by the entry.

The low-order p-12 bits of the real page number contained in the ARPN and LP fields must be 0s and are ignored by the hardware.

#### Programming Note

The actual page size specified by a given  $PTE_{LP}$  format is at least  $2^{12+(8-c)}$ , where c is the number of r bits in the format.

#### Programming Note

Implementations often have TLBs and implementation-specific lookaside buffers (e.g. ERATs) used to cache translations of recently used storage addresses. Mapping virtual storage to large pages may increase the effectiveness of such lookaside buffers, improving performance, because it is possible for such buffers to translate a larger range of addresses, reducing the frequency that the Page Table must be searched to translate an address.

Instructions cannot be executed from a No-execute (N=1) page.

## Page Table Size

The number of entries in the Page Table directly affects performance because it influences the hit ratio in the Page Table and thus the rate of page faults. If the table is too small, it is possible that not all the virtual pages that actually have real pages assigned can be mapped via the Page Table. This can happen if too many hash collisions occur and there are more than 16 entries for the same primary/secondary pair of PTEGs (when the secondary Page Table search is enabled) or more than 8 entries for the same primary PTEG (when the secondary Page Table search is disabled).

While this situation cannot be guaranteed not to occur for any size Page Table, making the Page Table larger than the minimum size (see Section 6.7.6.1) will reduce the frequency of occurrence of such collisions.

#### Programming Note

If large pages are not used, it is recommended that the number of PTEGs in the Page Table be at least half the number of real pages to be accessed. For example, if the amount of real storage to be accessed is  $2^{31}$  bytes (2 GB), then we have  $2^{31-12}=2^{19}$  real pages. The minimum recommended Page Table size would be  $2^{18}$  PTEGs, or  $2^{25}$  bytes (32 MB).

### 6.7.9.2 Page Table Search

When the hardware searches the Page Table, the accesses are performed as described in Section 6.7.3.4.

An outline of the HTAB search process is shown in Figure 33. Up to two hash functions are used to locate a PTE that may translate the given virtual address.

1. A 39-bit hash value is computed from the VA. The value of s is the value specified in the SLBE that was used to generate the virtual address; the value of b is equal to  $\log_2(\text{base page size specified})$ .

in the SLBE that was used to translate the address). **Primary Hash:**

If  $s=28$ , the hash value is computed by Exclusive ORing  $VA_{11:49}$  with  $(^{11+b}0||VA_{50:77-b})$

If  $s=40$ , the hash value is computed by Exclusive ORing the following three quantities:  $(VA_{24:37} ||^{25}0)$ ,  $(0||VA_{0:37})$ , and  $(^{b-1}0||VA_{38:77-b})$

The 60-bit real address of a PTEG is formed by concatenating the following values:

- Bits 0:27 of the 39-bit appropriate primary or secondary hash value ANDed with the mask generated from bits 59:63 of the first doubleword of the Partition Table Entry (HTABSIZE) and then added to the value of bits 4:45 of the first doubleword of the Partition Table Entry (HTABORG).
- Bits 28:38 of the 39-bit hash value.
- Seven 0-bits.

This operation identifies a particular PTEG, called the “primary PTEG”, whose eight PTEs will be tested.

## 2. Secondary Hash:

If the secondary Page Table search is enabled ( $LPCR_{TC}=0$ ), perform the secondary hash function as follows; otherwise do not perform step 2 and proceed to step 3 below.

If  $s=28$ , the hash value is computed by taking the ones complement of the Exclusive OR of  $VA_{11:49}$  with  $(^{11+b}0||VA_{50:77-b})$

If  $s=40$ , the hash value is computed by taking the ones complement of the Exclusive OR of the following three quantities:  $(VA_{24:37} ||^{25}0)$ ,  $(0||VA_{0:37})$ , and  $(^{b-1}0||VA_{38:77-b})$

The 60-bit real address of a PTEG is formed by concatenating the following values:

- Bits 0:27 of the 39-bit appropriate primary or secondary hash value ANDed with the mask generated from bits 59:63 of the first doubleword of the Partition Table Entry (HTABSIZE) and then added to the value of bits 4:45 of the first doubleword of the Partition Table Entry (HTABORG).
- Bits 28:38 of the 39-bit hash value.
- Seven 0-bits.

This operation identifies the “secondary PTEG”.

3. As many as 8 PTEs in the primary PTEG and, if the secondary Page Table search is enabled, 8 PTEs in the secondary PTEG are tested to determine if any translate the given virtual address. Let  $q = \text{minimum}(54, 77-b)$ . For a match to exist, the following conditions must be satisfied, where SLBE is the SLBE used to form the virtual address.
  - $PTE_H=0$  for the primary PTEG, 1 for the secondary PTEG
  - $PTE_V=1$

- $PTE_B=SLBE_B$
- $PTE_{AVA[0:q-10]}=VA_{10:q}$
- if  $b = 12$  then
  - ( $PTE_L = 0$ ) | ( $PTE_{LP}$  specifies the 4KB base page size)
  - else
  - ( $PTE_L = 1$ ) & ( $PTE_{LP}$  specifies the base page size specified by  $SLBE_{L|LP}$ )

If no match is found, the search fails. The result is a page fault -- a [Hypervisor] Instruction Storage exception or a [Hypervisor] Data Storage exception, depending on whether the effective address is for an instruction fetch or for a data access. If one match is found, the search succeeds. If more than one match is found, one of the matching entries is used as if it were the only matching entry, or a Machine Check occurs.

If the Page Table search succeeds, the real address (RA) is formed by concatenating the following values, where the  $p$  value is the  $\log_2$  (actual page size specified by  $PTE_{L|LP}$ ).

- three 0 bits
- bits 0:56- $p$  of  $ARNP||LP$  from the matching PTE
- bits 64- $p$ :63 of the effective address (the byte offset)

$$RA = 0b000 || (ARNP || LP)_{0:56-p} || EA_{64-p:63}$$

A TLB entry may be created as a result of the successful HPT translation. Depending on the specific TLB implementation, the scope of the entry may be the base page size, the virtual page size, or any page size in between. The TLB entry may omit the base and actual page sizes. When the TLB is searched during address translation, the set of VA bits that is used in the match check is determined by the scope of the TLB entry rather than by the base page size and the base page size may be omitted from the match check. In the absence of a TLB, software would be required to create a PTE for each base page sized piece of storage within the virtual page. The number of PTEs actually created to map a virtual page will depend on the scopes supported for TLB entries, the access pattern, and the lifetime of the TLB entries.

**Programming Note**

In versions of the architecture that precede Version 3.1B, the TLB entry was required to contain the base and actual page sizes and the match criteria for the TLB entry were identical to those for the Page Table Entry. This enabled the base page size specified by L||LP in the SLB Entry to select among multiple potential matching TLB entries whose match criteria differed only by base page size. The optionality of base page size in the TLB entry on processors that comply with Version 3.1B of the architecture or with any subsequent version requires that software invalidate all TLB entries mapping a virtual segment after changing L||LP in the Segment Table and/or SLB Entry for the segment and before creating any PTEs, for the segment, that contain the new base page size. Base page size continues to be part of the PTE match criteria and a base page size match is required to cache a PTE in the TLB. As a result, software may replace PTEs containing the old base page size lazily, rather than invalidating them along with the TLB Entries when the base page size for the segment is changed.

**Programming Note**

If  $PTE_L = 0$ , the actual page size (and base page size) are 4 KB. Otherwise the actual page size and base page size are specified by  $PTE_{LP}$ .

Since hardware searches the Page Table using a value of  $b$  equal to  $\log_2$  (base page size specified in the SLBE that was used to translate the address) regardless of the actual page size, the hardware Page Table search will identify different PTEs for VAs in different  $2^b$ -byte blocks of the virtual page if the actual page size is larger than the base page size. Therefore, there may need to be a valid PTE corresponding to each  $2^b$ -byte block of the virtual page that is referenced. For an actual page size that is larger than  $2^{23}$  (8 MB), the  $PTE_{AVA}$  will differ among some or all of these PTEs. Depending on the Page Table size, some or all of these PTEs may be in the same PTEG. Any such PTEs that are in the same PTEG will differ in the value of  $PTE_H$  or  $PTE_{AVA}$  or both.

All PTEs for the same virtual page should have the same values in the Page Protection, KEY, ARPN, WIMG, and N fields. A set of values from any one of the PTEs that maps the virtual page may be used for an access in the virtual page since lookaside buffer information may be used to translate the virtual address.

To avoid creating multiple matching PTEs, software should not create PTEs for each of two different virtual pages that overlap in the virtual address space. If the virtual page sizes differ, two virtual pages overlap if the values of virtual address bits 0:77-p for both virtual pages are the same, where  $2^p$  is the actual virtual page size of the larger page.

**Programming Note**

Because a segment may contain pages of different sizes, the Page Table search uses the segment's base page size (which is the same for all virtual pages in the segment).

- The value of  $b$  used when searching the Page Table to identify the PTEGs to be checked for a match is  $\log_2$ (segment's base page size).
- A PTE (in the selected PTEGs) satisfies the Page Table search only if the base page size specified in the PTE is equal to the segment's base page size.

The matching PTE supplies the actual page size,  $2^p$ ; this value of  $p$  is used in forming the real address.

A virtual page of  $2^p$  bytes in a segment with a base page size of  $2^b$  bytes may be mapped by as many as  $2^{(p-b)}$  PTEs.

**Programming Note**

To obtain the best performance, Page Table Entries should be allocated beginning with the first empty entry in the primary PTEG, or with the first empty entry in the secondary PTEG if the primary PTEG is full and the secondary Page Table search is enabled ( $LPCR_{TC}=0$ ).

In Paravirtualized HPT mode, the N (No-execute) value used for the storage access is the result of ORing the N bit from the matching PTE with the N bit from the SLB entry that was used to translate the effective address.

**6.7.10 Radix Tree Translation**

Radix Tree translation uses a nested set of tables to map storage with increasing granularity. Although there is no requirement for an individual table to have uniform content, Page Directories generally contain pointers to other Page Directories or Page Tables (Page Directory Entries, PDEs), while Page Tables are the leaf tables that contain PTEs. Each Page Directory Entry and Page Table Entry in the Radix Tree is 8 bytes long. A Radix Tree root descriptor (RTRD) specifies the size of the address being translated, the size of the root table, and its location. RTRDs appear in variants of the Partition and Process Table Entries. (See Figures 25 and 26.) The Root Page Directory Size (RPDS) is specified as  $\log_2$  (number of entries in the table). That number of bits is taken from the most significant end of the portion of the address being translated, as an index to choose an element in the Root Page Directory. The entries in the Root Page Directory each point to another page of entries, and give its size in the Next Level Size field,  $PDE_{NLS}$ . The next most significant NLS bits are taken from the address to choose an entry in that table. The process continues until an entry is found that has its Leaf bit set, indicating it is a Page Table Entry. The base size of the page mapped by the PTE is determined by the number of bits remaining in the address after removing the bits used to select the Page Directory and Page Table Entries. An example with  $RPDS = 13$  and  $PDE_{NLS} = 9$  in each Page Directory is shown in Figure 36.

The sizes of table supported at each level of the Radix Tree, as well as the ultimate page sizes supported, are implementation specific with the following exceptions. Implementations must support two Radix Tree configurations that map 52 bit effective addresses: each starting with a 64KB root page size followed by 2 levels of 4KB tables, ending with either a 256 byte table or a 4KB table. The former produces a page size of 64KB and the latter a 4KB page size. In both cases, a leaf node in the next to last level of table produces a 2MB page size.

For performance reasons, the result of each walk of a Radix Tree may be cached in a TLB. Logically, the

result of each walk is cached separately. For nested translation (see Section 6.7.10.3), the effective to guest real (process-scoped) translation may be cached, as well as the partition-scoped translation for each guest real address produced by the translation process. A minimum of two TLB accesses is required to complete a nested translation: one for the effective to guest real address and one for the guest real to host real address. (An implementation may optimize the process, as long as the optimization can be managed correctly using the *tlbie* instructions that software will use to manage the logical model.) The scope of a TLB entry is the size of the page that is mapped by the corresponding PTE. When the TLB is searched during address translation, the scope of the TLB entry determines the set of address bits that is used in the match check; however, the page size need not be part of the match check.

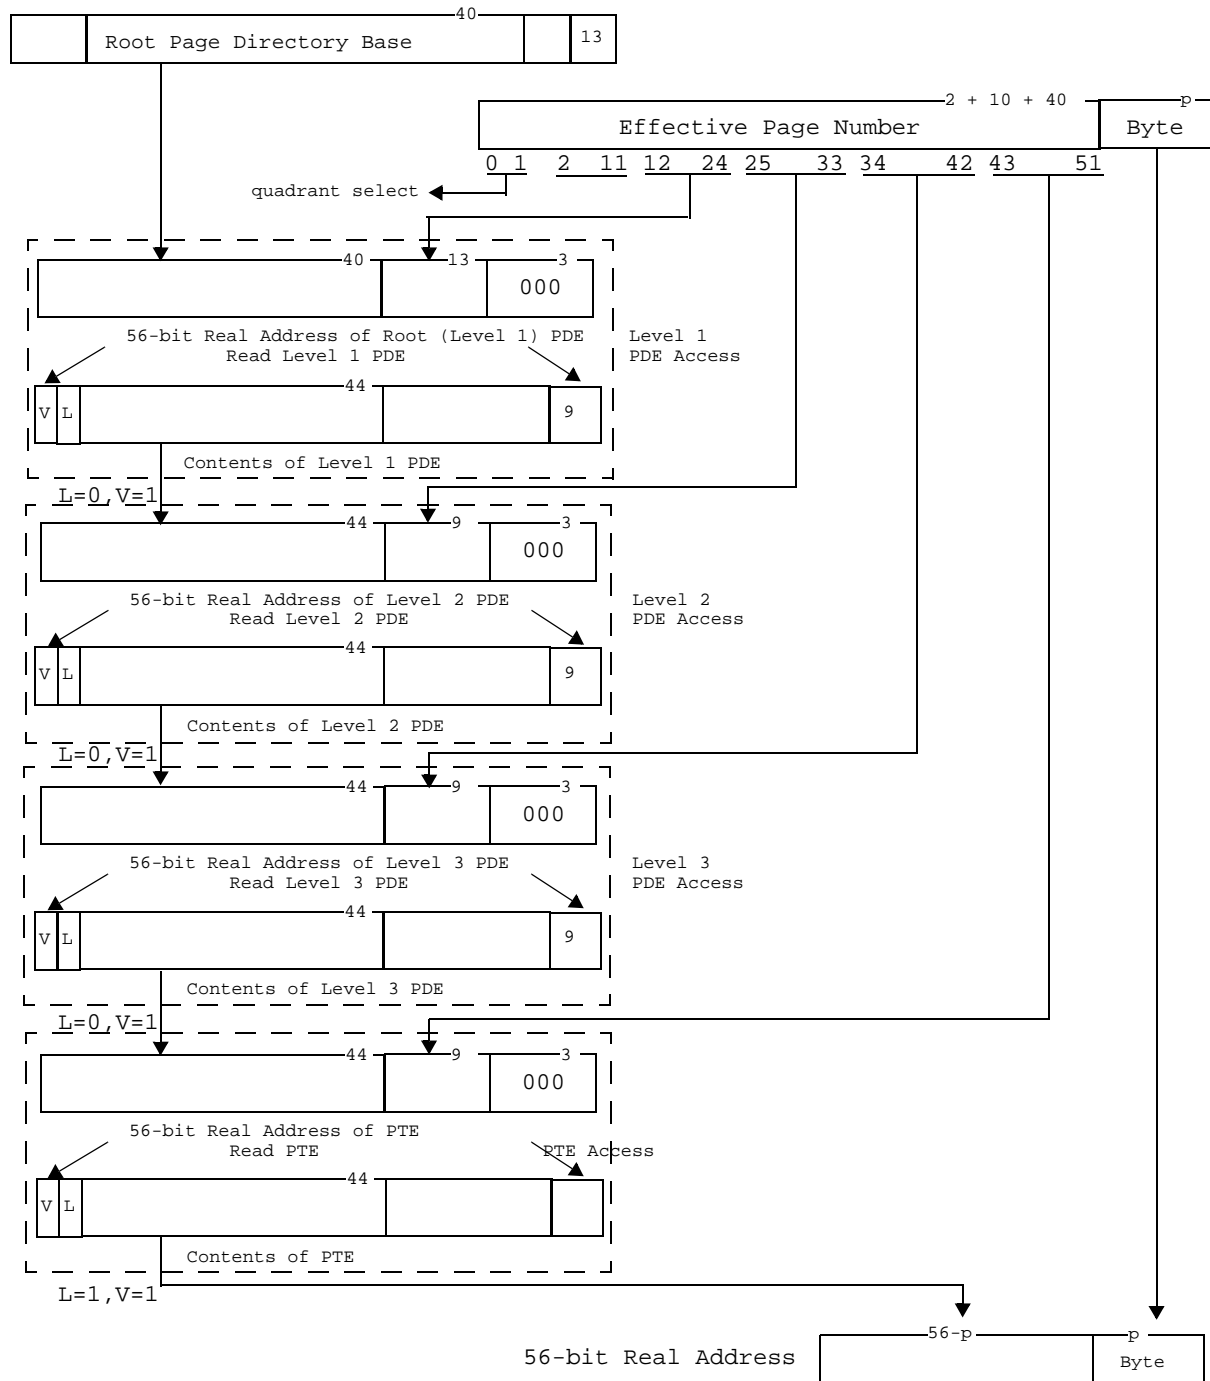

Figure 36. Four level Radix Tree walk translating a 52b EA with NLS=13 in the root PDE and NLS=9 in the other PDEs.

### 6.7.10.1 Radix Tree Page Directory Entry

Bit(s)	Name	Description
0	V	Valid
1	L	Leaf (entry is a PTE)
2	SW	Available for software use
4:55	NLB	Next Level Base
59:63	NLS	Next Level Size (size of next level of table is $2^{\text{NLS}+3}$ ), $\text{NLS} \geq 5$

All other fields are reserved.

**Figure 37. Radix Tree Page Directory Entry**

#### Programming Note

Although the SW field first appeared in the PDE in Version 3.1B of the architecture, it is available for software use on any implementation that supports Radix Tree translation.

All other fields are reserved.

**Figure 38. Radix Tree Page Table Entry**

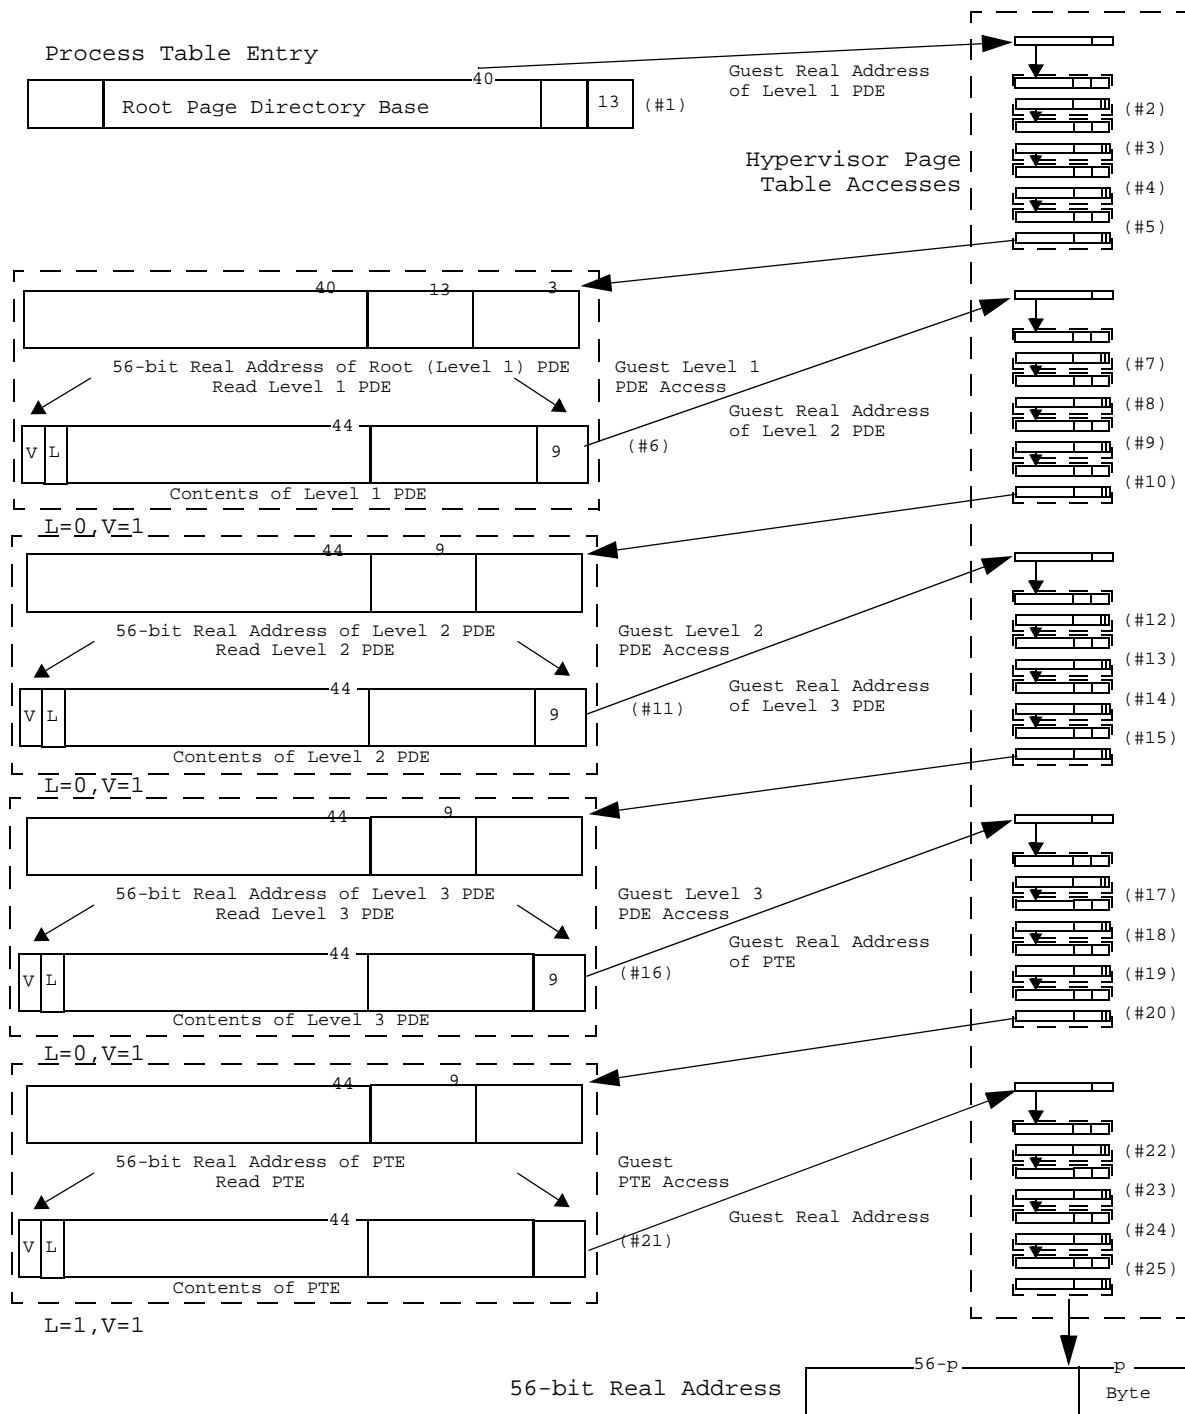

### 6.7.10.3 Nested Translation

When  $\text{MSR}_{\text{HV}}=0$  and translation is enabled, each guest real address must undergo partition-scoped translation using the hypervisor's Radix Tree for the partition. See Figure 39.

### 6.7.10.2 Radix Tree Page Table Entry

V	L	sw	//	RPN	sw	R	C	/	ATT	EAA
0	1	2	6	51	54	55	56	57	59	63

Bit(s)	Name	Description
0	V	Valid
1	L	Leaf (entry is a PTE)
2	sw	SW bit 0
7:51	RPN	Real Page Number
52:54	sw	SW bits 1:3
55	R	Reference
56	C	Change
58:59	ATT	Attributes (equivalent WIMG value) 0b00- normal memory (0010) 0b01- reserved 0b10- non-idempotent I/O (0111) 0b11- tolerant I/O (0110)
60:63	EAA	Encoded Access Authority
0		Privilege (applies only to process-scoped translation) 0 - problem state access permitted; privileged access controlled by key 0 of the [!]AMR 1 - privileged access only
1	Read	0 - loads not permitted 1 - loads permitted
2	Read/Write	0 - loads and stores not permitted 1 - loads and stores permitted
3	Execute	0 - instruction execution not permitted 1 - instruction execution permitted

**Figure 39. Radix on Radix Page Table search for a 52-bit EA depicting memory reads 1-24 numbered in sequence**

When nested translation is being performed, there is the potential for two different sets of protection settings and two different sets of storage attributes. For protection settings, the least permissive values take effect.

For read, write, and execute authority, each is controlled independently based on the least permissive setting of the two translation mechanisms (including all component authority mechanisms within each of them). The Guarded attribute is controlled by the process-scoped PTE. Mismatches of the Caching Inhibited attribute have the following behavior. If the process-scoped PTE specifies  $l=1$  when the parti-

tion-scoped PTE specifies  $I=0$ , the result is  $I=0$ . The reverse mismatch causes a Data Storage or Instruction Storage exception, as appropriate for the access. The results of these rules are shown in Table 5. Together these rules can produce the  $WIMG=0b0011$  state that any individual ATT value cannot express.

For instructions that cause a [Hypervisor] Data Storage interrupt if the storage operand is in Caching Inhibited storage, if  $I=1$  in both the process-scoped and the partition-scoped PTE that map the storage operand the interrupt is a Data Storage interrupt. Similar applies to prefixed instructions that are in Caching Inhibited storage: if  $I=1$  in both the process-scoped and the partition-scoped PTE that map the instruction, the interrupt caused by attempting to fetch the instruction is an Instruction Storage interrupt.

#### Programming Note

For the other cases in which access to storage with a particular storage control attribute causes a [Hypervisor] Data Storage or [Hypervisor] Instruction Storage interrupt the choice between the Hypervisor or the non-Hypervisor version of the interrupt is obvious.

- If the Radix Tree translation is not nested, the choice of interrupt is determined by the scope of the Radix Tree that is used.
- If the Radix Tree translation is nested and the attribute in question is the Guarded attribute, the interrupt is always the non-Hypervisor version because the G value used for the access is determined by the process-scoped PTE.

Unless otherwise stated or obvious from context, references elsewhere in the Books to storage control attributes for nested Radix Tree translations apply to the result of combining the guest and host storage control attributes as specified above. For example, the restrictions on the types of storage that can be accessed by AMOs in Section 4.5 of Book II apply to the results of the combining.

	<i>partition-scoped ATT</i>	00	10	11
<i>process-scoped ATT</i>	<i>I/G</i>	00	11	10
00	00	00	ATT conflict	ATT conflict
10	11	01	11	11
11	10	00	10	10

Table 5: Effective I and G attributes for nested translation

#### Programming Note

The mismatched Caching Inhibited attribute in which  $I=1$  in the process-scoped PTE and  $I=0$  in the partition-scoped PTE is given defined behavior instead of excepting in order to support frame buffer emulation. For frame buffer emulation, the guest believes it is writing to a frame buffer ( $I=1$ ) in address space that the hypervisor maps to normal memory ( $I=0$ ).

Reference and Change bit recording is done in both the process-scoped and partition-scoped Page Table Entries. Recording is done as described in Section 6.7.12, “Reference and Change Recording”.

## 6.7.11 Translation Process

As previously described, in its most complicated form the translation process includes the following steps:

- use of the PTCR to find the required Partition Table Entry
- use of the Partition Table Entry to find the partition-scoped Page Table
- use of the Partition Table Entry and the partition-scoped Page Table to find the required Process Table Entry
- use of the Process Table Entry and partition-scoped Page Table to find the required Segment Table Entry or walk the process-scoped Page Table (i.e. translate the effective address to a virtual or guest real address), and
- use of the partition-scoped Page Table to translate the virtual or guest real address.

Depending on the translation mode and process state, some of these steps may be skipped. The following subsections enumerate the cases and explain the steps in more detail.

### 6.7.11.1 Fully-Qualified Address

The storage control facilities enable hardware to perform the entire translation process given a “fully-qualified address” and context that makes it a unique input. In addition to its normal use, the term “effective address” is sometimes used as shorthand for the fully-qualified address, and the architecture should be read with this possibility in mind. The following are the components of the fully-qualified address.

- $effLPID$
- $effPID$
- EA

The additional context required to perform a translation or match a cached translation may include the following.

- $PATE_{HR}$  (selected using the value in LPIDR, not  $effLPID$ )
- $MSR_{HV PR IR DR}$

The translation mode is selected by the Host Radix bit found in the Partition Table Entry. The Host Radix bit indicates whether the partition is using HPT or Radix Tree translation. Given the overall process,  $MSR_{HV\_PR\_IR\_DR}$  determine where and how the process is entered.

### 6.7.11.2 Finding the Page Tables

[The following description assumes that no legacy mode is active, i.e.  $LPCR_{UPRT}=1$ .]

The components of the fully-qualified address are used to determine the table(s) used in the translation process. The effective LPID and effective PID are used to find the appropriate Page Table base address(es) using the In-Memory Table structures. Some types of translation use process-scoped Page Tables, some use partition-scoped Page Tables, and some use both.

Process-scoped table descriptors are found in the Process Tables as follows. The Partition Table Entry (PATE) host real address is calculated by adding the Partition Table Base Address ( $PATB||^{12}0$ ) in the PTCR with 16 times the effective LPID. The second doubleword of the entry contains the base address of the Process Table for the partition. The Process Table is assumed to be aligned in effective ( $HR=1$ ,  $effLPID=0$ ), virtual, or guest real address space. The Process Table Entry (PRTE) host real address is calculated by ORing the Process Table Base Address ( $PRTB||^{40}0$  for for an HPT host and  $PRTB||^{12}0$  for a radix host) in the PATE with 16 times the effective PID and then performing partition-scoped translation. (If the table is not aligned or is not large enough to support the PID value, an unreported error will most likely result.) The Process Table Entry at that location contains a process-scoped table base address, which is a guest real address for a radix guest ( $HV=0$ ), a host real address for a radix host ( $HV=1$ ), or a virtual address (all cases using HPT translation). The virtual or guest real address must be translated via the appropriate partition-scoped table.

#### Programming Note

The guest real or virtual address of the Process Table, for a radix or HPT guest, respectively, may be set via an hcall. The radix guest may choose to map the Process Table into its own effective address space. These matters are not visible to the architecture.

#### Programming Note

Note that the sole purpose of partition-scoped Page Table descriptor when  $LPID=0$  for a radix host is to translate the effective addresses of the Process Table Entries for  $LPID=0$ . (If the Process Table Base address for  $LPID=0$  was a real address, the Process Table would have to be in contiguous real storage.) This descriptor will commonly be the same as the descriptor found in the  $LPID=0$ ,  $PID=0$  Process Table Entry, both pointing to the hypervisor's own page table, but it may be set up to point to a table used solely to translate the addresses of Process Table Entries.

Partition-scoped Page Table descriptors are found in the Partition Table as follows. The Partition Table Base Address is found in the PTCR. The effective LPID (times 16 bytes per partition) is used to index off the Partition Table Base Address to find the appropriate Partition Table Entry. The first doubleword of the entry contains the base address of the Page Table.

### 6.7.11.3 Obtaining Host Real Address, Radix on Radix

The following cases exist.

- Guest access to quadrant 0 with translation on: process-scoped translation is performed on  $LPIDR||PIDR||EA$ , with the result subject to partition-scoped translation with effective  $LPID=LPIDR$ .
- Guest OS access to quadrant 3 with translation on: process-scoped translation is performed on  $LPIDR||0||EA$ , with the result subject to partition-scoped translation with effective  $LPID=LPIDR$ .
- Hypervisor access to quadrant 1 with translation on: process-scoped translation is performed on  $LPIDR||PIDR||EA$ , with the result subject to partition-scoped translation with effective  $LPID=LPIDR$  if  $LPIDR \neq 0$ .
- Hypervisor access to quadrant 2 with translation on: process-scoped translation is performed on  $LPIDR||0||EA$ , with the result subject to partition-scoped translation with effective  $LPID=LPIDR$  if  $LPIDR \neq 0$ .
- Guest OS access with translation off: partition-scoped translation is performed with effective  $LPID = LPIDR$ .
- Hypervisor or host application access to quadrant 0 with  $LPIDR=0$  and translation on: process-scoped translation is performed on  $0||PIDR||EA$ .
- Hypervisor access to quadrant 3 with translation on: process-scoped translation is performed with  $0||0||EA$ .
- Hypervisor or ultravisor real mode access: subject to  $EA_0$  and either  $HRMOR$  or  $URMOR$ , as described in Section 6.7.3.1.

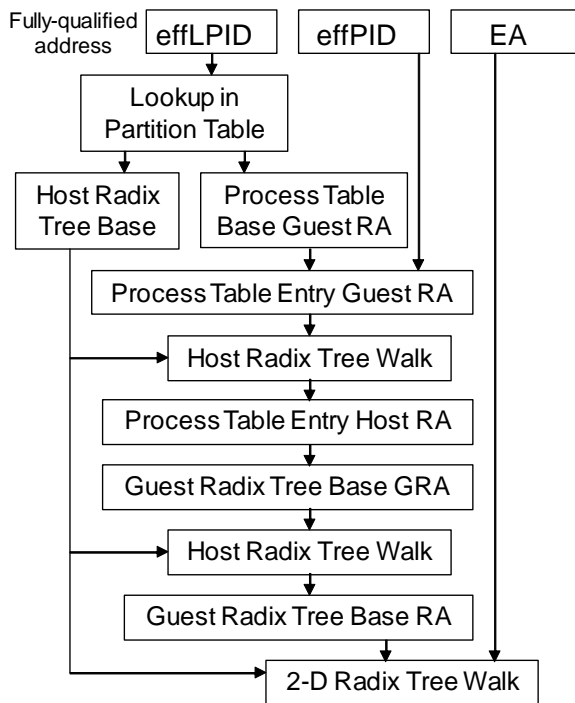

Figure 40. Radix on Radix translation, general case

#### 6.7.11.4 Obtaining Host Real Address, HPT

There are two scenarios for Paravirtualized HPT translation. The first is the legacy scenario with a native HPT hypervisor. The second scenario is for a Radix Tree translation hypervisor providing a Paravirtualized HPT environment for the guest. In this latter scenario, the LPID=0 Partition Table Entry will have HR=1. For both scenarios the LPID value is always taken from LPIDR and the PID value is always taken from PIDR, even when  $MSR_{HV}=1$ . In the latter scenario, the hypervisor will explicitly set LPIDR=0 when it wants to use its Radix Tree(s).

When using Paravirtualized HPT translation, the process-scoped Page Tables are replaced by Segment Tables, and the description in Section 6.7.11.2, “Finding the Page Tables” can be read with that substitution in mind. The process-scoped translation is the effective-to-virtual translation described in Section 6.7.8. In-Memory Table walks are processed via the LPID=LPIDR partition-scoped HPT.

As with the previous enumerations, this is done from a hardware point of view. As a result, it does not differentiate the software cases for which Segment translation should only be satisfied by bolted translations

The following cases exist.

- Guest access with translation on: process-scoped translation is performed on LPIDR||PIDR||EA with

the result subject to partition-scoped translation using parameters from the matching segment descriptor.

- Hypervisor or adjunct access with translation on and LPID≠0: process-scoped translation, limited to an SLB search with no Segment Table walk, is performed on LPIDR||PIDR||EA, with the result subject to partition-scoped translation using parameters from the matching segment descriptor.
- Hypervisor or adjunct access with translation on and LPID=0: process-scoped translation (with Segment Table walk) is performed on LPIDR||PIDR||EA, with the result subject to partition-scoped translation using parameters from the matching segment descriptor.
- Guest OS access with translation off: subject to VPM, as described in Section 6.7.3.3.
- Hypervisor or ultravisor real mode access: subject to  $EA_0$  and either HRMOR or URMOR, as described in Section 6.7.3.1.

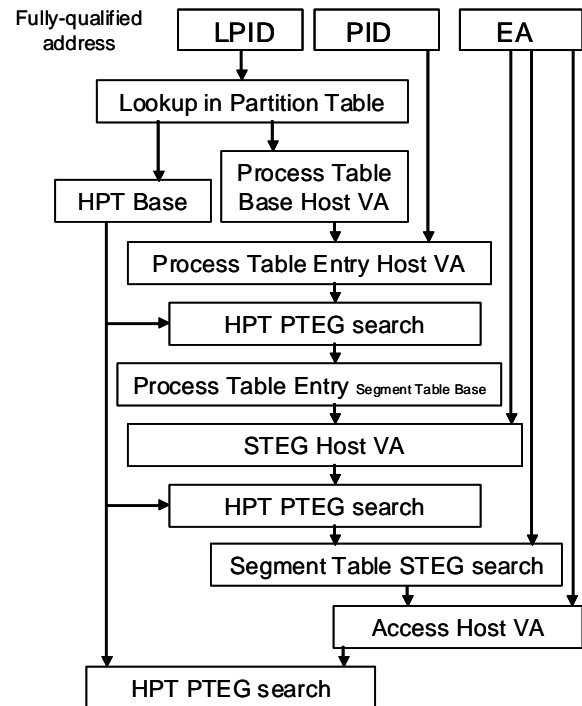

Figure 41. Paravirtualized HPT translation

#### 6.7.12 Reference and Change Recording

When operating in Paravirtualized HPT mode, Reference (R) and Change (C) bits are updated in any one of what could be multiple (because of the multiple base size PTEs mapping a virtual page) Page Table Entries that map the virtual page that is being accessed. When operating in Radix on Radix mode, Reference (R) and

Change (C) bits may be updated in multiple Page Table Entries that are accessed as part of the translation process. (For example, each access to a guest's Page Directory or Page Table Entry potentially sets a Reference bit in the partition-scoped table mapping it.) If the storage operand of a *Load* or *Store* instruction crosses a virtual page boundary, the accesses to the components of the operand in each page are treated as separate and independent accesses to each of the pages for the purpose of setting the Reference and Change bits.

For Radix Tree translation, hardware attempts to set the Reference and Change bits atomically, as though the PTE was read to perform the translation using a *Load And Reserve* instruction, and conditional on the translation being valid and correct (and on the existence of the reservation), the appropriate bit(s) are set as though with a *Store Conditional* instruction. (“as though” indicates that the reservation(s) held for this purpose are distinct from one another and from the reservation established by a *Load And Reserve* instruction.) If hardware is unable to set the bit(s) atomically, a [Hypervisor] Data Storage or [Hypervisor] Instruction Storage interrupt will be caused. For HPT translation, hardware sets the Reference and Change bits as though the PTE was read to perform the update using a (simple) *Load* instruction and the appropriate bit(s) are set as though with a (simple) *Store* instruction.

For both kinds of translation, setting the bits need not be atomic with respect to performing the access that causes the bits to be updated. For Radix Tree translation, the Reference bit must contain 1 in order to access the corresponding page and the Change bit must contain 1 in order to store to the corresponding page.

#### Programming Note

The interrupt indicates to software that it must set the appropriate bit(s) itself. Note that an instruction fetch can cause a Change bit to be set, for example in the host Page Table Entry that maps the guest Page Table Entry if the instruction fetch causes the Reference bit to be set in the guest Page Table Entry.

#### Programming Note

The atomic setting of the Reference and Change bits enables an optimized sampling of them, for example when determining what pages to reclaim for other uses. To accurately sample the bits under HPT translation, it is necessary to first invalidate the PTE and the corresponding TLB entries. The optimized sequence eliminates the requirement for the relatively expensive invalidation of the TLB entries before sampling the bits. Instead, software may simply load the PTE using a *Load And Reserve* instruction, and then set the PTE invalid using a *Store Conditional* instruction. The TLB invalidation may be deferred indefinitely. The Reference and Change bits sampled in this manner are accurate (if the store conditional succeeds) because with the PTE marked invalid, it will be impossible to access a page for which the appropriate bit is not already set.

#### Programming Note

In nested Radix Tree translation, as many as three Change bits may be set: in the process-scoped and partition-scoped PTEs for the access itself, and in the partition-scoped PTE that maps the process-scoped PTE. Similarly, a large number of Reference bits may be set, including for each partition-scoped PTE that maps a process-scoped PTE or PTE.

Reference and Change bits are set by the hardware as described below. An attempt to access storage may cause one or more of the bits to be set (as described below) even if the access is not performed. The bits are updated in the Page Table Entry if the new value would otherwise be different from the old value for the virtual page, as determined by examining either the Page Table Entry or any lookaside information for the virtual page (e.g., TLB) maintained by the hardware.

#### Reference Bit

The Reference bit is set to 1 if the corresponding access (load, store, implicit access, or instruction fetch) is required by the sequential execution model and is performed. Otherwise the Reference bit may be set to 1 if the corresponding access is attempted, either in-order or out-of-order, even if the attempt causes an exception, except that the Reference bit is not set to 1 for the access caused by an indexed *Move Assist* instruction for which the XER specifies a length of zero.

#### Change Bit

The Change bit is set to 1 if a *Store* instruction is executed and the store is performed or if an implicit update is performed. Otherwise in general

the Change bit may be set to 1 if a *Store* instruction is executed and the store is permitted by the storage protection mechanism and, if the *Store* instruction is executed out-of-order, the instruction would be required by the sequential execution model in the absence of the following kinds of interrupts:

- system-caused interrupts (see Section 7.4 on page 1269)
- Floating-Point Enabled Exception type Program interrupts when the thread is in an Imprecise mode.

The only exceptions to the preceding statement are that the Change bit is not set to 1 if the instruction is a *Store String Indexed* instruction for which the XER specifies a length of zero, if the instruction is a *Load Atomic* or *Store Atomic* instruction with a reserved function code, or if the instruction is a *Store Caching Inhibited* instruction executed when  $MSR_{DR}=1$ .

#### Programming Note

A virtual page in a segment with a smaller base page size may be mapped by multiple PTEs. For each access of a virtual page, hardware may search the Page Table to update the R and C bits. If lookaside buffer information for the virtual page already indicates that all such bits to be set have already been set in a PTE that maps the virtual page, hardware need not make an update. Consider the following sequence of events:

1. A virtual page is mapped by 2 PTEs A and B and the R and C bits in both PTEs are 0.
2. A Load instruction accesses the virtual page and the R bit is updated in PTE A.
3. A Load instruction accesses the virtual page and the R bit is updated in PTE B.
4. A Store instruction accesses the virtual page and the C bit is updated in PTE B.
5. The virtual page is paged out. Software must examine both PTE A and B to get the state of the R and C bits for the virtual page.

Furthermore, if in event 2, PTE A was not found, a Data Storage interrupt or Hypervisor Data Storage interrupt may occur. Subsequently, if in event 3 or 4, PTE B was not found, a Data Storage interrupt or Hypervisor Data Storage interrupt may occur.

#### Programming Note

Even though the execution of a *Store* instruction causes the Change bit to be set to 1, the store might not be performed or might be only partially performed in cases such as the following.

- A *Store Conditional* instruction (*stwcx.* or *stdcx.*) or a Load Atomic or Store Atomic instruction (e.g. Fetch and Increment Bounded, Store Twin) is executed, but no store is performed.
- The *Store* instruction causes a Data Storage exception (all cases except *Load Atomic* or *Store Atomic* with a reserved function code, *Store Caching Inhibited* executed when  $MSR_{DR}=1$ , EAO, or storage protection violation, which do not store and are not permitted to set the Change bit).
- The *Store* instruction causes an Alignment exception.
- The Page Table Entry that translates the virtual address of the storage operand is altered such that the new contents of the Page Table Entry preclude performing the store (e.g., the PTE is made invalid, or the PP bits are changed).

For example, when executing a *Store* instruction, the thread may search the Page Table for the purpose of setting the Change bit and then re-execute the instruction. When reexecuting the instruction, the thread may search the Page Table a second time. If the Page Table Entry has meanwhile been altered, by a program executing on another thread, the second search may obtain the new contents, which may preclude the store.

- A system-caused interrupt occurs before the store has been performed.

When the hardware updates the Reference and Change bits in a Page Table Entry, the accesses are performed as described in Section 6.7.3.4, “Storage Control Attributes for Implicit Storage Accesses” on page 1195. These Reference and Change bit updates are not necessarily immediately visible to software. Executing a *sync* instruction ensures that all Reference and Change bit updates associated with address translations that were performed, by the thread executing the *sync* instruction, before the *sync* instruction is executed will be performed with respect to that thread before the *sync* instruction’s memory barrier is created. There are additional requirements for synchronizing Reference and Change bit updates in multi-threaded systems; see Section 6.10, “Translation Table Update Synchronization Requirements” on page 1255.

**Programming Note**

Because the **sync** instruction is execution synchronizing, the set of Reference and Change bit updates that are performed with respect to the thread executing the **sync** instruction before the memory barrier is created includes all Reference and Change bit updates associated with instructions preceding the **sync** instruction.

If software refers to a Page Table Entry when  $MSR_{DR}=1$  or  $MSR_{HV}=0$ , the Reference and Change bits in the associated Page Table Entry are set as for ordinary loads and stores. See Section 6.10 for the rules software must follow when updating Reference and Change bits.

Figure 42 on page 1220 summarizes the rules for setting the Reference and Change bits. The table applies to each atomic storage reference. It should be read from the top down; the first line matching a given situation applies. For example, if **stwcx**. fails due to both a storage protection violation and the lack of a reservation, the Change bit is not altered. The figure applies to PTE(s) that map instructions or storage operands of instructions. When Radix Tree translation is in use, Reference and Change bits are set in other, partition-scoped, PTEs as described earlier in this section.

In the figure, the “Load-type” instructions are the *Load* instructions described in Books I, II, and III, and the *Cache Management* and other instructions that are stated in the instruction descriptions to be treated as a *Load*, and similarly for “Store-type” instructions. The *Load Atomic* and *Store Atomic* instructions are considered to be both loads and stores, and as a result could match “Load-type” and “Store-type” entries in the table. As a result, “Store-type” entries precede “Load-type” entries in the table so that AMOs match “Store-type” entries. The “ordinary” *Load* and *Store* instructions are those described in Books I, II, and III. “set” means “set to 1”.

Status of Access	R	C
Indexed <i>Move Assist</i> insn w 0 len in XER	No	No
<i>Load</i> or <i>Store Atomic</i> instruction with reserved function code, <i>Load</i> or <i>Store Caching Inhibited</i> executed when $MSR_{DR}=1$	No	No
Storage protection violation	Acc <sup>1</sup>	No
Out-of-order Store-type inst'n, excluding <b>dcbtst</b>		
Would be required by the sequential execution model in the absence of system-caused or imprecise interrupts <sup>3</sup>	Acc	Acc <sup>1 2</sup>
All other cases	Acc	No
Out-of-order I-fetch or Load-type Inst'n (including <b>dcbtst</b> )	Acc	No
In-order <i>Load</i> -type or <i>Store</i> -type insn, access not performed <sup>4</sup>		
Store-type insn	Acc	Acc <sup>2</sup>
Load-type insn	Acc	No
Other in-order access		
Other ordinary <i>Store</i> , <b>dcbz</b> , <b>paste</b> .	Yes	Yes
<b>icbi</b> , <b>icbt</b> , <b>dcbt</b> , <b>dcbtst</b> , <b>dcbst</b> , <b>dcbf</b>	Acc	No
I-fetch or ordinary <i>Load</i> , <b>copy</b> , <b>hashchk[p]</b>	Yes	No

“Acc” means that it is acceptable to set the bit.  
<sup>1</sup> It is preferable not to set the bit.  
<sup>2</sup> If C is set, R is also set unless it is already set.  
<sup>3</sup> For Floating-Point Enabled Exception type Program interrupts, “imprecise” refers to the exception mode controlled by  $MSR_{FE0 FE1}$ .  
<sup>4</sup> This case does not apply to the *Touch* instructions, because they do not cause a storage access.

**Figure 42. Setting the Reference and Change bits**

## 6.7.13 Storage Protection

The storage protection mechanism provides a means for selectively granting instruction fetch access, granting read access, granting write access, and prohibiting access to areas of storage based on a number of control criteria.

The operation of the storage protection mechanism depends on the value of one or more of the following.

- MSR bits HV, S, IR, DR, PR
- the key bits and N bit in the associated SLB entry
- the page protection bits, key bits, N bit, and G attribute in the associated PTE
- the AMR, IAMR, AMOR, and UAMOR
- the Secure Memory property

The storage protection mechanism consists of the Virtual Page Class Key Protection mechanism described in Section 6.7.13.1, the Basic Storage Protection mechanism described in Section 6.7.13.2 and Section 6.7.13.3, the Radix Tree Translation Storage Protection mechanism described in Section 6.7.13.4, and the Secure Memory Protection mechanism described in Section 6.7.13.5.

In order for a storage access to be permitted, it must be permitted by all of the mechanisms that apply to it. If  $SMFCTRL_E=1$ , each storage access is subject to Secure Memory Protection independent of the translation mode of the access. In addition, each access is subject to other protection mechanisms depending on its translation mode, as listed below.

- $MSR_{HV}=1$  and address translation is disabled: Basic Storage Protection mechanism
- $HR=0$ 
  - access to instruction or data when address translation is enabled: Virtual Page Class Key Protection mechanism and Basic Storage Protection mechanism
  - all other cases (access to Process Table Entry or Segment Table Entry when address translation is enabled; access to instruction or data when  $MSR_{HV}=0$  and address translation is disabled): Basic Storage Protection mechanism

### Programming Note

Because the assumed  $K_s$  and  $K_p$  values are either 0 or irrelevant, these accesses are always permitted by the Basic Storage Protection mechanism.

- $HR=1$

- access to instruction or data when address translation is enabled and  $effLPID \neq 0$ : Radix Tree Translation Storage Protection mechanisms of both the process-scoped and partition-scoped PTEs, except that the Guarded attribute (which affects storage protection for instruction fetches) is determined solely by the process-scoped PTE
- access to instruction or data when address translation is enabled and  $effLPID=0$ : Radix Tree Translation Storage Protection mechanism of the process-scoped PTE
- all other cases (access to Process Table Entry when address translation is enabled; access to process-scoped PDE or process-scoped PTE when address translation is enabled and  $effLPID \neq 0$ ; access to instruction or data when  $MSR_{HV}=0$  and address translation is disabled): Radix Tree Translation Storage Protection mechanism of the partition-scoped PTE

If an access associated with an instruction fetch is not permitted, an Instruction Storage exception or a Hypervisor Instruction Storage exception is generated. If an access associated with a data access is not permitted, a Data Storage exception or a Hypervisor Data Storage exception is generated. If  $HR=1$ , address translation is enabled,  $LPID \neq 0$ , and the access is not permitted by the process-scoped PTE, the exception is an Instruction Storage exception or Data Storage exception.

A *protection domain* is a maximal range of effective addresses, virtual addresses, or guest real addresses for which variables related to storage protection can be independently specified (including by default, as in virtual real, hypervisor real, and ultravisor real addressing modes), or a maximal range of addresses, effective, virtual, or guest real, for which variables related to storage protection cannot be specified. Examples include: a segment, a virtual page (including for the Virtualized Real Mode Area), the Virtualized Real Mode Area, the effective address range  $0:2^{60}-1$  in hypervisor and ultravisor real addressing modes, and a maximal range of effective, virtual, or guest real addresses that cannot be mapped to real addresses. A *protection boundary* is a boundary between protection domains.

### 6.7.13.1 Virtual Page Class Key Protection

The Virtual Page Class Key Protection mechanism provides the means to assign virtual pages to one of 32 classes, and to modify data access permissions for each class by modifying the Authority Mask Register (AMR), shown in Figure 43, and to modify instruction access permissions for each class by modifying the Instruction Authority Mask Register (IAMR) shown in Figure 44.

**Programming Note**

If address translation is disabled for a given access, the access is not affected by the Virtual Page Class Key Protection mechanism even if the access is made in virtual real addressing mode.

**Authority Mask Register**

Bits	Name	Description
0:1	Key0	Access mask for class number 0
2:3	Key1	Access mask for class number 1
...	...	...
2n:2n+1	Keyn	Access mask for class number n
...	...	...
62:63	Key31	Access mask for class number 31

**Figure 43. Authority Mask Register (AMR)**

The access mask for each class defines the access permissions that apply to loads and stores for which the virtual address is translated using a Page Table Entry that contains a Key field value equal to the class number. The access permissions associated with each class are defined as follows, where  $AMR_{2n}$  and  $AMR_{2n+1}$  refer to the first and second bits of the access mask corresponding to class number n.

- A store is permitted if  $AMR_{2n}=0b0$ ; otherwise the store is not permitted.
- A load is permitted if  $AMR_{2n+1}=0b0$ ; otherwise the load is not permitted.

The AMR can be accessed using either SPR 13 or SPR 29. Access to the AMR using SPR 29 is privileged.

**Programming Note**

Because the AMR is part of the program context (if address translation is enabled), and because it is desirable for most application programmers not to have to understand the software synchronization requirements for context alterations (or the nuances of address translation and storage protection), operating systems should provide a system library program that application programs can use to modify the AMR.

**Instruction Authority Mask Register**

Bits	Name	Description
0:1	Key0	Access mask for class number 0
2:3	Key1	Access mask for class number 1
...	...	...
2n:2n+1	Keyn	Access mask for class number n
...	...	...
62:63	Key31	Access mask for class number 31

**Figure 44. Instruction Authority Mask Register (IAMR)**

The access mask for each class defines the access permissions that apply to instruction fetches for which the virtual address is translated using a Page Table Entry that contains a Key field value equal to the class number. The access permission associated with each class is defined as follows, where  $IAMR_{2n+1}$  refers to the bit of the access mask corresponding to class number n.

- An instruction fetch is permitted if  $IAMR_{2n+1}=0b0$ ; otherwise the instruction fetch is not permitted.

Bit 0 of each key field is reserved

Access to the IAMR is privileged.

The Authority Mask Override Register (AMOR) and the User Authority Mask Override Register (UAMOR), shown in Figure 45 and Figure 46 respectively, can be used to restrict modifications (*mtspr*) of the AMR. Also, the AMOR can be used to restrict modifications of the UAMOR and IAMR. Access to both the AMOR and UAMOR is privileged. The AMOR is a hypervisor resource.

**Figure 45. Authority Mask Override Register (AMOR)**

**Figure 46. User Authority Mask Override Register (UAMOR)**

The bits of the AMOR and UAMOR are in 1-1 correspondence with the bits of the AMR (i.e.,  $[U]AMOR_i$  corresponds to  $AMR_i$ ). The AMOR affects modifications of the AMR and UAMOR in privileged but non-hypervisor state; the UAMOR affects modifications of the AMR in problem state.

Similarly, the odd bits of the AMOR are in 1-1 correspondence with the odd bits of the IAMR (i.e.,

$AMOR_{2j+1}$  corresponds to  $IAMR_{2j+1}$ ). The AMOR affects modifications of the IAMR in privileged but non-hypervisor state; the IAMR cannot be accessed in problem state.

- When *mtspr* specifying the AMR (using either SPR 13 or SPR 29) or the IAMR is executed in privileged non-hypervisor state, the AMOR is used as a mask that controls which bits of the resulting AMR or IAMR contents come from register RS and which AMR or IAMR bits are not modified.
- Similarly, when *mtspr* specifying the AMR (using SPR 13) is executed in problem state, the UAMOR is used as a mask that controls which bits of the resulting AMR contents come from register RS and which AMR bits are not modified.
- When *mtspr* specifying the UAMOR is executed in privileged non-hypervisor state, the AMOR is ANDed with the contents of register RS and the result is placed into the UAMOR; the AMOR thereby controls which bits of the resulting UAMOR contents come from register RS and which UAMOR bits are set to zero.

A complete description of these effects can be found in the description of the *mtspr* instruction in Section 5.4.4.

Software must ensure that both bits of each even/odd bit pair of the AMOR contain the same value. — i.e., the contents of register RS for *mtspr* specifying the AMOR must be such that  $(RS)_{2n} = (RS)_{2n+1}$  for every  $n$  in the range 0:31 — and likewise for the UAMOR. If this requirement is violated for the UAMOR the results of accessing the UAMOR (including implicitly by the hardware as described in the second item of the preceding list) are boundedly undefined; if the requirement is violated for the AMOR the results of accessing the AMOR (including implicitly by the hardware as described in the first and third items of the list) are undefined.

#### Programming Note

The preceding requirement permits designs to implement the AMOR and/or UAMOR as 32-bit registers — specifically, to implement only the even-numbered bits (or only the odd-numbered bits) of the register — in a manner such that the reduction, from the architecturally-required 64 bits to 32 bits, is not visible to (correct) software. This implementation technique saves space in the hardware. (A design that uses this technique does the appropriate “fan in/out” when the register is accessed, to provide the appearance, to (correct) software, of supporting all 64 bits of the register.)

Permitting designs to implement the [U]AMOR as 32-bit registers by virtue of the software requirement specified above, rather than by defining the [U]AMOR as 32-bit registers, permits the architecture to be extended in the future to support controlling modification of the “read access” AMR bits (the odd-numbered bits) independently from the “write access” AMR bits (the even-numbered bits), if that proves desirable. If this independent control does prove desirable, the only architecture change would be to eliminate the software requirement.

#### Programming Note

When modifying the AMOR and/or UAMOR, the hypervisor should ensure that the two registers are consistent with one another before giving control to a non-hypervisor program. In particular, the hypervisor should ensure that if  $AMOR_i=0$  then  $UAMOR_i=0$ , for all  $i$  in the range 0:63. (Having  $AMOR_i=0$  and  $UAMOR_i=1$  would permit problem state programs, but not the operating system, to modify AMR bit  $i$ .)

### Programming Note

The Virtual Page Class Key Protection mechanism replaces the Data Address Compare mechanism that was defined in versions of the architecture that precede Version 2.04 (e.g., the two facilities use some of the same resources, as described below). However, the Virtual Page Class Key Protection mechanism can be used to emulate the Data Address Compare mechanism. Moreover, programs that use the Data Address Compare mechanism can be modified in a manner such that they will work correctly both on implementations that comply with versions of the architecture that precede Version 2.04 (and hence implement the Data Address Compare mechanism) and on implementations that comply with Version 2.04 of the architecture or with any subsequent version (and hence instead implement the Virtual Page Class Key Protection mechanism). The technique takes advantage of the facts that the SPR number for privileged access to the AMR (29) is the same as the SPR number for the Data Address Compare mechanism's ACCR (Address Compare Control Register), that  $KEY_4$  occupies the same bit in the PTE as the Data Address Compare mechanism's AC (Address Compare) bit, and that the definition of  $ACCR_{62:63}$  is very similar to the definition of each even-odd pair of AMR bits. The technique is as follows, where PTE1 refers to doubleword 1 of the PTE.

- Set bits 2:3 and 62:63 of SPR 29 (which is either the ACCR or the AMR) to  $x$ , where  $x$  is the desired 2-bit value for controlling Data Address Compare matches, and set bits 0:1 to 0s.
- Set  $PTE1_{54}$  (which is either the AC bit or  $KEY_4$ ) to the same value that the AC bit would be set to, and set  $PTE1_{2:3}$  (which are either RPN bits, that correspond to a real address size larger than the size supported by any implementation that supports the Data Address Compare mechanism, or  $KEY_{0:1}$ ) and  $PTE1_{52:53}$  (which are either reserved bits or  $KEY_{2:3}$ ) to 0s.
- Use  $PTE_{KEY}$  values 0 and 1 only for purposes of emulating the Data Address Compare mechanism, except that  $PTE_{KEY}$  value 0 may also be used for any virtual pages for which it is desired that the Virtual Page Class Key Protection mechanism permit all accesses. Do not use  $PTE_{KEY}=31$ .
- When a Hypervisor Data Storage interrupt occurs, if  $HDSISR_{42}=1$  then ignore the interrupt for *Cache Management* instructions other than **dcbz**. (These instructions can cause a virtual page class key protection violation but cannot cause a Data Address Compare match.) Otherwise forward the interrupt to the operating system, which will treat the interrupt as if a Data Address Compare match had occurred. (Note: Cases for which it is undefined whether a Data Address Compare match occurs do not necessarily cause a virtual page class key protection violation.)

(Because privileged software can access the AMR using either SPR 13 or SPR 29, it might seem that, when SPR 13 was added to the architecture (in Version 2.06), SPR 29 should have been removed. SPR 29 is retained for two reasons: first, to avoid requiring privileged software to change to use the newer SPR number; and second, to retain the ability to emulate the Data Address Compare mechanism as described above.)

**Programming Note**

An example of the use of the AMOR (and UAMOR) is to support adjuncts (see Section 6.7.4, “Definitions”). The hypervisor could use KEY value  $j$  for all data virtual pages that only the adjunct must be able to access. Before dispatching the partition for the first time, the hypervisor would initialize the three registers as follows.

AMR: all 0s except bits  $2j$  and  $2j+1$ , which would contain 1s

UAMOR: all 0s

AMOR: all 1s except bits  $2j$  and  $2j+1$ , which would contain 0s

Before dispatching the adjunct, the hypervisor would set UAMOR to all 0s, and would set the AMR to all 1s except bits  $2j$  and  $2j+1$ , which would be set to 0s. (Because the adjunct would run in problem state, there is no need for the hypervisor to modify the AMOR, and the adjunct cannot modify the UAMOR.) In addition, the hypervisor would prevent the partition from modifying or deleting PTEs that contain translations used by the adjunct.

(It may be desirable to avoid using KEY values 0, 1, and 31 for storage that only the adjunct can access, because these KEY values may be needed by the partition to emulate the Data Address Compare mechanism, as described above. Also, old software, that was written for an implementation that complies with a version of the architecture that precedes Version 2.04 (the version in which virtual page class keys were added), effectively uses KEY 0 for all virtual pages.)

**Programming Note**

Initialization of the UAMOR to all 0s, by the hypervisor before dispatching a partition for the first time, as described in the preceding Programming Note, permits operating systems (in partitions that run in a compatibility mode corresponding to Version 2.06 of the architecture or a subsequent version) to migrate gradually to supporting problem state access to the AMR — specifically, to avoid having to be changed immediately to modify the UAMOR and to save the AMR contents when an interrupt occurs from problem state. Relatedly, having the UAMOR contain all 0s while an application program is running protects old application programs that are “AMR-unaware”. In the absence of programming errors, such application programs would not attempt to read or modify the AMR. However, having the UAMOR contain all 0s protects such programs against modifying the AMR inadvertently.

Permitting an “AMR-unaware” application program to modify the AMR (inadvertently) is potentially harmful for the obvious reasons. (The program might set to 1 an AMR bit corresponding to accesses that are necessary in order for the program to work correctly.) Moreover, even for an operating system that includes support for problem state modification of the AMR, having the UAMOR contain all 0s allows the operating system to avoid saving and restoring the AMR for “AMR-unaware” application programs. Such an operating system would provide a system service program that allows an application program to declare itself to be “AMR-aware” — i.e., potentially to need to modify the AMR. When an application program invokes this service, the operating system would set the UAMOR to the non-zero value appropriate to the access authorities (load and/or store, for one or more key values) that the application program is allowed to modify, and thereafter would save and restore the AMR (and preserve the UAMOR) for this application program. (Having the UAMOR contain all 0s does not prevent an “AMR-unaware” program from reading the AMR, but inadvertent reading of the AMR is likely to be much less harmful than inadvertently modifying it.)

(For partitions that run in a compatibility mode corresponding to a version of the architecture that precedes Version 2.06, the PCR provides sufficient protection to application programs.)

### 6.7.13.2 Basic Storage Protection, Address Translation Enabled

When address translation is enabled, , the Basic Storage Protection mechanism is controlled by the following.

- $MSR_{PR}$ , which distinguishes between supervisor (privileged) state and problem state
- $K_S$  and  $K_P$ , the supervisor (privileged) state and problem state storage key bits in the SLB entry used to translate the effective address
- PP, page protection bits 0:2 in the Page Table Entry used to translate the effective address
- For instruction fetches only:
  - the N (No-execute) value used for the access (see Sections 6.7.8.1 and 6.7.9.2)
  - $PTE_G$ , the G (Guarded) bit in the Page Table Entry used to translate the effective address

Using the above values, the following rules are applied.

1. For an instruction fetch, the access is not permitted if the N value is 1 or if  $PTE_G=1$ .
2. For any access except an instruction fetch that is not permitted by rule 1, a “Key” value is computed using the following formula:

$$\text{Key} \leftarrow (K_P \& MSR_{PR}) \mid (K_S \& \neg MSR_{PR})$$

Using the computed Key, Figure 47 is applied. An instruction fetch is permitted for any entry in the figure except “no access”. A load is permitted for any entry except “no access”. A store is permitted only for entries with “read/write”.

Key	PP	Access Authority
0	000	read/write
0	001	read/write
0	010	read/write
0	011	read only
0	110	read only
1	000	no access
1	001	read only
1	010	read/write
1	011	read only
1	110	no access

All PP encodings not shown above are reserved. The results of using reserved PP encodings are boundedly undefined.

**Figure 47. PP bit protection states, address translation enabled**

### 6.7.13.3 Basic Storage Protection, Address Translation Disabled

When address translation is disabled, the Basic Storage Protection mechanism is controlled by  $MSR_{HV}$ , which (when  $MSR_{PR}=0$ ) distinguishes between hypervisor state and privileged non-hypervisor state (see Chapter 2 and Section 6.7.3, “Ultravisor Real, Hypervisor Real, and Virtual Real Addressing Modes”). The following rules apply.

1. If  $MSR_{HV}=0$ , access authority is determined as described in Section 6.7.3.3.
2. If  $MSR_{HV}=1$ , the access is permitted.

### 6.7.13.4 Radix Tree Translation Storage Protection

For Radix Tree translation, an attempt to fetch instructions from Guarded storage is a storage protection violation. In all other respects, the storage protection mechanism for Radix Tree translation is completely different from what is provided for HPT translation.  $EAA_{1:3}$  provide control over read, read/write, and execute access if the process has the appropriate privilege.  $EAA_0$ , together with key 0 in the AMR or IAMR, provide three protection configurations for process-scoped translation: (1) a mode that gives equivalent access to privileged and problem state processes, (2) a mode that gives access only to problem state, and (3) a mode that gives access only to privileged processes. (Note that privileged includes hypervisor privileged.) For partition-scoped translation, including translation of table entry addresses, either value of  $EAA_0$  permits the access. See Figure 38 and Figure 48 for details. The choice of whether to limit access to problem state for process-scoped protection of privileged read and write is determined by key 0 of the AMR. When bit 0 is 0, the Privilege bit in the PTE is ignored for a privileged store. When bit 0 is 1, the Privilege bit must be 1 for a privileged store. Similarly when bit 1 is 0, the Privilege bit in the PTE is ignored for a privileged load. When bit 1 is 1, the Privilege bit must be 1 for a privileged load. The choice of whether to limit access to problem state for process-scoped protection of execute is determined by key 0 of the IAMR. When bit 1 is 0, the Privilege bit in the PTE is ignored for an attempt to execute the instruction in privileged state. When bit 1 is 1, the Privilege bit must be 1 to execute the instruction in privileged state.

Privilege (EAA <sub>0</sub> )	Read (EAA <sub>1</sub> )	Read/Write (EAA <sub>2</sub> )	Execute (EAA <sub>3</sub> )	Access Authority problem state (MSR <sub>PR</sub> =1)	Access Authority privileged state (MSR <sub>PR</sub> =0)
0	0	0	0	na	na
0	0	0	1	e	e*
0	0	1	0	rw	rw*
0	0	1	1	rwe	rwe*
0	1	0	0	r	r*
0	1	0	1	re	re*
0	1	1	0	rw	rw*
0	1	1	1	rwe	rwe*
1	0	0	0	na	na
1	0	0	1	na	e
1	0	1	0	na	rw
1	0	1	1	na	rwe
1	1	0	0	na	r
1	1	0	1	na	re
1	1	1	0	na	rw
1	1	1	1	na	rwe

Key:

na: no access

r : read

w : write

e : execute

\* : For partition-scoped translation, including all translation of table entry addresses, all accesses in the entry are permitted.

For process-scoped translation, each access in the entry is permitted if and only if the relevant bit of key 0 of the [I]AMR is 0.

**Figure 48. Encoded Access Authority (aka page protection)**

### 6.7.13.5 Secure Memory Protection

When SMFCTRL<sub>E</sub>=1, Secure Memory Protection is enabled. Each location in main storage has a Secure Memory property mem<sub>SM</sub>. mem<sub>SM</sub>=1 indicates secure memory. mem<sub>SM</sub>=0 indicates ordinary memory. Generally, only secure partitions and the ultravisor may access secure memory for explicit and implicit accesses. The one exception is that the Partition Table is commonly located in secure memory, but may be accessed implicitly as part of the translation process for software running with MSR<sub>S</sub>=0. The granularity and method with which main storage is mapped for the Secure Memory property is implementation specific.

For each kind of access to a host real address that can cause a violation of Basic or Radix Tree Translation Storage Protection, a Secure Memory Protection exception is reported by the same type of interrupt as its Basic or Radix Tree Translation Storage Protection counterpart, except setting [H]DSISR or [H]SRR1 bit 43 instead of 36, as follows. For HPT translation, the exception is reported as an ISI or DSI if the thread is in hypervisor state, or if the thread is in non-hypervisor state when IR or DR is 1 for the appropriate type of access and VPM=0; otherwise as HISI or HDSI. For Radix Tree translation, the exception is reported as an ISI or DSI if effLPID=0; otherwise as HISI or HDSI. For

HPT translation, the reporting approach described above is used for accesses which require translation but for which no Basic Storage Protection exception is possible. This includes accesses to the Segment Table Entry Group and Process Table Entry.

In the preceding cases the host real address for the access is a result of address translation. A Secure Memory Protection exception can also be caused by accesses to a host real address that is not the result of address translation. (Such accesses cannot cause a violation of Basic or Radix Tree Translation Storage Protection.) These additional cases are reported as follows. For a hypervisor real mode access the exception is reported as an ISI or DSI. For a process-scoped radix tree access for effLPID=0 the exception is reported as an ISI or DSI. For a PTEG access the exception is reported as an ISI or DSI if MSR<sub>HV</sub><sub>PR</sub>=0b10; otherwise as HISI or HDSI. For a partition-scoped radix tree access the exception is reported as an HISI or HDSI unless effLPID=0, in which case the exception is reported as an ISI or DSI. These cases also set [H]DSISR or [H]SRR1 bit 43 to 1.

## 6.8 Storage Control Attributes

This section describes aspects of the storage control attributes that are relevant only to privileged software programmers. The rest of the description of storage

control attributes may be found in Section 1.6 of Book II and subsections.

## 6.8.1 Guarded Storage

Storage is said to be “well-behaved” if the corresponding real storage exists and is not defective, and if the effects of a single access to it are indistinguishable from the effects of multiple identical accesses to it. Data and instructions can be fetched out-of-order from well-behaved storage without causing undesired side effects.

Storage is said to be Guarded if any of the following conditions is satisfied.

- MSR bit IR or DR is 1 for instruction fetches or data accesses respectively, or  $MSR_{HV}=0$ , and either  $G=1$  or  $ATT=0b010$  in the relevant Page Table Entry.
- MSR bit IR or DR is 0 for instruction fetches or data accesses respectively,  $MSR_{HV}=1$ , and the storage is specified by the Hypervisor Real Mode Storage Control facility to be treated as Guarded (see Section 6.7.3.2.1).

In general, storage that is not well-behaved should be Guarded. Because such storage may represent a control register on an I/O device or may include locations that do not exist, an out-of-order access to such storage may cause an I/O device to perform unintended operations or may result in a Machine Check.

The following rules apply to in-order execution of *Load* and *Store* instructions for which the first byte of the storage operand is in storage that is both Caching Inhibited and Guarded.

- *Load* or *Store* instruction that causes an atomic access

If any portion of the storage operand has been accessed and an External, Decrementer, Hypervisor Decrementer, Performance Monitor, or Imprecise mode Floating-Point Enabled exception is pending, the instruction completes before the interrupt occurs.

- *Load* or *Store* instruction that causes an Alignment exception, or that causes a [Hypervisor] Data Storage exception for reasons other than Data Address Watchpoint match.

The portion of the storage operand that is in Caching Inhibited and Guarded storage is not accessed.

(The corresponding rules for instructions that cause a Data Address Watchpoint match are given in Section 10.4.)

### 6.8.1.1 Out-of-Order Accesses to Guarded Storage

In general, Guarded storage is not accessed out-of-order. The only exceptions to this rule are the following.

#### Load Instruction

If a copy of any byte of the storage operand is in a cache then that byte may be accessed in the cache or in main storage.

#### Instruction Fetch

If  $MSR_{HV,IR}=0b10$  then an instruction may be fetched if any of the following conditions are met.

1. The instruction is in a cache. In this case it may be fetched from the cache or from main storage.
2. The instruction is in a real page from which an instruction has previously been fetched, except that if that previous fetch was based on condition 1 then the previously fetched instruction must have been in the instruction cache.
3. The instruction is in the same real page as an instruction that is required by the sequential execution model, or is in the real page immediately following such a page.

#### Programming Note

Software should ensure that only well-behaved storage is copied into a cache, either by accessing as Caching Inhibited (and Guarded) all storage that may not be well-behaved, or by accessing such storage as not Caching Inhibited (but Guarded) and referring only to cache blocks that are well-behaved.

If a real page contains instructions that will be executed when  $MSR_{IR}=0$  and  $MSR_{HV}=1$ , software should ensure that this real page and the next real page contain only well-behaved storage (or that the Hypervisor Real Mode Storage Control facility specifies that this real page is not Guarded).

## 6.8.2 Storage Control Bits

When the thread is not in hypervisor or ultravisor real addressing mode, each storage access is performed under the control of the Page Table Entry used to translate the effective address. Each Page Table Entry contains storage control bits that specify the presence or absence of the corresponding storage control for all accesses translated by the entry as shown in Figure 49 and Figure 50. In the following description, references to individual WIMG bits apply to the corresponding Radix ATT encoding, or to the result of combining the process-scoped and partition-scoped ATT encodings

(see Section 6.7.10.3), except where otherwise stated or obvious from context.

Bit	Storage Control Attribute
W <sup>1</sup>	0 - not Write Through Required 1 - Write Through Required
I	0 - not Caching Inhibited 1 - Caching Inhibited
M <sup>2</sup>	0 - not Memory Coherence Required 1 - Memory Coherence Required
G	0 - not Guarded 1 - Guarded
<sup>1</sup> Support for the 1 value of the W bit is optional. Implementations that do not support the 1 value treat the bit as reserved and assume its value to be 0. <sup>2</sup> Support for the 0 value of the M bit is optional, implementations that do not support the 0 value assume the value of the bit to be 1, and may either preserve the value of the bit or write it as 1.	

Figure 49. Storage control bits, HPT PTE

ATT value	Storage Type
00	normal memory (WIMG=0010)
01	reserved
10	non-idempotent I/O (WIMG=0111)
11	tolerant I/O (WIMG=0110)
W=0 always for Radix Tree translation M=1 always for Radix Tree translation	

Figure 50. Storage control bits, Radix PTE

When the thread is not in hypervisor or ultravisor real addressing mode, instructions are not fetched from storage for which the G bit in the Page Table Entry is set to 1; see Section 6.7.13.

When the thread is in hypervisor or ultravisor real addressing mode, the storage control attributes are implicit; see Section 6.7.3.2.

In Sections 6.8.2.1 and 6.8.2.2, “access” includes accesses that are performed out-of-order, and references to W, I, M, and G bits include the values of those bits that are implied when the thread is in hypervisor or ultravisor real addressing mode.

#### Programming Note

In a system consisting of only a single-threaded processor which has caches, correct coherent execution does not require storage to be accessed as Memory Coherence Required, and accessing storage as not Memory Coherence Required may give better performance.

### 6.8.2.1 Storage Control Bit Restrictions

Process- and partition-scoped ATT combinations that specify not Caching Inhibited for the process scope and Caching Inhibited for the partition scope are not permitted. See Table 5.

All combinations of W, I, M, and G values are permitted except those for which both W and I are 1.

#### Programming Note

If an application program requests both the Write Through Required and the Caching Inhibited attributes for a given storage location, the operating system should set the I bit to 1 and the W bit to 0.

At any given time, the value of the W bit must be the same for all accesses to a given real page.

At any given time, the value of the I bit must be the same for all accesses to a given real page.

### 6.8.2.2 Altering the Storage Control Bits

When changing the value of the W bit for a given real page from 0 to 1, software must ensure that no thread modifies any location in the page until after all copies of locations in the page that are considered to be modified in the data caches have been copied to main storage using *dcbst* or *dcbf[!]* (or *dcbstps* or *dcbfps*).

When changing the value of the I bit for a given real page from 0 to 1, software must set the I bit to 1 and then flush all copies of locations in the page from the caches using *dcbf[!]* (or *dcbfps*) and *icbi* before permitting any other accesses to the page. Note that similar cache management is required before using the Fixed-Point Load and Store Caching Inhibited instructions to access storage that has formerly been cached. (See Section 5.4.1 on page 1173.)

**Programming Note**

It is recommended that ***dcbf*** be used, rather than ***dcbfI***, when changing the value of the I or W bit from 0 to 1. (***dcbfI*** would have to be executed on all threads for which the contents of the data cache may be inconsistent with the new value of the bit, whereas, if the M bit for the page is 1, ***dcbf*** need be executed on only one thread in the system.)

When changing the value of the M bit for a given real page, software must ensure that all data caches are consistent with main storage. The actions required to do this are system-dependent.

**Programming Note**

For example, when changing the M bit in some directory-based systems, software may be required to execute ***dcbfI*** on each thread to flush all storage locations accessed with the old M value before permitting the locations to be accessed with the new M value.

Additional requirements for changing the storage control bits in the Page Table are given in Section 6.10.

## 6.9 Storage Control Instructions

### 6.9.1 Cache Management Instructions

This section describes aspects of cache management that are relevant only to privileged software programmers.

For a **dcbz** instruction that causes the target block to be newly established in the data cache without being fetched from main storage, the hardware need not verify that the associated real address is valid. The existence of a data cache block that is associated with an invalid real address (see Section 6.6) can cause a

delayed Machine Check interrupt or a delayed Check-stop.

Each implementation provides an efficient means by which software can ensure that all blocks that are considered to be modified in the data cache have been copied to main storage before the thread enters any power conserving mode in which data cache contents are not maintained.

### 6.9.2 Synchronize Instruction

The *Synchronize* instruction is described in Section 4.6.3 of Book II, but only at the level required by an application programmer. This section describes properties of the instruction that are relevant only to operating system, hypervisor, and ultravisor software programmers.

The *Synchronize* instruction provides an ordering function for stores that are in set A of the memory barrier created by the *Synchronize* instruction, relative to data accesses caused by instructions that are executed on other threads after the occurrence of the interrupt that is caused by a **msgsndp**, **msgsnd**, or **msgsndu** instruction that follows the *Synchronize* instruction. The thread that is the target of the **msgsndp**, **msgsnd**, or **msgsndu** instruction is here called the "target thread".

- For **msgsndp**, and L = 0, 1, or 2 (or 4 or 5) for the *Synchronize* instruction, the stores are performed with respect to the target thread before any data accesses caused by instructions that are executed on the target thread after the corresponding Directed Privileged Doorbell interrupt has occurred.
- For **msgsnd** or **msgsndu**, and L = 0 or 2 (or 4) for the *Synchronize* instruction, the stores are performed with respect to any given other thread before any data accesses caused by instructions that are executed on the given thread after a **msgsync** instruction is executed on that thread after the corresponding Directed Hypervisor or Ultravisor Doorbell interrupt has occurred on the target thread.

#### Programming Note

*Synchronize* with L=1 (**lwsync**) or L=5 (**plwsync**) should not be used with **msgsnd** or **msgsndu**. (If used, it will not have the desired ordering effect.)

#### Programming Note

The **msgsync** instruction, which is needed when **msgsnd** or **msgsndu** is used, is not needed when **msgsndp** is used because **msgsndp** targets only threads on the same multi-threaded processor as the thread executing the **msgsndp**, while **msgsnd** and **msgsndu** can target any thread in the system. (If the target thread for **msgsnd** or **msgsndu** is on the same multi-threaded processor as the thread executing the **msgsnd** or **msgsndu**, in principle the **msgsync** can be omitted. This optimization is practical only when the **msgsnd/msgsndu** topology is appropriately constrained, however, because the Directed Hypervisor or Ultravisor Doorbell interrupt provides no indication of which thread executed the **msgsnd** or **msgsndu** that caused the interrupt, so there is no easy way for the interrupt handler to determine whether the **msgsync** can be omitted.) **msgsync** is not needed or defined in V. 2.07 for a similar reason: **msgsnd** in V. 2.07 can target only threads on the same multi-threaded processor as the thread executing the **msgsnd**.

The ordering done by **sync** (and **phwsync** and **ptesync**) provides the appearance of "causality" across a sequence of **msgsnd** (or **msgsndu**) instructions, as in the following example. "**msgsnd**->T1" means "**msgsnd** instruction targeting thread T1". "<DHDI 0>" means "occurrence of Directed Hypervisor Doorbell interrupt caused by **msgsnd** executed on T0". On T0, register r1 is assumed to contain the value 1.

T0	T1	T2
std r1,X	<DHDI 0>	<DHDI 1>
sync	msgsnd->T2	msgsync
msgsnd->T1		ld r1,X

In this example, T2's load from X must return 1.

Another variant of the *Synchronize* instruction is described below. It is designated the Page Table Entry Synchronize instruction, and is specified by the extended mnemonic ***ptesync*** (equivalent to ***sync*** with L=2).

The ***ptesync*** instruction has all of the properties of ***sync*** with L=4 and also the following additional properties.

- The memory barrier created by the ***ptesync*** instruction provides an ordering function for the storage accesses associated with all instructions that are executed by the thread executing the ***ptesync*** instruction and, as elements of set A, for all Reference and Change bit updates associated with additional address translations that were performed, by the thread executing the ***ptesync*** instruction, before the ***ptesync*** instruction is executed. The applicable pairs are all pairs  $a_i, b_j$  in which  $b_j$  is a data access and  $a_i$  is not an instruction fetch.
- The ***ptesync*** instruction causes all Reference and Change bit updates associated with address translations that were performed, by the thread executing the ***ptesync*** instruction, before the ***ptesync*** instruction is executed, to be performed with respect to that thread before the ***ptesync*** instruction's memory barrier is created.
- The memory barrier created by the ***ptesync*** instruction provides an ordering function for all stores to the Partition Table, Process Tables, Segment Tables, Page Directories, and Page Tables caused by *Store* instructions preceding the ***ptesync*** instruction with respect to invalidations, of cached copies of information derived from these tables, caused by ***slbieg***, ***slbiag***, and ***tlbie*** instructions following the ***ptesync*** instruction. The memory barrier ensures that all searches of these tables by another thread, that are performed after an invalidation caused by such an ***slbieg***, ***slbiag***, or ***tlbie*** instruction has been performed with respect to the other thread and that implicitly load from the target location of such a store, will obtain the value stored (or a value stored subsequently).

#### Programming Note

The next bullet is sufficient to order the stores with respect to the invalidations on the thread executing the ***ptesync*** instruction. That bullet is also sufficient to provide the ordering with respect to invalidations caused by ***slbie***, ***slbia***, and ***tlbiel*** instructions, which affect only the thread executing them.

- The ***ptesync*** instruction provides an ordering function for all stores to the Partition Table, Process Tables, Segment Tables, Page Directories, and Page Tables caused by *Store* instructions preced-

ing the ***ptesync*** instruction with respect to searches of these tables that are performed, by the thread executing the ***ptesync*** instruction, after the ***ptesync*** instruction completes. Executing a ***ptesync*** instruction ensures that all such searches that implicitly load from the target location of such a store will obtain the value stored (or a value stored subsequently). Also, the memory barrier created by the ***ptesync*** instruction ensures that all searches of these tables by any other thread, that are performed after a store in set B of the memory barrier has been performed with respect to the other thread and that implicitly load from the target location of such a store, will obtain the value stored (or a value stored subsequently).

- In conjunction with the ***tlbie*** and ***tlbsync*** instructions, the ***ptesync*** instruction provides an ordering function for TLB invalidations and related storage accesses on other threads as described in the ***tlbsync*** instruction description on page 1254.

Similarly, in conjunction with the ***slbieg*** or ***slbiag*** and ***slbsync*** instructions, the ***ptesync*** instruction provides an ordering function for SLB invalidations and related storage accesses on other threads as described in the ***slbsync*** instruction description on page 1243.

#### Programming Note

For instructions following a ***ptesync*** instruction, the memory barrier need not order implicit storage accesses for purposes of address translation and reference and change recording.

The functions performed by the ***ptesync*** instruction may take a significant amount of time to complete, so this form of the instruction should be used only if the functions listed above are needed. Otherwise ***sync*** with L=0 should be used (or ***sync*** with L=1 or with SC≠0, or ***eieio***, or ***sync*** with L=4 or L=5 if appropriate).

Section 6.10, "Translation Table Update Synchronization Requirements" on page 1255 gives examples of uses of ***ptesync***.

## 6.9.3 Lookaside Buffer Management

All implementations have a Segment Lookaside Buffer (SLB). Independent of whether the executing partition operates in a mode that uses hardware SLB loading and bolting versus pure software loading (controlled by the value of `LPCRUPRT`), software is responsible for keeping the SLB current with the segment mapping for the process that is executing. Proper management of the SLB across context switches is described in programming notes.

For performance reasons, most implementations also cache other information that is used in address translation. These caches may include: a Translation Lookaside Buffer (TLB) which is a cache of recently used Page Table Entries (PTEs); a cache of recently used translations of effective addresses to real addresses; a Page Walk Cache for Radix Tree translation; caching of the In-Memory Tables; or any combination of these. Lookaside information, including the SLB, is managed using the instructions described in the subsections of this section unless additional requirements are provided in implementation-specific documentation.

To simplify lookaside buffer management, hardware will only perform speculative translation for the context that is executing, in particular using the current effective values of LPID and PID. Except when LPIDR=0, no translations will be created and cached speculatively when HR=0 and MSR<sub>HV</sub>=1. Furthermore, no translations will be created and cached speculatively in hypervisor or ultravisor real addressing mode. The limitation of speculative behavior in these situations is to cache a PATE when LPIDR is loaded and a PRTE when PIDR is loaded.

#### Programming Note

Speculative Segment Table walks are prohibited when MSR<sub>HV</sub>=1 and LPIDR≠0 because adjunct translations are thread-specific and bolted.

Speculative Segment Table walks are allowed when MSR<sub>HV</sub>=1 and LPIDR=0 to improve performance for "bare metal" operating systems (operating systems that run in hypervisor state). Bare metal operating systems would use LPIDR=0.

Lookaside information derived from PTEs is not necessarily kept consistent with the Page Table. When software alters the contents of a PTE, in general it must also invalidate all corresponding TLB entries and implementation-specific lookaside information; exceptions to this rule are described in Section 6.10.1.2.

The effects of the *slbie*, *slbieg*, *slbia*, *slbiag*, and *TLB Management* instructions on address translations, as specified in Sections 6.9.3.2 for the SLB and 6.9.3.3 for the TLB, Page Walk Cache, and In-Memory Table caches, apply to all implementation-specific lookaside information that is used in address translation. Unless otherwise stated or obvious from context, references to SLB entry invalidation and TLB entry invalidation elsewhere in the Books apply also to invalidation of Page Walk Cache content, In-Memory Table cache content, and all implementation-specific lookaside information that is derived from SLB entries and PTEs, respectively.

All implementations provide a means by which software can invalidate all implementation-specific lookaside information that is derived from PTEs.

Implementation-specific lookaside information that contains translations of effective addresses to real addresses may include "translations" that apply in real addressing mode. Because such "translations" are affected by the contents of the LPCR, HRMOR, and URMOR, when software alters the (relevant) contents of these registers it must also invalidate the corresponding implementation-specific lookaside information. Software can invalidate all such lookaside information by using the *slbia* instruction with IH=0b000. However, performance is likely to be better if other, appropriate, IH values are used to limit the amount of lookaside information that is invalidated.

All implementations that have such lookaside information provide a means by which software can invalidate all such lookaside information.

For simplicity, elsewhere in the Books it is assumed that the TLB exists. Also, unless otherwise stated or obvious from context, in material about TLB invalidations on other threads, "other threads" includes non-processor mechanisms that have synchronously-managed TLBs (e.g., nMMUs), and similarly for SLB invalidations.

#### Programming Note

Because the instructions used to manage TLBs, SLBs, Page Walk Caches, caches of Partition and Process Table Entries, and implementation-specific lookaside information may be changed in a future version of the architecture, it is recommended that software "encapsulate" their use into subroutines.

#### Programming Note

The function of all the instructions described in Sections 6.9.3.2 - 6.9.3.3 is independent of whether address translation is enabled or disabled.

For a discussion of software synchronization requirements when invalidating SLB and TLB entries, see Chapter 13.

### 6.9.3.1 Thread-Specific Segment Translations

It is necessary to provide thread-specific temporary ESID to VSID translations. These translations cannot be placed in valid entries in the Segment Table because the Segment Table has a process scope rather than a thread scope. Instead, software will use *slbnte* to install such translations in the SLB. All SLB entries created using *slbnte* are considered to be "software created." Software created entries will only translate accesses from the hardware thread by which they are installed. When LPCR<sub>UPRT</sub>=1, they are also considered to be "bolted." Each thread has the ability to bolt four entries.

### 6.9.3.2 SLB Management Instructions

The only functionality described in this section that is relevant to Radix Tree translation is the use of *slbia* to invalidate implementation-specific lookaside information. The results of executing any other instruction in this section when HR=1 are boundedly undefined.

Software establishes translations in the SLB using *slb-**mte***. Care must be taken to avoid creating multiple effective-to-virtual translations for any given effective address. Software-created entries will remain in the SLB until invalidated using *slbie* or *slbia* (which also invalidate related implementation-specific lookaside information) or overwritten using *slbmte*. After updating a Segment Table Entry, software must use an *slbie* or *slbiog* instruction to remove lookaside information associated with the old contents of the entry. *slbie* may be used to invalidate software-created entries, but will not invalidate outboard translation caches. *slbiog* does not invalidate software-created entries, but, together with *slbiag*, is the only way to invalidate outboard translation caches. When taking a PID or LPID out of service with the intent of reusing it, software should use *slbiag* to remove stale translations from SLBs and ERATs in the “nest.” (Nest refers to the platform external to the processor cores. Here the reference is to translations cached for use by accelerators.) *slbsync* will establish order between *slbiog* and *slbiag* instructions and a subsequent *ptesync*. *ptesync* must also be used to synchronize the Segment Table update prior to performing the lookaside management. When performing a context switch, software must use an *slbia* instruction to remove lookaside information associated with the old context. *slbmfee* and *slbmfev* may be used by the hypervisor to save software-created entries. *slbmte* is used to restore software-created entries. *slbfee* has no function when LPCR<sub>UPRT</sub>=1 for the partition that is running.

#### Programming Note

Accesses to a given SLB entry caused by the instructions described in this section obey the sequential execution model with respect to the contents of the entry and with respect to data dependencies on those contents. That is, if an instruction sequence contains two or more of these instructions, when the sequence has completed, the final contents of the SLB entry and of General Purpose Registers is as if the instructions had been executed in program order.

However, software synchronization is required in order to ensure that any alterations of the entry take effect correctly with respect to address translation; see Chapter 13.

### SLB Invalidate Entry

*X-form*

slbie RB

0	31	///	///	RB	434	/
	6		11	16	21	31

```

ea0:35 ← (RB)0:35
if, for SLB entry that translates
  or most recently translated ea,
  entry_class = (RB)36 and
  entry_seg_size = size specified in (RB)37:38
then for SLB entry (if any) that translates ea
  SLBEv ← 0
  all other fields of SLBE ← undefined
else
  s ← log_base_2(entry_seg_size)
  esid ← (RB)0:63-s
  u ← undefined 1-bit value
  if u then
    if an SLB entry translates esid
      SLBEv ← 0
      all other fields of SLBE ← undefined
    
```

The operation performed by this instruction is based on the contents of register RB. The contents of this register shown below.

RB

0	ESID	C	B	0s	63
		36	37	39	

- RS<sub>0:31</sub> PID
- RS<sub>32:63</sub> LPID
- RB<sub>0:35</sub> ESID
- RB<sub>36</sub> Class
- RB<sub>37:38</sub> B
- RB<sub>39:63</sub> must be 0b0 || 0x000000

Let the Effective Address (EA) be any EA for which EA<sub>0:35</sub> = (RB)<sub>0:35</sub>. Let the class be (RB)<sub>36</sub>. Let the segment size be equal to the segment size specified in (RB)<sub>37:38</sub>; the allowed values of (RB)<sub>37:38</sub>, and the correspondence between the values and the segment size, are the same as for the B field in the SLBE (see Figure 30 on page 1203).

The class value and segment size must be the same as the class value and segment size in the SLB entry that translates the EA, or the values that were in the SLB entry that most recently translated the EA if the translation is no longer in the SLB; if these values are not the same, it is implementation-dependent whether the SLB entry (or implementation-dependent translation information) that translates the EA is invalidated, and the next paragraph need not apply.

If the SLB contains only a single entry that translates the EA, then that is the only SLB entry that is invalidated, except that it is implementation-dependent whether an implementation-specific lookaside entry for

a real mode address “translation” is invalidated. If the SLB contains more than one such entry, then zero or more such entries are invalidated, and similarly for any implementation-specific lookaside information used in address translation; additionally, a machine check may occur.

SLB entries are invalidated by setting the V bit in the entry to 0, and the remaining fields of the entry are set to undefined values.

This instruction terminates any Segment Table walks being performed on behalf of the thread that executes it.

The hardware ignores the contents of RB listed below and software must set them to 0s.

- (RB)<sub>37</sub>
- (RB)<sub>39</sub>
- (RB)<sub>40:63</sub>
- If s = 40, (RB)<sub>24:35</sub>

If this instruction is executed in 32-bit mode, (RB)<sub>0:31</sub> must be zeros.

This instruction is privileged.

**Special Registers Altered:**

None

**Programming Note**

*slbie* does not affect SLBs on other threads.

**Programming Note**

The reason the class value specified by *slbie* must be the same as the Class value that is or was in the relevant SLB entry is that the hardware may use these values to optimize invalidation of implementation-specific lookaside information used in address translation. If the value specified by *slbie* differs from the value that is or was in the relevant SLB entry, these optimizations may produce incorrect results. (An example of implementation-specific address translation lookaside information is the set of recently used translations of effective addresses to real addresses that some implementations maintain in an Effective to Real Address Translation (ERAT) lookaside buffer.) Note that Radix Tree translations have no defined Class value, so frequent translation mode transitions may perform poorly under these optimizations.

When switching tasks in certain cases, it may be advantageous to preserve some implementation-specific lookaside entries while invalidating others. The *slbia* instruction specifying IH value 0b001 or 0b011 can be used for this purpose if SLB class values are appropriately assigned, i.e., a class value of 0 indicates that the entry should be preserved and a class value of 1 indicates the entry must be invalidated. Also, it is advantageous to assign a class value of 1 to entries that need to be invalidated via an *slbie* instruction while preserving implementation-specific lookaside entries that are derived from real mode address “translation,” SLS address translation, or translations required to access the Segment Table Entry Group, since such entries are assigned a class value of 0.

**Programming Note**

The B value in register RB may be needed for invalidating ERAT entries corresponding to the translation being invalidated.

**Programming Note**

When switching to execute an adjunct, a hypervisor will disable translation and use *slbie* to be sure there is no SLB entry mapping the effective address space that will be used by the incoming adjunct. It will then bolt an entry for the incoming adjunct and transfer control to that adjunct. While the thread is in hypervisor real addressing mode and during adjunct execution, no speculative Segment Table walks will be performed.

**SLB Invalidate Entry Global X-form**

slbieg RS,RB

31	RS	///	RB	466	/
0	6	11	16	21	31

```

target_PID = RS0:31
if MSRHV=1 then target_LPID = RS32:63
else target_LPID = LPIDR
ea0:35 ← (RB)0:35
for each thread with LPIDR=target_LPID and
    PIDR=target_PID
  if, for each SLB entry that
  translates or most recently translated ea
    entry_class = (RB)36 and
    entry_seg_size = size specified in (RB)37:38
  then for SLB entry (if any)
  that translates ea and is not software-created
    SLBEV ← 0
    all other fields of SLBE ← undefined
  else
    s ← log_base_2(entry_seg_size)
    esid ← (RB)0:63-s
    u ← undefined 1-bit value
    if u then
      if an SLB entry translates esid and the entry
      is not software-created
        SLBEV ← 0
        all other fields of SLBE ← undefined

```

The operation performed by this instruction is based on the contents of registers RS and RB. The contents of these registers are shown below.

RS

PID	LPID
0	32
	63

RB

ESID	C	B	0s
0	36	37	39
			63

RS<sub>0:31</sub> PID  
 RS<sub>32:63</sub> LPID  
 RB<sub>0:35</sub> ESID  
 RB<sub>36</sub> Class  
 RB<sub>37:38</sub> B  
 RB<sub>39:63</sub> must be 0b0 || 0x000000

Let the target PID be RS<sub>0:31</sub>. If the instruction is executed in hypervisor state, let the target LPID be RS<sub>32:63</sub>; otherwise let the target LPID be the contents of LPIDR. Let the Effective Address (EA) be any EA for which EA<sub>0:35</sub> = (RB)<sub>0:35</sub>. Let the class be (RB)<sub>36</sub>. Let the segment size be equal to the segment size specified in (RB)<sub>37:38</sub>; the allowed values of (RB)<sub>37:38</sub>, and

the correspondence between the values and the segment size, are the same as for the B field in the SLBE (see Figure 30 on page 1203).

Only SLBs for threads running on behalf of target\_LPID and target\_PID are searched. Software-created entries are not invalidated. The class value and segment size must be the same as the class value and segment size in the SLB entry that translates the EA, or the values that were in the SLB entry that most recently translated the EA if the translation is no longer in the SLB; if these values are not the same, it is implementation-dependent whether the SLB entry (or implementation-dependent translation information) that translates the EA is invalidated, and the next paragraph need not apply.

If the SLB contains only a single entry that translates the EA, then that is the only SLB entry that is invalidated, except that it is implementation-dependent whether an implementation-specific lookaside entry for a real mode address “translation” is invalidated. If the SLB contains more than one such entry, then zero or more such entries are invalidated, and similarly for any implementation-specific lookaside information used in address translation; additionally, a machine check may occur.

SLB entries are invalidated by setting the V bit in the entry to 0, and the remaining fields of the entry are set to undefined values.

The hardware ignores the contents of RB listed below and software must set them to 0s.

- (RB)<sub>37</sub>
- (RB)<sub>39</sub>
- (RB)<sub>40:63</sub>
- If s = 40, (RB)<sub>24:35</sub>

If this instruction is executed in 32-bit mode, (RB)<sub>0:31</sub> must be zeros.

The operation performed by this instruction is ordered by the *ei*eo (or *[p]hwsync* or *ptesync*) instruction with respect to a subsequent *slbsync* instruction executed by the thread executing the *slbieg* instruction. The operations caused by *slbieg* and *slbsync* are ordered by *ei*eo as a fifth set of operations, which is independent of the other four sets that *ei*eo orders.

This instruction is privileged except when LPCR<sub>G-TSE</sub>=0, making it hypervisor privileged.

**Special Registers Altered:**  
None

**Programming Note**

*slbieg* does affect SLBs on other threads.

**Programming Note**

The reason the class value specified by *slbieg* must be the same as the Class value that is or was in the relevant SLB entry is that the hardware may use these values to optimize invalidation of implementation-specific lookaside information used in address translation. If the value specified by *slbieg* differs from the value that is or was in the relevant SLB entry, these optimizations may produce incorrect results. (An example of implementation-specific address translation lookaside information is the set of recently used translations of effective addresses to real addresses that some implementations maintain in an Effective to Real Address Translation (ERAT) lookaside buffer.) Note that Radix Tree translations have no defined Class value, so frequent translation mode transitions may perform poorly under these optimizations.

When switching tasks in certain cases, it may be advantageous to preserve some implementation-specific lookaside entries while invalidating others. The *slbia* instruction specifying IH value 0b001 or 0b011 can be used for this purpose if SLB class values are appropriately assigned, i.e., a class value of 0 indicates that the entry should be preserved and a class value of 1 indicates the entry must be invalidated. Also, it is advantageous to assign a class value of 1 to entries that need to be invalidated via an *slbieg* instruction while preserving implementation-specific lookaside entries that are derived from real mode address "translation," SLS address translation, or translations required to access the Segment Table Entry Group, since such entries are assigned a class value of 0.

**Programming Note**

The B value in register RB may be needed for invalidating ERAT entries corresponding to the translation being invalidated.

**Programming Note**

Use of *slbieg* to invalidate software-created segment descriptors is a programming error. The architecture requires that bolted entries not be invalidated by the instruction.

      SLBEV ← 0
      all other fields of SLBE ← undefined
  case (0b100):
    for each SLB entry
      SLBEV ← 0
      all other fields of SLBE ← undefined
  case (0b111):
```

*slbia* invalidates the contents of the SLB, and of implementation-specific lookaside information for effective to real address translations, based on the contents of the IH field as described below. SLB entries are invalidated by setting the V bit in the entry to 0. When an SLB entry is invalidated, the remaining fields of the entry are set to undefined values.

In the description of the IH values, "implementation-specific lookaside information" is shorthand for "implementation-specific lookaside information for effective to real address translations," and "when address translation was enabled" is shorthand for "when MSR<sub>IR</sub> was equal to 1 or MSR<sub>DR</sub> was equal to 1, as appropriate for the type of access," and correspondingly for "when address translation was disabled." The descriptions specify which entries must be invalidated; additional entries may be invalidated except where the description states that certain SLB entries are not invalidated.

- 0b000 All SLB entries except entry 0 are invalidated; SLB entry 0 is not invalidated. All implementation-specific lookaside information is invalidated.
- 0b001 All SLB entries except entry 0 are invalidated; SLB entry 0 is not invalidated. All implementation-specific lookaside information that was created when address translation was enabled and satisfies either of the following conditions is invalidated.
  - The information is for an SLB-derived translation and has a Class value of 1.
  - The information is for a Radix Tree-derived translation for which effPID≠0.
- 0b010 All SLB entries except entry 0 are invalidated; SLB entry 0 is not invalidated. All implementation-specific lookaside information that was created when address translation was enabled is invalidated.
- 0b011 All SLB entries having a Class value of 1 are invalidated; SLB entry 0 is not invalidated if it has a Class value of 0. All implementation-specific lookaside information that was created when address translation was enabled and satisfies either of the following conditions is invalidated.

- The information is for an SLB-derived translation and has a Class value of 1.
- The information is for a Radix Tree-derived translation for which  $\text{effPID} \neq 0$ .

0b100 All SLB entries are invalidated.  
All implementation-specific lookaside information is invalidated.

0b110 All SLB entries except entry 0 are invalidated; SLB entry 0 is not invalidated.  
All implementation-specific lookaside information that satisfies any of the following conditions is invalidated.

- The information is for an SLB-derived or SLS translation.
- The information is for a Radix Tree-derived translation for which  $\text{effLPID} \neq 0$  or  $\text{effPID} \neq 0$ .
- The information was created when address translation was disabled and  $\text{MSR}_{\text{HV PR}}$  was equal to 0b00.

0b111 No SLB entries are invalidated.  
All implementation-specific lookaside information is invalidated.

#### Programming Note

In the preceding description, “SLB-derived translation” excludes any SLS translation, since SLS translation does not use segmentation.

All other IH values are reserved. If the IH field contains a reserved value, the set of SLB entries and implementation-specific lookaside information that is invalidated by the instruction is undefined.

When  $\text{IH} = 0\text{b}000$ ,  $0\text{b}100$ , or  $0\text{b}111$ , execution of this instruction has the side effect of clearing the storage access history associated with the Hypervisor Real Mode Storage Control facility. See Section 6.7.3.2.1, “Hypervisor Real Mode Storage Control” for more details.

This instruction terminates any Segment Table walks being performed on behalf of the thread that executes it, and ensures that any new table walks will be performed using the current PIDR value.

This instruction is privileged.

#### Special Registers Altered:

None

#### Programming Note

When performing a context switch between processes, an HPT operating system will use *mtPIDR* followed by *slbia*. The synchronization of the PID value and termination of outstanding Segment Table walks ensures that SLB will not contain multiple entries mapping the same EA range (i.e. from the former and new PIDs). Note that if this sequence is performed with translation enabled, care must be taken to avoid an implicit branch. (i.e. the same translation(s) for the locations containing the context switch routine must be valid for both processes.)

For the corresponding situation when changing partitions from or to a partition using HPT translation, hypervisor software should get all the affected threads into real mode, execute *mtLPIDR*, and then perform the *slbia* on all the affected threads. (If the affected threads were not in real mode, avoiding implicit branches due to the *mtLPIDR* would be very difficult.)

#### Programming Note

*slbia* does not affect SLBs on other threads.

#### Programming Note

If *slbia* is executed when instruction address translation is enabled, software can ensure that attempting to fetch the instruction following the *slbia* does not cause an Instruction Segment interrupt by placing the *slbia* and the subsequent instruction in the effective segment mapped by SLB entry 0. (The preceding assumes that no other interrupts occur between executing the *slbia* and executing the subsequent instruction. It also assumes that IH values other than  $0\text{b}011$  and  $0\text{b}100$  are used.)

**Programming Note**

Examples of the intended use of the IH values follow.

- 0b000 This setting should be used by a bare metal operating system or hypervisor to make extensive translation changes with address translation enabled and using  $LPCR_{UPRT}=0$ .
- 0b001 This setting should be used by an operating system that uses HPT translation and manages the Class bit but doesn't trust its use to manage the SLB (an extension to the longer-standing base function that could have compatibility implications) when switching tasks. Operating systems that use Radix Tree translation may also use this setting.
- 0b010 This setting should be used by an operating system that uses HPT translation and does not manage the Class bit when switching tasks.
- 0b011 This setting should be used by an operating system that uses HPT translation, manages the Class bit and trusts its use to manage the SLB when switching tasks. Operating systems that use Radix Tree translation may also use this setting.
- 0b100 This setting should be used by a bare metal operating system or hypervisor to make extensive translation changes with address translation disabled or using  $LPCR_{UPRT}=1$ .
- 0b110 This setting should be used by the hypervisor when switching partitions when  $LPCR_{UPRT}=0$  and address translation is enabled.
- 0b111 This setting is provided mainly for use prior to product shipment, but may provide benefit in an environment that uses Radix Tree translation if SLB invalidation is much slower than ERAT invalidation.

**Programming Note**

*slbia* serves as both a basic and an extended mnemonic. The Assembler will recognize an *slbia* mnemonic with one operand as the basic form, and an *slbia* mnemonic with no operand as the extended form. In the extended form the IH operand is omitted and assumed to be 0.

**SLB Invalidate All Global****X-form**

slbiag RS, L

31	RS	///	L	///	850	/
0	6	11	15	16	21	31

```

if L=0 then target_PID = RS0:31
if MSRHV=1 then target_LPID = RS32:63
else target_LPID = LPIDR
for each nest SLB
  for each SLBE with LPID=target_LPID and
    (PID=target_PID | L=1)
    SLBEV ← 0
  all other fields of SLBE ← undefined

```

The operation performed by this instruction is based on the contents of register RS. The contents of this register is shown below.

RS

PID		LPID	
0	32	63	

RS<sub>0:31</sub> PID  
RS<sub>32:63</sub> LPID

If L=0, let the target PID be RS<sub>0:31</sub>. If the instruction is executed in hypervisor state, let the target LPID be RS<sub>32:63</sub>; otherwise let the target LPID be the contents of LPIDR.

All nest SLBs are searched. If L=0, each SLBE for process PID in partition LPID is invalidated. If L=1, each SLBE for partition LPID is invalidated.

SLB entries are invalidated by setting the V bit in the entry to 0, and the remaining fields of the entry are set to undefined values.

All implementation specific lookaside information associated with SLB-derived translations for the target LPID || PID (L=0) or for the target LPID (L=1) is invalidated. Additional implementation specific lookaside information may be invalidated.

The operation performed by this instruction is ordered by the *eiemo* (or *[p]hwsync* or *ptesync*) instruction with respect to a subsequent *slbsync* instruction executed by the thread executing the *slbiag* instruction. The operations caused by *slbiag* and *slbsync* are ordered by *eiemo* as a fifth set of operations, which is independent of the other four sets that *eiemo* orders.

This instruction is privileged except when  $LPCR_{GTSE}=0$ , making it hypervisor privileged.

**Special Registers Altered:**

None

**Programming Note**

**slbiag** does not affect SLBs on processor threads.

“g” (Global) in the name of the instruction reflects the fact that a future version of the architecture may extend the definition of **slbiag** to allow programs to specify additional sets of SLBs that the instruction affects, possibly including SLBs on processor threads.

**Programming Note**

**slbiag** serves as both a basic and an extended mnemonic. The Assembler will recognize an **slbiag** mnemonic with two operands as the basic form, and an **slbiag** mnemonic with one operand as the extended form. In the extended form the L operand is omitted and assumed to be 0.

**SLB Move To Entry**

**X-form**

slbmtc RS, RB

When  $LPCR_{UPRT}=0$ , this instruction is the sole means for specifying Segment translations to the hardware. When  $LPCR_{UPRT}=1$ , Segment Table walks populate the SLB, and this instruction is used only to bolt thread-specific Segment translations.

The SLB entry specified by bits 52:63 of register RB is loaded from register RS and from the remainder of register RB. The contents of these registers are interpreted as shown in Figure 51.

RS

RB

- RS<sub>0:1</sub> B
- RS<sub>2:51</sub> VSID
- RS<sub>52</sub>  $K_s$
- RS<sub>53</sub>  $K_p$
- RS<sub>54</sub> N
- RS<sub>55</sub> L
- RS<sub>56</sub> C
- RS<sub>57</sub> must be 0b0
- RS<sub>58:59</sub> LP
- RS<sub>60:63</sub> must be 0b0000
- RB<sub>0:35</sub> ESID
- RB<sub>36</sub> V
- RB<sub>37:51</sub> must be 0b000 || 0x000
- RB<sub>52:63</sub> index, which selects the SLB entry

**Figure 51. GPR contents for slbmtc**

On implementations that support a virtual address size of only n bits,  $n < 78$ , (RS)<sub>2:79-n</sub> must be zeros.

When  $LPCR_{UPRT}=1$ , the value of index must not exceed 3. (RB)<sub>52:61</sub> are ignored.

High-order bits of (RB)<sub>52:63</sub> that correspond to SLB entries beyond the size of the SLB provided by the implementation must be zeros.

The hardware ignores the contents of RS and RB listed below and software must set them to 0s.

- (RS)<sub>57</sub>
- (RS)<sub>60:63</sub>
- (RB)<sub>37:51</sub>

If this instruction is executed in 32-bit mode, (RB)<sub>0:31</sub> must be zeros (i.e., the ESID must be in the range 0:15).

This instruction must not be used to load a segment descriptor that is in the Segment Table when  $LPCR_{UPRT}=1$ , and cannot be used to invalidate the translation contained in an SLB entry.

This instruction is privileged.

**Special Registers Altered:**

None

**Programming Note**

The reason *slbmt* must not be used to load segment descriptors that are in the Segment Table is that there could be a race condition with hardware loading the same segment descriptor, resulting in duplicate SLB entries. Software must not allow duplicate SLB entries to be created; see Section 6.7.8.2, “SLB Search”.

The reason *slbmt* cannot be used to invalidate an SLB entry is that it does not necessarily affect implementation-specific address translation lookaside information. *slbie* (or *slbia*) must be used for this purpose.

**SLB Move From Entry VSID** **X-form**

slbmfev RT, RB

31	RT	///	L	RB	851	/
0	6	11	15	16	21	31

This instruction is used to read software-loaded SLB entries. When  $LPCR_{UPRT}=0$ , the entry is specified by bits 52:63 of register RB. When  $LPCR_{UPRT}=1$ , only the first four entries can be read, so bits 52:61 of register RB are ignored. If the specified entry is valid ( $V=1$ ), the contents of the B, VSID,  $K_s$ ,  $K_p$ , N, L, C, and LP fields of the entry are placed into register RT. The contents of these registers are interpreted as shown in Figure 52.

RT

B	VSID	$K_s$	$K_p$	NLC	0	LP	0s
0	2	52	57	58	60	63	63

RB

0s	index
0	52
52	63

RT <sub>0:1</sub>	B
RT <sub>2:51</sub>	VSID
RT <sub>52</sub>	$K_s$
RT <sub>53</sub>	$K_p$
RT <sub>54</sub>	N
RT <sub>55</sub>	L
RT <sub>56</sub>	C
RT <sub>57</sub>	set to 0b0
RT <sub>58:59</sub>	LP
RT <sub>60:63</sub>	set to 0b0000

RB <sub>0:51</sub>	must be 0x0_0000_0000_0000
RB <sub>52:63</sub>	index, which selects the SLB entry

**Figure 52. GPR contents for slbmfev**

On implementations that support a virtual address size of only  $n$  bits,  $n < 78$ ,  $RT_{2:79-n}$  are set to zeros.

If the SLB entry specified by bits 52:63 of register RB is invalid ( $V=0$ ), the contents of register RT are set to 0.

High-order bits of  $(RB)_{52:63}$  that correspond to SLB entries beyond the size of the SLB provided by the implementation must be zeros.

The hardware ignores the contents of  $RB_{0:51}$ .

This instruction is privileged.

The use of the L field is implementation specific.

**Special Registers Altered:**

None

**SLB Move From Entry ESID****X-form**

slbmfee RT, RB

This instruction is used to read software-loaded SLB entries. When  $LPCR_{UPRT}=0$ , the entry is specified by bits 52:63 of register RB. When  $LPCR_{UPRT}=1$ , only the first four entries can be read, so bits 52:61 of register RB are ignored. If the specified entry is valid ( $V=1$ ), the contents of the ESID and V fields of the entry are placed into register RT. If  $LPCR_{UPRT}=1$ , the value of the BO field of the entry is also placed into register RT. The contents of these registers are interpreted as shown in Figure 53.

RT

RB

RT<sub>0:35</sub> ESID  
 RT<sub>36</sub> V  
 RT<sub>37</sub> BO, entry is bolted  
 RT<sub>38:63</sub> set to 0b000 || 0x00\_0000  
 RB<sub>0:51</sub> must be 0x0\_0000\_0000\_0000  
 RB<sub>52:63</sub> index, which selects the SLB entry

**Figure 53. GPR contents for slbmfee**

If the SLB entry specified by bits 52:63 of register RB is invalid ( $V=0$ ), the contents of register RT are set to 0.

High-order bits of  $(RB)_{52:63}$  that correspond to SLB entries beyond the size of the SLB provided by the implementation must be zeros.

The hardware ignores the contents of  $RB_{0:51}$ .

This instruction is privileged.

The use of the L field is implementation specific.

**Special Registers Altered:**

None

**SLB Find Entry ESID****X-form**

slbfee. RT, RB

The SLB is searched for an entry that matches the effective address specified by register RB. When  $LPCR_{UPRT}=1$ , this instruction is nonfunctional. The search is performed as if it were being performed for purposes of address translation. That is, in order for a given entry to satisfy the search, the entry must be valid ( $V=1$ ), and  $(RB)_{0:63-s}$  must equal  $SLBE[ESID_{0:63-s}]$  (where  $2^s$  is the segment size selected by the B field in the entry). If exactly one matching entry is found, the contents of the B, VSID,  $K_s$ ,  $K_p$ , N, L, C, and LP fields of the entry are placed into register RT. If no matching entry is found, register RT is set to 0. If more than one matching entry is found, either one of the matching entries is used, as if it were the only matching entry, or a Machine Check occurs. If a Machine Check occurs, register RT, and CR Field 0 are set to undefined values, and the description below of how this register and this field is set does not apply.

The contents of registers RT and RB are interpreted as shown in Figure 54.

RT

RB

RT<sub>0:1</sub> B  
 RT<sub>2:51</sub> VSID  
 RT<sub>52</sub>  $K_s$   
 RT<sub>53</sub>  $K_p$   
 RT<sub>54</sub> N  
 RT<sub>55</sub> L  
 RT<sub>56</sub> C  
 RT<sub>57</sub> set to 0b0  
 RT<sub>58:59</sub> LP  
 RT<sub>60:63</sub> set to 0b0000  
 RB<sub>0:35</sub> ESID  
 RB<sub>36:39</sub> must be 0b0000  
 RB<sub>40:63</sub> must be 0x000000

**Figure 54. GPR contents for slbfee.**

If  $s > 28$ ,  $RT_{80-s:51}$  are set to zeros. On implementations that support a virtual address size of only n bits,  $n < 78$ ,  $RT_{2:79-n}$  are set to zeros.

CR Field 0 is set as follows. j is a 1-bit value that is equal to 0b1 if a matching entry was found. Otherwise, j is 0b0. When  $LPCR_{UPRT} \neq 0$ ,  $j=0b0$ .

$$CR0_{LTGT EQ SO} = 0b00 \parallel j \parallel XER_{SO}$$

The hardware ignores the contents of  $RB_{36:38 40:63}$ .

If this instruction is executed in 32-bit mode,  $(RB)_{0:31}$  must be zeros (i.e., the ESID must be in the range 0-15).

This instruction is privileged.

**Special Registers Altered:**

CR0

**Programming Note**

When  $LPCR_{UPRT}=0$ , the hypervisor can use *slbfee* to save the contents of any SLBE that the partition has created to map an ESID that is needed by an adjunct, and later use the saved contents to restore the partition-created SLBE after the adjunct has completed execution. The hypervisor must also use *slbie*, twice, first to invalidate the partition-created mapping and later to invalidate the adjunct's mapping.

When  $LPCR_{UPRT}=1$ , the partition's SLBE will be restored from the Segment Table by hardware, on demand, after the second *slbie* has been executed. There is no need for the hypervisor to save and restore the partition's SLBE and hence no need to use *slbfee*.

When the need for  $LPCR_{UPRT}=0$  has ended, *slbfee* may be removed from the architecture. Programs that run with  $LPCR_{UPRT}=1$  should not use *slbfee*.

## SLB Synchronize

**X-form**

*slbsync*

0	31	///	///	///	338	/
	6	11	16	21	31	

The *slbsync* instruction provides an ordering function for the effects of all *slbieg* and *slbiag* instructions executed by the thread executing the *slbsync* instruction, with respect to the memory barrier created by a subsequent *ptesync* instruction executed by the same thread. Executing a *slbsync* instruction ensures that all of the following will occur.

- All SLB invalidations caused by *slbieg* and *slbiag* instructions preceding the *slbsync* instruction will have completed on any other thread before any data accesses caused by instructions following the *ptesync* instruction are performed with respect to that thread.
- All storage accesses by other threads for which the address was translated using the translations being invalidated will have been performed with respect to the thread executing the *ptesync* instruction, to the extent required by the associated Memory Coherence Required attributes, before the *ptesync* instruction's memory barrier is created.

The operation performed by this instruction is ordered by the *eieio* (or *[p]hwsync* or *ptesync*) instruction with respect to preceding *slbieg* and *slbiag* instructions executed by the thread executing the *slbsync* instruction. The operations caused by *slbieg* or *slbiag* and *slbsync* are ordered by *eieio* as a fifth set of operations, which is independent of the other four sets that *eieio* orders.

The *slbsync* instruction may complete before operations caused by *slbieg* or *slbiag* instructions preceding the *slbsync* instruction have been performed.

This instruction is privileged except when  $LPCR_{GTSE}=0$ , making it hypervisor privileged.

See Section 6.10 for a description of other requirements associated with the use of this instruction.

**Special Registers Altered:**

None

**Programming Note**

*slbsync* should not be used to synchronize the completion of *slbie*.

### 6.9.3.3 TLB Management Instructions

In addition to managing the TLB, *tlbie* and *tlbiel* are also used to manage the Page Walk Cache, In-Memory Table caching, and implementation-specific lookaside information that depends on the values of the PTEs. The parameters described below specify the type of translations to invalidate and the scope of the invalidation to be performed.

Radix Invalidation Control (RIC) specifies whether to invalidate the TLB, the Page Walk Cache, or both together with partition and Process Table caching. The RIC values and functions are as follows.

- 0 Just invalidate TLB.
- 1 Invalidate just Page Walk Cache.
- 2 Invalidate TLB, Page Walk Cache, and any caching of Partition and Process Table Entries.
- 3 Invalidate a group of translations (just in the TLB).

Process Scoped (PRS) specifies whether the translation(s) to be invalidated are partition scoped or process scoped including, for RIC=2, whether Process or Partition Table caching is being invalidated.

- 0 Invalidate partition-scoped translation(s).
- 1 Invalidate process-scoped translation(s).

Radix (R) specifies whether the translation(s) to be invalidated are Radix Tree translations or HPT translations. (R is ignored for invalidates with IS=3 and MSR<sub>HV</sub>=1 because they have the potential to target translations for multiple partitions.)

- 0 Invalidate HPT translation(s).
- 1 Invalidate Radix Tree translation(s).

When MSR<sub>HV</sub>=0, LPCR<sub>HR</sub> is used instead of R. To indicate the possibility of this substitution, the shorthand "effR" (effective R) is used in the instruction descriptions. effR=R when MSR<sub>HV</sub>=1, and effR=LPCR<sub>HR</sub> when MSR<sub>HV</sub>=0. If the effR value is incorrect for the target partition, the results of the operation are boundedly undefined.

Invalidation Selector (IS) (found in RB) specifies the scope of the context to be invalidated.

- 0 Invalidate just the target VA.
- 1 Invalidate matching PID.
- 2 Invalidate matching LPID.
- 3 If MSR<sub>HV</sub>=1, invalidate all entries, otherwise invalidate matching LPID.

#### Programming Note

The hypervisor needs to be able to invalidate translations for any partition. The operating system, on the other hand, is restricted to invalidate translations for its own partition. Using effR in the description of *tlbie* permits this difference to be conveyed succinctly. *tlbiel* affects only the partition in which it is executed, so *tlbiel* could be described using LPCR<sub>HR</sub> instead of effR. effR is used for *tlbiel* for consistency with *tlbie*.

The use of effR in the RTL and verbal descriptions of *tlbie[!]* beginning in Version 3.1B of the architecture is a clarification of earlier architecture, not a functional change.

The IS≠0 RIC=2 variants of *tlbie* and *tlbiel* perform the same TLB invalidations as the corresponding RIC=0 variants, but in addition invalidate Page Walk Cache Entries and Partition or Process Table caching associated with the specified LPID or LPID/PID. When RIC=1 and IS≠0, the Page Walk Cache Entries for the specified LPID or LPID/PID are invalidated while leaving the corresponding TLB entries intact. The ability to target an individual Page Walk Cache Entry or the set of entries associated with a given Page Table Entry (i.e. IS=0 for RIC=1 or RIC=2) is not supported by the Power ISA. When RIC=3 and IS=0, *tlbie* invalidates a series of consecutive translations for HPT translation. For IS=0 invalidations of Radix Tree translations, the use of *tlbie[!]* is limited to translations for quadrant 0.

When reassigning an LPID or PID, after updating the Partition and/or Process Table(s) software must use a *tlbie* instruction to remove lookaside information associated with the old partition or process.

To invalidate TLB entries, software must supply an effective page number for process-scoped Radix Tree translations, a guest real page number for partition-scoped Radix Tree translations, and an abbreviated base virtual page number for HPT translations. The RTL, RB illustration, and verbal description for effR=1 require the reader to make the appropriate mental substitution for partition-scoped invalidation. Note also that where page size is specified to be a function of L and AP, it may also be a function of L and LP. The architecture allows for three independent sets of page sizes, one for effR=1, one for RIC=3 (requires effR=0), and one for all other cases. An implementation may choose to have a single set of encodings work consistently between any two or all three states.

As described in Section 6.7.7, software must manage the Page Table and TLB so that there are no overlapping translations in the TLB. Failure to do so may result in *tlbie[!]* specifying IS=0 not invalidating the appropriate TLB entries.

**Programming Note**

As shown in the instruction descriptions, the abbreviated virtual address supplied by *tlbie[]* for HPT translations omits the high-order 14 bits of the virtual address. Translations in the TLB that differ only in these 14 bits are not considered to be overlapping translations, and a *tlbie[]* instruction with *effR=0* and *IS=0* that invalidates one of the corresponding TLB entries will invalidate all of them.

The operation performed by this instruction is based on the contents of registers RS and RB. The contents of these registers are shown below, where IS is (RB)<sub>52:53</sub> and L is (RB)<sub>63</sub>.

RS:

**Programming Note**

Note that although there is no PID compare for partition-scoped translation, software must still place the PID in RS when IS=0 or 1. It may be used, for example, in the TLB hash.

RB for effR=1 and IS=0b00:

RB for effR=0, IS=0b00, RIC≠3, and L=0:

RB for effR=0, IS=0b00, RIC≠3, and L=1:

RB for effR=0, IS=0b00, and RIC=3:

RB for IS=0b01, 0b10, or 0b11:

If this instruction is executed in hypervisor state, RS<sub>32:63</sub> contains the search\_LPID, which is the partition ID (LPID) of the partition for which one or more translations are being invalidated. Otherwise, the value in LPIDR is used as the search\_LPID. The supported (RS)<sub>32:63</sub> values are the same as the LPID values supported in LPIDR. RS<sub>0:31</sub> contains a PID value. The supported values of RS<sub>0:31</sub> are the same as the PID values supported in PIDR.

The following forms are treated as if the instruction form were invalid.

- PRS=1, effR=0, and RIC≠2 (The only process-scoped HPT caching is of the Process Table.)
- RIC=1 and effR=0 (There is no Page Walk Cache for HPT translation.)
- RIC=3 and effR=1 (Group invalidation is only supported for HPT translation.)
- RIC=1 and IS=0 (The architecture does not support shutdown of individual translations in the Page Walk Cache.)

- RIC=2 and IS=0 (RIC is for comprehensive invalidation that is not supported at the level of an individual page.)
- RIC=3 and IS≠0 (Group invalidation is only supported for individual pages.)
- PRS=0 and IS=1 (Partition-scoped translations are not associated with processes.)
- $effR=0$ , IS=1, and RIC≠2 (HPT translations are not associated with processes.)
- $effR=0$ , RIC=2, PRS=0, HV=0, and IS=2 or 3 (The similar cases with RIC=0 allow the HPT OS to invalidate all of its TLB entries. The only incremental function of these cases is to invalidate partition table caching, which the OS is not permitted to do.)

The results of an attempt to invalidate a translation outside of quadrant 0 for Radix Tree translation ( $effR=1$ , RIC=0, PRS=1, IS=0, and  $EA_{0:1} \neq 0b00$ ) are boundedly undefined.

### IS field in RB contains 0b00

If RIC=0, this is a search for a single TLB entry. The following relationships must be true and tests and actions are performed to search for an HPT translation.

Variable  $i$  is equal to  $63 - \log_2$  (scope of the TLB entry)

If the base page size specified by the PTE that was used to create the TLB entry to be invalidated is 4 KB, the L field in register RB must contain 0.

If the L field in RB contains 0, the base page size is 4 KB and  $RB_{56:58}$  (AP - Actual Page size field) must be set to the  $SLBE_{L||LP}$  encoding for the page size corresponding to the actual page size specified by the PTE that was used to create the TLB entry to be invalidated. Thus,  $b$  is equal to 12 and  $p$  is equal to  $\log_2$  (actual page size specified by  $RB_{56:58}$ ). The Abbreviated Virtual Address (AVA) field in register RB must contain bits 14:65 of the virtual address translated by the TLB entry to be invalidated. Variable  $inst\_AVA$  is equal to the AVA field of RB.

If the L field in RB contains 1, the following rules apply.

- The base page size and actual page size are specified in the LP field in register RB, where the relationship between  $(RB)_{44:51}$  (LP - Large Page size selector field) and the base page size and actual page size is the same as the relationship between  $PTE_{LP}$  and the base page size and actual page size (see Section 6.7.9.1 on page 1207 and Figure 35 on page 1208). Thus,  $b$  is equal to  $\log_2$  (base page size specified by  $(RB)_{44:51}$ ) and  $p$  is equal to  $\log_2$  (actual page size specified by  $(RB)_{44:51}$ ). Specifically,  $(RB)_{44+c:51}$  must be equal to the contents of bits  $c:7$  of the LP field

of the PTE that was used to create the TLB entry to be invalidated, where  $c$  is the number of “r” bits in the LP field of the PTE that was used to create the TLB entry to be invalidated.

- Variable  $j$  is the larger of  $(63-p)$  and the value that is the smaller of 43 and  $(63-b)$ .  $(RB)_{0:j}$  must contain bits 14:( $j+14$ ) of the virtual address translated by the TLB entry to be invalidated. If  $b > 20$ ,  $RB_{64-b:43}$  may contain any value and are ignored by the hardware.
- If  $b < 20$ ,  $(RB)_{56:75-b}$  must contain bits 58:77- $b$  of the virtual address translated by the TLB entry to be invalidated, and other bits in  $(RB)_{56:62}$  may contain any value and are ignored by the hardware.
- If  $b \geq 20$ ,  $(RB)_{56:62}$  (AVAL - Abbreviated Virtual Address, Lower) may contain any value and are ignored by the hardware.
- Variable  $inst\_AVA$  is equal to the AVA field of RB concatenated with the AVAL field and 0b0.

Let the segment size be equal to the segment size specified in  $(RB)_{54:55}$  (B field). The contents of  $RB_{54:55}$  must be the same as the contents of the B field of the PTE that was used to create the TLB entry to be invalidated.

$RB_{52:53}$  and  $RB_{59:62}$  (when  $(RB)_{63} = 0$ ) must contain zeros and are ignored by the hardware.

All TLB entries on all threads that have all of the following properties are made invalid.

- $VA_{14:14+i}$  is equal to  $inst\_AVA_{0:i}$ .
- The segment size of the entry is the same as the segment size specified in  $(RB)_{54:55}$ .
- The entry is partition scoped.
- $TLBE_{LPID} = search\_LPID$ .

The following relationships must be true and tests and actions are performed to search for a Radix Tree translation. For a partition-scoped invalidation, references to the effective address are understood to refer to the guest real address.

The page size is encoded in  $RB_{56:58}$  (AP - Actual Page size field). Thus  $p$  is equal to  $\log_2$  (page size specified by  $RB_{56:58}$ ). The Effective Page Number (EPN) field in register RB must contain the bits 0: $i$  of the effective address translated by the TLB entry to be invalidated. Variable  $i$  is equal to  $63-p$ .

The fields shown as zeros must be set to zero and are ignored by the hardware.

All TLB entries on all threads that have all of the following properties are made invalid.

- The entry translates an effective address for which  $EA_{0:i}$  is equal to  $(RB)_{0:i}$ .

- The page size of the entry matches the page size specified in (RB)<sub>56:58</sub>.
- The entry has the appropriate scope (partition or process).
- The process ID specified in RS matches the process ID in the TLB entry if not invalidating a partition-scoped translation.
- TLBE<sub>LPID</sub> = search\_LPID.

Additional TLB entries may also be made invalid if those TLB entries contain an LPID that matches search\_LPID.

If RIC=3, then the TLB entries mapping an aligned sequence of virtual pages are made invalid on all threads. The number of virtual pages in the sequence, and their page size (base page size = actual page size), are provided using an implementation-specific encoding of the GS field of RB. The number of virtual pages is a power of two. The abbreviated virtual address of the beginning of the sequence is provided by the AVA field of RB with the appropriate number of low-order bits treated as zero to cause the affected region of VA space to be aligned at a multiple of its size. The effect is as if a *tlbie* instruction with RIC=PRS=effR=0 were executed for each virtual page in the sequence, using the supplied contents of RS and RB except using the AVA value corresponding to the virtual page and using the base and actual page size provided by GS, and with the additional match criterion that the base and actual page sizes match the scope of the TLB entry.

### IS field in RB is non-zero

If RIC=0 or RIC=2, all partition-scoped TLB entries when PRS=0 and either MSR<sub>HV</sub>=1 or effR=0, or all process-scoped TLB entries when PRS=1 on all threads for which any of the following conditions are met for the entry are made invalid.

- The IS field in RB contains 0b10 or MSR<sub>HV</sub>=0 and the IS field contains 0b11, and TLBE<sub>LPID</sub> matches the partition ID of the partition for which the translation is to be invalidated.
- The IS field in RB contains 0b01, TLBE<sub>LPID</sub> matches the partition ID of the partition for which the translation is to be invalidated, and TLBE<sub>PID</sub>=RS<sub>0:31</sub>.
- The IS field in RB contains 0b11 and MSR<sub>HV</sub>=1.

If RIC=1 or RIC=2, if the following conditions are met, the respective partition-scoped contents when PRS=0 and MSR<sub>HV</sub>=1 or process-scoped contents when PRS=1 of the page walk cache are invalidated.

- If the IS field in RB contains 0b10 or if IS contains 0b11 and MSR<sub>HV</sub>=0, for all threads, all properly-scoped page walk caching associated with the partition for which the translation is to be invalidated is invalidated.
- If the IS field in RB contains 0b11 and MSR<sub>HV</sub>=1, the entire properly-scoped page walk caching for each thread is invalidated.

- If the IS field in RB contains 0b01 (and PRS=1), for all threads, all properly-scoped page walk caching associated with process RS<sub>0:31</sub> in the partition for which the translation is to be invalidated is invalidated.

If RIC=2, if the following conditions are met, the respective partition and Process Table caching are invalidated for all threads.

- If the IS field in RB contains 0b01 and PRS=1, for all threads, caching of Process Table Entries for process RS<sub>0:31</sub> in the partition for which the translation is to be invalidated is invalidated.
- If the IS field in RB contains 0b10, MSR<sub>HV</sub>=1, and PRS=0, for all threads, caching of Partition Tables for the partition for which the translation is to be invalidated is invalidated.
- If the IS field in RB contains 0b10 and PRS=1, for all threads, caching of Process Tables for the partition for which the translation is to be invalidated is invalidated.
- If the IS field in RB contains 0b11, MSR<sub>HV</sub>=1, and PRS=0, for all threads, all Partition Table caching is invalidated.
- If the IS field in RB contains 0b11, MSR<sub>HV</sub>=1, and PRS=1, for all threads, all Process Table caching is invalidated.
- If the IS field in RB contains 0b11, MSR<sub>HV</sub>=0, and PRS=1, for all threads, caching of Process Tables for the partition for which the translation is to be invalidated is invalidated.

When i>40, RB<sub>40:i-1</sub> may contain any value and are ignored by the hardware.

### For all IS values

For all threads, any implementation specific lookaside information that is based on any TLB entry that would be invalidated by this instruction will also be invalidated.

Depending on the variant of the instruction, RB<sub>0:51</sub>, RB<sub>59:62</sub>, RB<sub>59:63</sub>, RB<sub>54:55</sub>, and RB<sub>54:63</sub> are the equivalent of reserved fields, should contain 0s, and are ignored by the hardware. When the thread is in privileged non-hypervisor state, RS<sub>32:63</sub> is the equivalent of a reserved field, should contain 0s, and is ignored by the hardware.

MSR<sub>SF</sub> must be 1 when this instruction is executed; otherwise the results are undefined.

If the value specified in RS<sub>0:31</sub>, RS<sub>32:63</sub>, RB<sub>54:55</sub>, RB<sub>56:58</sub>, RB<sub>44:51</sub>, or RB<sub>56:63</sub>, when it is needed to perform the specified operation, is not supported by the implementation, the instruction is treated as if the instruction form were invalid.

The operation performed by this instruction is ordered by the *eiio* (or *[p]hwsync* or *ptesync*) instruction with respect to a subsequent *tlbsync* instruction executed by the thread executing the *tlbie* instruction. The oper-

ations caused by *tlbie* and *tlbsync* are ordered by *eieio* as a fourth set of operations, which is independent of the other four sets that *eieio* orders.

This instruction is privileged except when  $LPCR_{GTSE}=0$  or when  $PRS=0$  and  $HR=1$ , making it hypervisor privileged.

See Section 6.10, “Translation Table Update Synchronization Requirements” for a description of other requirements associated with the use of this instruction.

#### Special Registers Altered:

None

#### Extended Mnemonics:

Extended mnemonic for *tlbie*:

Extended:	Equivalent to:
<i>tlbie</i> RB,RS	<i>tlbie</i> RB,RS,0,0,0

#### Programming Note

*tlbie* serves as both a basic and an extended mnemonic. The Assembler will recognize a *tlbie* mnemonic with five operands as the basic form, and a *tlbie* mnemonic with two operands as the extended form. In the extended form the RIC, PRS, and R operands are omitted and assumed to be 0.

#### Programming Note

Making the privilege of *tlbie* depend on HR instead of effR is a pragmatic choice to reduce hardware complexity. When the hypervisor executes *tlbie*, the privilege assigned to the instruction will sometimes be wrong, but the error will not prevent the instruction from being executed.

#### Programming Note

In versions of the architecture that precede Version 3.1B, the actual page size was part of the match criteria for *tlbie*[*l*], and the base page size was part of the match criteria for *tlbie*[*l*] for HPT translations. Inclusion of the actual page size in the match criteria provided a straightforward means for software to recover from TLB multi-hit situations, but consumed extra space and made the match check more complicated, particularly for cases in which the scope of the TLB entry was less than the actual page size (possible only for HPT translations). On processors that comply with Version 3.1B of the architecture or with any subsequent version, software should use *tlbie*[*l*] specifying  $IS=2$  for this purpose.

The actual page size continues to be provided in RB, for both HPT and Radix Tree translations, in order that it may be used by hardware to determine the scope of the TLB entries to be searched. For HPT translations the base page size continues to be supplied in RB because the distinction between base page size 4 KB and larger base page sizes is needed in order to interpret the rest of the contents of RB, and because, for base page sizes larger than 4 KB, base page size and actual page size are encoded together, in the LP field of RB.

For HPT translations, if the base page size is greater than 4 KB then, depending on the base and actual page sizes, certain bits of the virtual address may be supplied in high-order bits of the LP field of RB as well as in the AVAL field of RB. In the most extreme example, if the base and actual page sizes are both 8 KB,  $LP_{0:6}$  will contain the same bits as AVAL, namely VA bits 58:64. This duplication sometimes permits hardware to obtain all needed VA bits from a contiguous sequence of bits of RB. In particular, on implementations for which the scope of TLB entries is always the actual page size, all needed VA bits can be obtained contiguously, from  $RB_{0:(63-p)}$ .

**Programming Note**

For *tlbie[]* instructions in which (RB)<sub>63</sub>=0, the AP value in RB is provided to make it easier for the hardware to locate address translations, in lookaside buffers, corresponding to the address translation being invalidated.

For *tlbie[]* instructions the AP specification is not binary compatible with versions of the architecture that precede Version 2.06. As an example, for an actual page size of 64 KB AP=0b101, whereas software written for an implementation that complies with a version of the architecture that precedes V. 2.06 would have AP=100 since AP was a 1 bit value followed by 0s in RB<sub>57:58</sub>. If binary compatibility is important, for a 64 KB page software can use AP=0b101 on these earlier implementations since these implementations were required to ignore RB<sub>57:58</sub>.

**Programming Note**

For *tlbie[]* instructions the AVA and AVAL fields in RB contain different VA bits from those in PTE<sub>AVA</sub>.

**Programming Note**

An operating system that uses HPT translation should only use *tlbie* to invalidate the translation for a specific page when it knows whether VPM is active, and more specifically, what page size is actually in use for the target translation. The address comparison performed by *tlbie* is not sensitive to whether VPM is active. As a result, the operating system must supply an AVA value that is appropriate for the page size that is in use.

                if (MSRHV=0)&(PRS=0)&(effR=0) then
                    for each partition-scoped TLB entry
                        if entry_LPID=search_LPID
                            then TLB entry ← invalid
            if RIC=1 | RIC=2 then
                if MSRHV then
                    if PRS=0 then
                        invalidate all partition-scoped
                        page walk caching
                    else
                        invalidate all process-scoped
                        page walk caching
                if (MSRHV=0) & (PRS=1) then
                    invalidate process-scoped page walk
                    caching associated with partition
                    search_LPID
            if RIC=2 then
                if MSRHV then
                    if PRS=0 then
                        invalidate all Partition Table caching
                    else
                        invalidate all Process Table caching
                if (MSRHV=0) & (PRS=1) then
                    invalidate Process Table caching
                    associated with partition search_LPID

```

The operation performed by this instruction is based on the contents of registers RS and RB. The contents of these registers are shown below, where IS is (RB)<sub>52:53</sub> and L is (RB)<sub>63</sub>.

RS:

PID	///
0	63

**Programming Note**

Note that although there is no PID compare for partition-scoped translation, software must still place the PID in RS when IS=0 or 1. It may be used, for example, in the TLB hash.

RB for effR=1 and IS=0b00:

EPN	IS	0s	AP	0s
0	52	54	56	63

RB for effR=0, IS=0b00, and L=0:

AVA	IS	B	AP	0s	L
0	52	54	56	59	63

RB for effR=0, IS=0b00, and L=1:

AVA	LP	IS	B	AVAL	L
0	44	52	54	56	63

RB for IS=0b01, 0b10, or 0b11:

0s	SET	IS	0s
0	40	52	63

**Programming Note**

In versions of the architecture that precede Version 3.1, *tlbiel* with IS= 1, 2, or 3 invalidated appropriate entries only in a specific congruence class of the TLB, specified by SET in register RB. As a result, software was required to use a *tlbiel* loop to iterate through all congruence classes in order to invalidate the TLB. Software that will not be run on hardware complying with those versions should specify SET=0 in register RB. The description for *tlbiel* specifies SET instead of 0 in register RB to illustrate compatibility with software written to run on hardware complying with those versions.

LPIDR contains the search\_LPID, which is the partition ID (LPID) of the partition for which the translation is being invalidated. RS<sub>0:31</sub> contains a PID value. The supported values of RS<sub>0:31</sub> are the same as the PID values supported in PIDR.

The following forms are invalid.

- RIC=3 (Group invalidation is not supported for *tlbiel*.)

The following forms are treated as though the instruction form was invalid.

- PRS=1, effR=0, and RIC≠2 (The only process-scoped HPT caching is of the Process Table.)
- RIC=1 and effR=0 (There is no Page Walk Cache for HPT translation.)
- RIC=1 and IS=0 (The architecture does not support shutdown of individual translations in the Page Walk Cache.)

- RIC=1 and SET≠0 (PWC invalidation never required a loop to iterate across congruence classes.)
- RIC=2 and IS=0 (RIC is for comprehensive invalidation that is not supported at the level of an individual page.)
- PRS=0 and IS=1 (Partition-scoped translations are not associated with processes.)
- $effR=0$ , IS=1, and RIC≠2 (HPT translations are not associated with processes.)
- $effR=0$ , RIC=2, PRS=0, HV=0, and IS=2 or 3 (The similar cases with RIC=0 allow the HPT OS to invalidate all of its TLB entries. The only incremental function of these cases is to invalidate partition table caching, which the OS is not permitted to do.)

The results of an attempt to invalidate a translation outside of quadrant 0 for Radix Tree translation ( $effR=1$ , RIC=0, PRS=1, IS=0, and  $EA_{0:1} \neq 0b00$ ) are boundedly undefined.

### IS field in RB contains 0b00

If RIC=0, this is a search for a single TLB entry. The following relationships must be true and tests and actions are performed to search for an HPT translation.

Variable  $i$  is equal to  $63 - \log_2$  (scope of the TLB entry).

If the base page size specified by the PTE that was used to create the TLB entry to be invalidated is 4 KB, the L field in register RB must contain 0.

If the L field in RB contains 0, the base page size is 4 KB and  $RB_{56:58}$  (AP - Actual Page size field) must be set to the  $SLBE_{L|LP}$  encoding for the page size corresponding to the actual page size specified by the PTE that was used to create the TLB entry to be invalidated. Thus,  $b$  is equal to 12 and  $p$  is equal to  $\log_2$  (actual page size specified by  $RB_{56:58}$ ). The Abbreviated Virtual Address (AVA) field in register RB must contain bits 14:65 of the virtual address translated by the TLB entry to be invalidated. Variable  $inst\_AVA$  is equal to the AVA field of RB.

If the L field in RB contains 1, the following rules apply.

- The base page size and actual page size are specified in the LP field in register RB, where the relationship between  $RB_{44:51}$  (LP - Large Page size selector field) and the base page size and actual page size is the same as the relationship between  $PTE_{LP}$  and the base page size and actual page size (see Section 6.7.9.1 on page 1207 and Figure 35 on page 1208). Thus,  $b$  is equal to  $\log_2$  (base page size specified by  $RB_{44:51}$ ) and  $p$  is equal to  $\log_2$  (actual page size specified by  $RB_{44:51}$ ). Specifically,  $RB_{44+c:51}$  must be equal to the contents of bits  $c:7$  of the LP field

of the PTE that was used to create the TLB entry to be invalidated, where  $c$  is the number of “r” bits in the LP field of the PTE that was used to create the TLB entry to be invalidated.

- Variable  $j$  is the larger of  $(63-p)$  and the value that is the smaller of 43 and  $(63-b)$ .  $RB_{0:j}$  must contain bits  $14:(j+14)$  of the virtual address translated by the TLB entry to be invalidated. If  $b > 20$ ,  $RB_{64-b:43}$  may contain any value and are ignored by the hardware.
- If  $b < 20$ ,  $RB_{56:75-b}$  must contain bits 58:77- $b$  of the virtual address translated by the TLB entry to be invalidated, and other bits in  $RB_{56:62}$  may contain any value and are ignored by the hardware.
- If  $b \geq 20$ ,  $RB_{56:62}$  (AVAL - Abbreviated Virtual Address, Lower) may contain any value and are ignored by the hardware.
- Variable  $inst\_AVA$  is equal to the AVA field of RB concatenated with the AVAL field and 0b0.

Let the segment size be equal to the segment size specified in  $RB_{54:55}$  (B field). The contents of  $RB_{54:55}$  must be the same as the contents of the B field of the PTE that was used to create the TLB entry to be invalidated.

All TLB entries that have all of the following properties are made invalid on the thread executing the *tlbicl* instruction.

- $VA_{14:14+i}$  is equal to  $inst\_AVA_{0:i}$ .
- The segment size of the entry is the same as the segment size specified in  $RB_{54:55}$ .
- The entry is partition scoped.
- $TLBE_{LPID} = search\_LPID$ .

The following relationships must be true and tests and actions are performed to search for a Radix Tree translation. For a partition-scoped invalidation, references to the effective address are understood to refer to the guest real address.

The page size is encoded in  $RB_{56:58}$  (AP - Actual Page size field). Thus  $p$  is equal to  $\log_2$  (page size specified by  $RB_{56:58}$ ). The Effective Page Number (EPN) field in register RB must contain the bits 0: $i$  of the effective address translated by the TLB entry to be invalidated. Variable  $i$  is equal to  $63-p$ .

The fields shown as zeros must be set to zero and are ignored by the hardware.

All TLB entries that have all of the following properties are made invalid on the thread executing the *tlbicl* instruction..

- The entry translates an effective address for which  $EA_{0:i}$  is equal to  $RB_{0:i}$ .
- The page size of the entry matches the page size specified in  $RB_{56:58}$ .
- The entry has the appropriate scope (partition or process).

- The process ID specified in RS matches the process ID in the TLB entry if not invalidating a partition-scoped translation.
- $TLBE_{LPID} = search\_LPID$ .

Additional TLB entries may also be made invalid if those TLB entries contain an LPID that matches  $search\_LPID$ .

### IS field in RB is non-zero

When  $SET=0$  is specified and either  $RIC=0$  or  $RIC=2$ , each partition-scoped entry when  $PRS=0$  and either  $MSR_{HV}=1$  or  $effR=0$ , or each process-scoped entry when  $PRS=1$  is invalidated if any of the following conditions are met for the entry.

- The IS field in RB contains 0b10, or  $MSR_{HV}=0$  and the IS field contains 0b11, and  $TLBE_{LPID} = LPIDR_{LPID}$ .
- The IS field in RB contains 0b01,  $TLBE_{LPID}=LPIDR_{LPID}$ , and  $TLBE_{PID}=RS_{0:31}$ .
- The IS field in RB contains 0b11 and  $MSR_{HV}=1$ .

When  $SET=0$  is specified and either  $RIC=1$  or  $RIC=2$ , if the following conditions are met, the respective partition-scoped contents when  $PRS=0$  and  $MSR_{HV}=1$  or process-scoped contents when  $PRS=1$  of the page walk cache are invalidated.

- If the IS field in RB contains 0b10 or if IS contains 0b11 and  $MSR_{HV}=0$ , all properly-scoped page walk caching associated with partition  $LPDIR_{LPID}$  is invalidated.
- If the IS field in RB contains 0b11 and  $MSR_{HV}=1$ , the entire properly-scoped page walk caching is invalidated.
- If the IS field in RB contains 0b01 (and  $PRS=1$ ), all properly-scoped page walk caching associated with process  $RS_{0:31}$  in partition  $LPIDR_{LPID}$  is invalidated.

When  $SET=0$  is specified and  $RIC=2$ , if the following conditions are met, the respective partition and Process Table caching are invalidated.

- If the IS field in RB contains 0b01 and  $PRS=1$ , caching of Process Table Entries for process  $RS_{0:31}$  in partition  $LPIDR_{LPID}$  is invalidated.
- If the IS field in RB contains 0b10,  $MSR_{HV}=1$ , and  $PRS=0$ , caching of Partition Tables for partition  $LPIDR_{LPID}$  is invalidated.
- If the IS field in RB contains 0b10 and  $PRS=1$ , caching of Process Tables for partition  $LPIDR_{LPID}$  is invalidated.
- if the IS field in RB contains 0b11,  $MSR_{HV}=1$ , and  $PRS=0$ , all Partition Table caching is invalidated.
- if the IS field in RB contains 0b11,  $MSR_{HV}=1$ , and  $PRS=1$ , all Process Table caching is invalidated.
- If the IS field in RB contains 0b11,  $MSR_{HV}=0$ , and  $PRS=1$ , caching of Process Tables for partition  $LIDR_{LPID}$  is invalidated.

### For all IS values

Any implementation specific lookaside information that is based on any TLB entry that would be invalidated by this instruction will also be invalidated.

Depending on the variant of the instruction,  $RB_{0:39}$ ,  $RB_{59:62}$ ,  $RB_{59:63}$ ,  $RB_{54:55}$ , and  $RB_{54:63}$  are the equivalent of reserved fields, should contain 0s, and are ignored by the hardware.  $RS_{32:63}$  is always the equivalent of a reserved field, should contain 0s, and is ignored by the hardware.

Only TLB entries, page walk caching, and Process and Partition Table caching on the thread executing the *tlbiel* instruction are affected.

$MSR_{SF}$  must be 1 when this instruction is executed; otherwise the results are boundedly undefined.

If the value specified in  $RS_{0:31}$ ,  $RB_{54:55}$ ,  $RB_{56:58}$ , or  $RB_{44:51}$ , when it is needed to perform the specified operation, is not supported by the implementation, the instruction is treated as if the instruction form were invalid.

This instruction is privileged except when  $PRS=0$  and  $HR=1$ , making it hypervisor privileged.

See Section 6.10, “Translation Table Update Synchronization Requirements” on page 1255 for a description of other requirements associated with the use of this instruction.

### Special Registers Altered:

None

### Extended Mnemonics:

Extended mnemonic for *tlbiel*:

Extended:	Equivalent to:
<i>tlbiel</i> RB	<i>tlbiel</i> RB,r0,0,0,0

### Programming Note

*tlbiel* serves as both a basic and an extended mnemonic. The Assembler will recognize a *tlbiel* mnemonic with five operands as the basic form, and a *tlbiel* mnemonic with one operand as the extended form. In the extended form the RS, RIC, PRS, and R operands are omitted and assumed to be 0.

### Programming Note

Making the privilege of *tlbiel* depend on HR instead of  $effR$  is a pragmatic choice to reduce hardware complexity. When the hypervisor executes *tlbiel*, the privilege assigned to the instruction will sometimes be wrong, but the error will not prevent the instruction from being executed.

**Programming Note**

An operating system that uses HPT translation should only use **tlbiel** to invalidate the translation for a specific page when it knows whether VPM is active, and more specifically, what page size is actually in use for the target translation. The address comparison performed by **tlbiel** is not sensitive to whether VPM is active. As a result, the operating system must supply an AVA value that is appropriate for the page size that is in use.

**Programming Note**

See also the Programming Notes with the description of the **tlbie** instruction.

**TLB Synchronize****X-form**

tlbsync

31	///	///	///	566	/
0	6	11	16	21	31

The **tlbsync** instruction provides an ordering function for the effects of all **tlbie** instructions executed by the thread executing the **tlbsync** instruction, with respect to the memory barrier created by a subsequent **ptesync** instruction executed by the same thread. Executing a **tlbsync** instruction ensures that all of the following will occur.

- All TLB invalidations caused by **tlbie** instructions preceding the **tlbsync** instruction will have completed on any other thread before any data accesses caused by instructions following the **ptesync** instruction are performed with respect to that thread.
- All storage accesses by other threads for which the address was translated using the translations being invalidated, and all Reference and Change bit updates associated with address translations that were performed by other threads using the translations being invalidated, will have been performed with respect to the thread executing the **ptesync** instruction, to the extent required by the associated Memory Coherence Required attributes, before the **ptesync** instruction's memory barrier is created.

The operation performed by this instruction is ordered by the **eiemo** (or **[p]hwsync** or **ptesync**) instruction with respect to preceding **tlbie** instructions executed by the thread executing the **tlbsync** instruction. The operations caused by **tlbie** and **tlbsync** are ordered by **eiemo** as a fourth set of operations, which is independent of the other three sets that **eiemo** orders.

The **tlbsync** instruction may complete before operations caused by **tlbie** instructions preceding the **tlbsync** instruction have been performed.

This instruction is privileged except when LPCR<sub>G</sub>.TSE=0, making it hypervisor privileged.

See Section 6.10 for a description of other requirements associated with the use of this instruction.

**Special Registers Altered:**

None

**Programming Note**

**tlbsync** should not be used to synchronize the completion of **tlbiel**.

## 6.10 Translation Table Update Synchronization Requirements

This section describes rules that software must follow when updating the Translation Tables, and includes suggested sequences of operations for some representative cases. The sequences required for other cases may be deduced from the sequences that are provided and from this accompanying description.

In the sequences of operations shown in the following subsections, the Page Table Entry is assumed to be for a virtual page for which the base page size is equal to the actual page size. If these page sizes are different, multiple *tlbie* instructions are needed, one for each PTE corresponding to the virtual page.

In the sequences of operations shown in the following subsections, any alteration of a translation table entry that corresponds to a single line in the sequence is assumed to be done using a *Store* instruction for which the access is atomic. Appropriate modifications must be made to these sequences if this assumption is not satisfied (e.g., if a store doubleword operation is done using two *Store Word* instructions).

Two correctness-related considerations when choosing translation table update sequences are to be safe for multiple asynchronous sources of update (potentially both hardware and software), and to avoid paradoxes that in some cases could show up as multi-hits in the various translation caches. These considerations lead to the simple, contiguous sequences for general case updates that appear later in this section. Good performance is a third consideration that motivates deferring and/or batching invalidations or even omitting synchronization or invalidation from the general case. The viability of these techniques is determined by whether the lack of a single clear state across the system has problematic repercussions. The discussion of atomic Reference and Change bit updates alludes to one such example. (See Section 6.7.12.) Simpler optimizations are illustrated below.

The following are guidelines for safety when multiple sources of asynchronous updates are possible. To interact correctly with hardware that atomically updates Reference and Change bits (as well as with updates from other software threads), software should use atomic updates to modify valid PTEs. Academically speaking, if hardware uses simple loads and stores, software may either use locking and first invalidate the PTE and cached translations, or may attempt to optimize using atomic updates that don't change the values of the bytes containing the Reference and Change bits with the exception of potentially setting those specific bits to 1 or the Reference bit to 0. When modifying only bytes not subject to hardware modification, software may use either locking or atomic updates, subject to the limitations and optimizations described below. The realities of Reference and Change bit placement may severely limit what optimizations are possible

when hardware uses normal loads and stores to update those bits.

To simplify verification and avoid paradoxes, non-impactful limitations are placed on translation table update sequence optimizations. One limitation is that software must not have two or more valid overlapping translations at any level of the translation process with different page or segment sizes. This means that one translation must be marked invalid in the translation table and invalidated from any caches prior to instating the second. The other limitation is that software must not have two or more valid translations with different attributes (i.e. WIMG, ATT). The example of  $I=1$  and  $I=0$  is obvious, but in general there is not enough to be gained to attempt to avoid invalidating one attribute setting before establishing another. In both of these cases, the translation cache invalidation may lag indefinitely behind the table entry invalidations and the cache invalidations may be batched, but must precede enabling the new attributes.

To protect software's ability to have reasonable performance, optimizations that hardware must support are also identified. (These optimizations are understood to be limited by the techniques used for hardware and software updates as described above, and by the properties of the table structure itself. A convention for atomic updates will yield more opportunity than locking. Hardware that does not use atomic updates may limit or eliminate the opportunity for software to optimize. The table structure for Radix Tree translation will yield more opportunity than the dual PTEG structure of HPT translation.) Access authority downgrades and setting Change bits to zero may be done without first marking the PTE invalid and invalidating the translation caches. The translation cache invalidation may lag the PTE change indefinitely and be done in bulk. Access authority upgrades and setting Reference and Change bits to 1 may be done without any PTE or translation cache invalidation. Software bits may be changed without any PTE or translation cache invalidation. Finally, any complete change to the RPN (non-overlapping with the original value) does not of itself require synchronization (though other changes to the PTE made at the same time might).

In the following examples, when the same type of sequence works for both types of translation, the HPT PTE is shown because it is more complex. In this description, and in references in subsequent subsections to "safe for multithreaded software," the safety is with respect to the risk of one thread overwriting another's update. There may also be concern for the creation of multiple matching translations, e.g. within a PTEG or pair of PTEGs. When the reservation granule is equal to or larger in size than the structure on which mutual exclusion must be ensured (e.g. PTE for Radix

Tree translation but PTEG for HPT translation), multiple entries will also be prevented. (Secondary hash groups will generally not be covered by the same reservation granule as primary hash groups.)

Updates (by software) to the tables are performed only when they are known to be required by the sequential execution model (see Section 6.5). Because address translation for instructions preceding a given *Store* instruction might cause an interrupt, and thereby prevent the corresponding store from being required by the sequential execution model, address translations for instructions preceding the *Store* instruction must be performed before the corresponding store is performed. As a result, an update to a translation table need not be preceded by a context synchronizing instruction.

All of the sequences require a context synchronizing operation after the sequence if the new contents of the translation table are to be used for address translations associated with subsequent instructions.

As noted in the description of the *Synchronize* instruction in Section 4.6.3 of Book II, address translation associated with instructions which occur in program order subsequent to the *Synchronize* (and this includes the *ptesync* variant) may be performed prior to the completion of the *Synchronize*. To ensure that these instructions and data which may have been speculatively fetched are discarded, a context synchronizing operation is required.

#### Programming Note

In many cases this context synchronization will occur naturally; for example, if the sequence is executed within an interrupt handler the *rfid*, *rfscv*, *hrfid*, or *urfid* instruction that returns from the interrupt handler may provide the required context synchronization.

Translation table entries must not be changed in a manner that causes an implicit branch.

### 6.10.1 Translation Table Updates

TLBs are non-coherent caches of the HTABs and Radix Trees. TLB entries must be invalidated explicitly with one of the *TLB Invalidate* instructions. SLBs are non-coherent caches of the Segment Tables, SLB entries must be invalidated explicitly with one of the *SLB Invalidate* instructions. Page Walk Caches are non-coherent caches of the intermediate steps in Radix Tree translation. Non-coherent caching of the Partition and Process Tables is permitted. Provision has been made for the use of the *TLB Invalidate* instructions to manage the types of caching described in the preceding two sentences at a PID or LPID granularity.

Unsynchronized lookups in the Page, Segment, and when HR=0, Process Tables continue even while they

are being modified. (For Partition Table Entries, and for Process Table Entries when HR=1, the process or partition affected must be inactive because the entries do not have valid bits.) With the exceptions previously identified for Segment Table walks (see Section 6.9.3, “Lookaside Buffer Management”), any thread, including a thread on which software is modifying any of the set of tables described in the first sentence, may look in those tables at any time in an attempt to translate an address. When modifying an entry in any of the former set of tables, software must ensure that the table entry’s V bit is 0 if the table entry does not correctly specify its portion of the translation (e.g., if the RPN field is not correct for the current AVA field).

**For HPT translation, updates of Reference and Change bits by the hardware are not synchronized with the accesses that cause the updates.** When modifying doubleword 1 of a PTE, software must take care to avoid overwriting a hardware update of these bits and to avoid having the value written by a *Store* instruction overwritten by a hardware update.

The most basic sequence that will achieve proper system synchronization for PTE updates is the following.

```
tlbie instruction(s) specifying the same LPID oper-
and value
eieio
tlbsync
ptesync
```

Other instructions may be interleaved among these instructions. Operating system and hypervisor software that updates Page Table Entries should use this sequence.

Operating systems and nested hypervisors are exposed to being interrupted during this sequence. The interrupting hypervisor is responsible for completing the sequence above. In general this will require the hypervisor to include the following sequence in an interrupt handler.

```
eieio
tlbsync
ptesync
```

This sequence itself may be interrupted by a higher level hypervisor. When returning to the interrupted software, the original sequence will be completed. Hardware must tolerate the result of nested interleaving of these sequences. *tlbie* and *tlbsync* instructions should only be used as part of these sequences.

The corresponding sequence for Segment Table updates uses *slbieg* in place of *tlbie* and *slbsync* in place of *tlbsync*. Similarly *slbieg* and *slbsync* should only be used as part of these sequences. In circumstances where a hypervisor may be interrupting either a PTE update or a Segment Table update, it must include both *tlbsync* and *slbsync* in its completing sequence, in either order. Hardware must tolerate the result of nested interleaving of these additional sequences.

The PTE sequence is also used when **tlbie** is used for purposes other than synchronizing PTE updates, such as invalidating cached copies of Partition Table Entries or Process Table Entries (RIC=2). Mutual exclusion must be added if the update processes are multi-threaded.

On systems consisting of only a single-threaded processor, the **eiemo** and **tlbsync** or **slbsync** instructions can be omitted.

The following subsections illustrate sequences that must be used for translation table updates to tables that are subject to concurrent use by hardware (i.e. that have valid bits in their entries). For Partition Table Entries and for Process Table Entries that do not have valid bits, simpler sequences consisting of just the preceding sequences, perhaps with mutual exclusion if the update processes are multithreaded, is sufficient.

#### Programming Note

The **eiemo** instruction prevents the reordering of the preceding **tlbie**, **slbieg**, or **slbiag** instructions with respect to the subsequent **tlbsync** or **slbsync** instruction. The **tlbsync** or **slbsync** instruction and the subsequent **ptesync** instruction together ensure that all storage accesses for which the address was translated using the translations being invalidated (by the **tlbie**, **slbieg**, or **slbiag** instructions), and all Reference and Change bit updates associated with address translations that were performed using the translations being invalidated, will be performed with respect to any thread or mechanism, to the extent required by the associated Memory Coherence Required attributes, before any data accesses caused by instructions following the **ptesync** instruction are performed with respect to that thread or mechanism.

For Page Table update sequences that mark the PTE invalid (see Section 6.10.1.2, “Modifying a Translation Table Entry”), Reference and Change bit updates cease when the sequence is complete. When the PTE is marked invalid using an atomic update and the *Store Conditional* setting the entry invalid is successful, the Reference and Change bits obtained by the corresponding *Load And Reserve* instruction are stable/final values.

The sequences of operations shown in the following subsections assume a multi-threaded environment. In an environment consisting of only a single-threaded processor, the **tlbsync** or **slbsync** and the **eiemo** that separates the **tlbie** or **slbieg** from the **tlbsync** or **slbsync** can be omitted. In a multi-threaded environment, when **tlbiel** or **slbie** is used instead of **tlbie** or **slbieg** in a Page or Segment Table update, the synchronization requirements are the same as when **tlbie** or **slbieg** is used in an environment consisting of only a single-threaded processor. If there is no Segment Table (LPCR<sub>UPRT</sub>=0), the synchronization requirements for

using **slbie** apply when there is need to order SLB invalidations and/or to order storage accesses for which the address was translated using the translations being invalidated. The synchronization requirements for using **slbia** are the same as the synchronization requirements for using **slbie**.

#### Programming Note

For all of the sequences shown in the following subsections, if it is necessary to communicate completion of the sequence to software running on another thread, the **ptesync** instruction at the end of the sequence should be followed by a *Store* instruction that stores a chosen value to some chosen storage location X. The memory barrier created by the **ptesync** instruction ensures that if a *Load* instruction executed by another thread returns the chosen value from location X, all subsequent searches of the Page or Segment Table by the other thread, that implicitly load from the PTE or STE specified by the sequence's stores, will obtain the values stored (or values stored subsequently). The *Load* instruction that returns the chosen value should be followed by a context synchronizing instruction in order to ensure that all instructions following the context synchronizing instruction will be fetched and executed using the values stored by the sequence (or values stored subsequently). (These instructions may have been fetched or executed out-of-order using the old contents of the PTE or STE.)

This Note assumes that the Page or Segment Table and location X are in storage that is Memory Coherence Required.

### 6.10.1.1 Adding a Page Table Entry

This is the simplest Page Table case. The V bit of the old entry is assumed to be 0. The following sequence can be used to create a PTE, maintain a consistent state, and ensure that a subsequent reference to the virtual address translated by the new entry will use the correct real address and associated attributes. A single quadword store would avoid the need for the **eiemo**. A similar sequence may be used to add a new Segment Table Entry. Mutual exclusion with respect to other software threads may be required, but there is no concern for interaction with hardware updates because the entry is invalid until the last store in the sequence.

```
PTEpp key B ARPN LP key R C WIMG N pp ← new values
eiemo /* order 1st update before 2nd */
PTEAVA SW L H V ← new values (V=1)
ptesync /* order updates before next
        Page Table search and before
        next data access */
```

### 6.10.1.2 Modifying a Translation Table Entry

#### General Case (PTE)

If a valid entry is to be modified and the translation instantiated by the entry being modified is to be invalidated, the sequences below can be used to modify the PTE, maintain a consistent state (subject to the limitations described in the introduction to Section 6.10 such as avoiding overlapping translations), ensure that the translation instantiated by the old entry is no longer available, and ensure that a subsequent reference to the virtual address translated by the new entry will use the correct real address and associated attributes.

The following sequence is to interact correctly with atomic hardware updates. It can be used to return stable Reference and Change bit values for the old translation (e.g., by setting  $PTE_V$  to 0), and is safe for multi-threaded software. If the purpose of the sequence is mainly to collect Reference and Change bit values, the part of the sequence beginning with *tlbie* may be deferred and performed as a bulk invalidation (e.g. for a range of storage or an entire process) after collecting values for a plurality of pages. A similar sequence (i.e. using *Load And Reserve* and *Store Conditional* instructions) can be used to update a Segment Table Entry but will not interact correctly with non-atomic hardware Reference and Change bit updates.

```
r6 ← PTE_V L SW RPN R C ATT EAA
r4 ← addr(pte)
loop:
  ldarx r2,0,r4
  if V=0 abort, else /* to interact with locking */
  stdcx r6,0,r4
  bne- loop
ptesync /* order update before tlbie and
         before next Page Table search */
tlbie(old_EA0:63-B,old_AP,old_PID, old_LPID)
eieio /* order tlbie before tlbsync */
tlbsync /* order tlbie before ptesync */
ptesync /* complete the sequence, update ordered
         by first ptesync */
```

The corresponding sequence for non-atomic hardware updates is the following. (The sequence is equivalent to deleting the PTE and then adding a new one.) Mutual exclusion with respect to other software threads may be required. The Reference and Change bit values will not be stable until the entire sequence is completed.

```
PTE_V ← 0 /* (other fields don't matter) */
ptesync /* order update before tlbie and
         before next Page Table search */
tlbie(old_B,old_VA14:77-B,old_L,old_LP,old_AP,
      old_LPID)
/*invalidate old translation*/
eieio /* order tlbie before tlbsync */
tlbsync /* order tlbie before ptesync */
ptesync /* order tlbie, tlbsync and 1st
         update before 2nd update */
```

```
PTE_ARPN,LP,AC,R,C,WIMG,N,PP ← new values
eieio /* order 2nd update before 3rd */
PTE_B,AVA,SW,L,H,V ← new values (V=1)
ptesync /* order 2nd and 3rd updates before
         next Page Table search and
         before next data access */
```

#### General Case(STE)

If a valid entry is to be modified and the translation instantiated by the entry being modified is to be invalidated, the following sequence can be used to modify the STE, maintain a consistent state, ensure that the translation instantiated by the old entry is no longer available, and ensure that a subsequent reference to the effective address translated by the new entry will use the correct virtual address and associated attributes. (The sequence is much like the general case for a change to a PTE that is subject to non-atomic hardware updates, and is equivalent to deleting the STE and then adding a new one.) Mutual exclusion with respect to other software threads may be required. A similar sequence (except using *tlbie* with  $RIC=2$  and *tlbsync*) may be used to modify  $HR=0$  Process Table Entries.

```
STE_V ← 0 /* (other fields don't matter) */
ptesync /* order update before slbieg and
         before next Segment Table search */
slbieg(old_B,old_ESID,old_TA,old_PID,old_LPID)
/* invalidate old translation */
eieio /* order slbieg before slbsync */
slbsync /* order slbieg before ptesync */
ptesync /* order slbieg, slbsync and 1st
         update before 2nd update */
/* deletion sequence ends here */
STE_VSID, Ks, Kp, N, L, C, LP, SW ← new values
eieio /* order 2nd update before 3rd */
STE_ESID,V ← new values (V=1)
ptesync /* order 2nd and 3rd updates before
         next Segment Table search and
         before next data access */
```

#### Resetting the Reference Bit (PTE)

If the only change being made to a valid entry is to set the Reference bit to 0, a simpler sequence suffices because the Reference bit need not be maintained exactly. The byte store is exposed to overwriting another change being performed by multithreaded software, so mutual exclusion may be required.

```
oldR ← PTE_R /* get old R */
if oldR = 1 then
  PTE_R ← 0 /* store byte (R=0, other bits
             unchanged) */
  tlbie(B,VA14:77-B,L,LP,AP,LPID) /* invalidate
                                   entry */
  eieio /* order tlbie before tlbsync */
  tlbsync /* order tlbie before ptesync */
  ptesync /* order tlbie, tlbsync, and update
           before next Page Table search
           and before next data access */
```

## Setting a Reference or Change Bit or Upgrading Access Authority (PTE Subject to Atomic Hardware Updates)

If the only change being made to a valid PTE that is subject to atomic hardware updates is to set the Reference or Change bit to 1 or to upgrade access authority, a simpler sequence suffices because the translation hardware will refetch the PTE if an access is attempted for which the only problems were reference and/or change bits needing to be set or insufficient access authority. The store is exposed to overwriting another change being performed by multithreaded software, so mutual exclusion may be required. (Note that changing  $EAA_0$  can be both an upgrade and a downgrade, depending on the value of Key0 of the [I]AMR. If it is not solely an upgrade, the simpler sequence must not be used.)

```
PTEV L SW RPN R C ATT EAA ← new values (V=1)
ptesync /* order update before next Page Table
        search and before next data access */
```

## Modifying the SW field (PTE)

If the only change being made to a valid entry is to modify the SW field, the following sequence suffices, because the SW field is not used by the hardware (i.e. is not cached in the TLB and has no effect on hardware behavior).

```
loop: ldarx r1 ← PTE_dwd_0 /* load dwd 0 of PTE */
      if V=0 abort, else/*to interact with locking*/
      r157:60 ← new SW value /* replace SW, in r1 */
      stdcx. PTE_dwd_0 ← r1 /* store dwd 0 of PTE
        if still reserved (new SW value, other
        fields unchanged) */
      bne- loop /* loop if lost reservation */
```

A *lbarx/stbcx.*, *lharx/sthcx.*, or *lwarx/stwcx.* pair (specifying the low-order byte, halfword, or word respectively of doubleword 0 of the PTE) can be used instead of the *ldarx/stdcx.* pair shown above for HPT translation. The split SW field in the radix PTE cannot be updated with a single smaller atomic update. This sequence interacts correctly with hardware updates and is safe for multithreaded software. A similar sequence (including the possibility of using a smaller atomic update) can be used to update a Segment Table Entry.

## Modifying the Effective Address (STE)

If the effective address translated by a valid STE is to be modified and the new effective address hashes to the same STEG as does the old effective address, the following sequence can be used to modify the STE, maintain a consistent state, ensure that the translation instantiated by the old entry is no longer available, and ensure that a subsequent reference to the effective address translated by the new entry will use the correct virtual address and associated attributes. Mutual

exclusion with respect to other software threads may be required. The corresponding change of the virtual address in the PTE for HPT translation can be performed using a similar sequence, interacting correctly with non-atomic hardware table updates, as long as the second doubleword of the PTE is not stored.

```
STEESID,V ← new values (V=1)
ptesync /* order update before slbieg and
        before next Segment Table search */
slbieg(old_B,old_ESID,old_TA,old_PID,old_LPID)
        /* invalidate old translation */
eieio /* order slbieg before slbsync */
slbsync /* order slbieg before ptesync */
ptesync /* order slbieg, slbsync, and update
        before next data access */
```

## Chapter 7. Interrupts

### 7.1 Overview

The Power ISA provides an interrupt mechanism to allow the thread to change state as a result of external signals, errors, or unusual conditions arising in the execution of instructions.

System Reset and Machine Check interrupts are not ordered. All other interrupts are ordered such that only one interrupt is reported, and when it is processed (taken) no program state is lost. Since Save/Restore Registers SRR0 and SRR1 are serially reusable resources used by most interrupts, program state may be lost when an unordered interrupt is taken.

### 7.2 Interrupt Registers

#### 7.2.1 Machine Status Save/Restore Registers

When various interrupts occur, the state of the machine is saved in the Machine Status Save/Restore registers (SRR0 and SRR1). Section 7.5 describes which registers are altered by each interrupt.

**Figure 55. Save/Restore Registers**

SRR1 bits may be treated as reserved in a given implementation if they correspond to MSR bits that are reserved or are treated as reserved in that implementation and, for SRR1 bits in the range 33:36, 42:43, and 45:47, they are specified as being set either to 0 or to an undefined value for all interrupts that set SRR1 (including implementation-dependent setting, e.g. by the Machine Check interrupt or by implementation-specific interrupts). SRR1<sub>44</sub> cannot be treated as reserved, regardless of how it is set by interrupts, because it is used by software, as described in a Programming Note

near the end of Section 7.5.9, “Program Interrupt” on page 1287.

#### 7.2.2 Hypervisor Machine Status Save/Restore Registers

When various interrupts occur, the state of the machine is saved in the Hypervisor Machine Status Save/Restore registers (HSRR0 and HSRR1). Section 7.5 describes which registers are altered by each interrupt.

**Figure 56. Hypervisor Save/Restore Registers**

HSRR1 bits may be treated as reserved in a given implementation if they correspond to MSR bits that are reserved or are treated as reserved in that implementation and, for HSRR1 bits in the range 33:36 and 42:47, they are specified as being set either to 0 or to an undefined value for all interrupts that set HSRR1 (including implementation-dependent setting, e.g. by implementation-specific interrupts).

The HSRR0 and HSRR1 are hypervisor resources; see Chapter 2.

#### Programming Note

Execution of some instructions, and fetching instructions when MSR<sub>IR</sub>=1 or MSR<sub>HV</sub>=0, may have the side effect of modifying HSRR0 and HSRR1; see Section 7.4.4.

#### 7.2.3 Ultravisor Machine Status Save/Restore Registers

When a Directed Ultravisor Doorbell interrupt occurs, the state of the machine is saved in the Ultravisor Machine Status Save/Restore Registers (USRR0 and USRR1).

**Figure 57. Ultravisor Save/Restore Registers**

USRR1 bits may be treated as reserved in a given implementation if they correspond to MSR bits that are reserved or are treated as reserved in that implementation and, for USRR1 bits in the range 33:36 and 42:47, they are specified as being set either to 0 or to an undefined value by the Directed Ultravisor Doorbell interrupt.

The USRR0 and USRR1 are ultravisor resources; see Chapter 3.

### 7.2.4 Access Segment Descriptor Register

The DAR, HDAR, SRR0, and HSRRO generally provide the EA for storage exceptions. For hypervisor storage interrupts, additional information is often necessary to enable the hypervisor to handle the interrupt. This information is provided in a 64b SPR called the Access Segment Descriptor Register (ASDR). When nested Radix Tree translation is taking place, the ASDR will generally provide the guest real address down to bit 51. (The smallest supported page size is 4k.) When using paravirtualized HPT translation, information from the segment descriptor that was used to perform the effective to virtual translation is provided in the ASDR. For a big segment the values of the bits of the VSID field that are not part of the VSID are undefined. For exceptions that take place when translating the address of the process table entry or segment table entry group, only the VSID will be provided, because those addresses are specified as virtual addresses and the rest of the segment descriptor is implied. Some instances of the Machine Check interrupt may require the ASDR to be set similarly to how it is set for the hypervisor storage

interrupts. The ASDR is set independent of the value of UPRT for the partition that is running.

**Figure 58. Access Segment Descriptor Register format for a Segment Descriptor**

**Figure 59. Access Segment Descriptor Register format for a Guest Real Address**

### 7.2.5 Data Address Register

The Data Address Register (DAR) is a 64-bit register that is set by the Machine Check, Data Storage, Data Segment, and Alignment interrupts; see Sections 7.5.2, 7.5.3, 7.5.4, and 7.5.8. In general, when one of these interrupts occurs the DAR is set to an effective address associated with the storage access that caused the interrupt, with the high-order 32 bits of the DAR set to 0 if the interrupt occurs in 32-bit mode.

**Figure 60. Data Address Register**

### 7.2.6 Hypervisor Data Address Register

The Hypervisor Data Address Register (HDAR) is a 64-bit register that is set by the Hypervisor Data Storage Interrupt; see Section 7.5.16. In general, when this interrupt occurs, the HDAR is set to an effective address associated with the storage access that caused the interrupt, with the high-order 32 bits of the HDAR set to 0 if the interrupt occurs in 32-bit mode.

**Figure 61. Hypervisor Data Address Register**

### 7.2.7 Data Storage Interrupt Status Register

The Data Storage Interrupt Status Register (DSISR) is a 32-bit register that is set by the Machine Check, Data Storage, and Data Segment interrupts; see Sections 7.5.2, 7.5.3, and 7.5.4.

**Figure 62. Data Storage Interrupt Status Register**

DSISR bits may be treated as reserved in a given implementation if they are specified as being set either to 0 or to an undefined value for all interrupts that set the DSISR.

## 7.2.8 Hypervisor Data Storage Interrupt Status Register

The Hypervisor Data Storage Interrupt Status Register (HDSISR) is a 32-bit register that is set by the Hypervisor Data Storage interrupt. In general, when one of these interrupts occurs the HDSISR is set to indicate the cause of the interrupt.

**Figure 63. Hypervisor Data Storage Interrupt Status Register**

## 7.2.9 Hypervisor Emulation Instruction Register

The Hypervisor Emulation Instruction Register (HEIR) is a 64-bit register that is set by the Hypervisor Emulation Assistance interrupt; see Section 7.5.18. When a word instruction causes the interrupt, the image of the instruction that caused the interrupt is loaded into bits 32:63 of the register, and bits 0:31 are set to 0s. When a prefixed instruction causes the interrupt, the image of the instruction that caused the interrupt is loaded into bits 0:63 of the register.

There may be circumstances in which the suffix cannot be loaded, such as when the instruction is located in storage that is Caching Inhibited, or when the value of the suffix corresponds to a *Branch* instruction, *rfebb*, a context synchronizing instruction other than *isync*, or a “Service Processor Attention” instruction.

In such circumstances, bits 32:63 are set to 0s.

**Figure 64. Hypervisor Emulation Instruction Register**

### Programming Note

When all prefixed instructions are made unavailable by the PCR setting, the prefix will be recognized as an illegal word instruction and placed in HEIR<sub>32:63</sub>.

## 7.2.10 Hypervisor Maintenance Exception Register

Each bit in the Hypervisor Maintenance Exception Register (HMER) is associated with one or more causes of the Hypervisor Maintenance exception, and is set when the associated exception(s) occur. If the corresponding bit in the Hypervisor Maintenance Exception Enable Register (HMEER) is set, a Hypervisor Maintenance Interrupt (HMI) may occur. If the thread is in a power-saving mode when the interrupt would have occurred, the thread will exit the power-saving mode; see Section 7.5.19 and Section 4.3.2.

**Figure 65. Hypervisor Maintenance Exception Register**

The contents of the HMER are as follows:

- 0** Set to 1 for a Malfunction Alert.
- 1** Set to 1 when performance is degraded for thermal reasons.
- 2** Set to 1 when thread recovery is invoked.
- Others** Implementation-specific.

When the *mtspr* instruction is executed with the HMER as the encoded Special Purpose Register, the contents of register RS are ANDed with the contents of the HMER and the result is placed into the HMER.

The exception bits in the HMER are sticky; that is, once set to 1 they remain set to 1 until they are set to 0 by an *mtmer* instruction.

### Programming Note

An access to the HMER is likely to be very slow. Software should access it sparingly.

## 7.2.11 Hypervisor Maintenance Exception Enable Register

The Hypervisor Maintenance Exception Enable Register (HMEER) is a 64-bit register in which each bit enables the corresponding exception in the HMER to cause the Hypervisor Maintenance interrupt, potentially causing exit from power-saving mode; see Section 7.5.19 and Section 4.3.2.

**Figure 66. Hypervisor Maintenance Exception Enable Register**

## 7.2.12 Facility Status and Control Register

The Facility Status and Control Register (FSCR) controls the availability of various facilities in problem state and indicates the cause of a Facility Unavailable interrupt.

When the FSCR makes a facility unavailable, attempted usage of the facility in problem state is treated as follows:

- Execution of an instruction causes a Facility Unavailable exception.
- Access of an SPR using *mf spr/mt spr* causes a Facility Unavailable exception.
- *rfebb, rfid, rfscv, hr fid, ur fid,* and *mtmsr[d]* instructions have the same effect on bits in system registers as they would if the bits were available. The same is true for *mt spr* and *mf spr* unless the preceding item applies.

MMCR0 can also make various components of the Performance Monitor unavailable when accessed in problem state. An access to one of these components when it is unavailable causes a Facility Unavailable exception.

When the PCR makes a facility unavailable in problem state, the facility is treated as not defined in problem state; any Facility Unavailable interrupt that would occur if the facility were not made unavailable by the PCR does not occur.

When a Facility Unavailable interrupt occurs, the unavailable facility that was accessed is indicated in the most-significant byte of the FSCR.

**Figure 67. Facility Status and Control Register**

The contents of the FSCR are specified below.

**Value    Meaning**

- 0:7    **Interruption Cause (IC)**
- When a Facility Unavailable interrupt occurs, the IC field contains a binary number indicating the facility for which access was attempted. The values and their meanings are specified below.
- 02 Access to the DSCR at SPR 3
  - 03 Access to a Performance Monitor SPR in group A or B when MMCR0<sub>PMCC</sub> is set to a value for which the access results in a Facility Unavailable interrupt. (See the definition of MMCR0<sub>PMCC</sub> in Section 11.4.4.)
  - 04 Execution of a BHRB Instruction

- 07 Access to an Event-Based Branch SPR or execution of an Event-Based Branch instruction
- 08 Access to the Target Address Register
- 0C Execution of **scv**
- 0D Execution of a prefixed instruction

All other values are reserved.

8:63    **Facility Enable (FE)**

The FE field controls the availability of various facilities in problem state as specified below.

8:49    Reserved

50    **Prefixed Instruction**

- 0 Prefixed instructions are not available in problem state.
- 1 Prefixed instructions are available in problem state unless made unavailable by another register.

51    **scv instruction**

- 0 The **scv** instruction is not available.
- 1 The **scv** instruction is available.

52:54    Reserved

55    **Target Address Register (TAR)**

- 0 The TAR and **bctar** instruction are not available in problem state.
- 1 The TAR and **bctar** instruction are available in problem state unless made unavailable by another register.

56    **Event-Based Branch Facility (EBB)**

- 0 The Event-Based Branch facility SPRs and instructions are not available in problem state, and event-based exceptions and branches do not occur.
- 1 The Event-Based Branch facility SPRs and instructions (see Chapter 6 of Book II) are available in problem state unless made unavailable by another register, and event-based exceptions and branches are allowed to occur if enabled by other registers.

57:60    Reserved

**Programming Note**

HFSCR<sub>59:60</sub> are used to control the availability of the Performance Monitor and the BHRB in problem and privileged non-hypervisor states. FSCR<sub>59:60</sub> are reserved since the availability of the Performance Monitor and BHRB is controlled by MMCR0.

61    **Data Stream Control Register at SPR 3 (DSCR)**

- 0 SPR 3 is not available in problem state.

- 1 SPR 3 is available in problem state unless made unavailable by another register.

62:63 Reserved

**Programming Note**

When an OS has set the FSCR such that a facility is unavailable, the OS should either emulate the facility when it is accessed or provide an application interface that requires the application to request use of the facility before it accesses the facility.

### 7.2.13 Hypervisor Facility Status and Control Register

The Hypervisor Facility Status and Control Register (HFSCR) controls the availability of various facilities in problem and privileged non-hypervisor states, and indicates the cause of a Hypervisor Facility Unavailable interrupt.

When the HFSCR makes a facility unavailable, attempted usage of the facility in problem or privileged non-hypervisor states is treated as follows:

- Execution of an instruction causes a Hypervisor Facility Unavailable exception.
- Access of an SPR using *mfspr/mtspr* causes a Hypervisor Facility Unavailable exception
- *rfebb, rfid, rfscv, hrfid, urfid*, and *mtmsr[d]* instructions have the same effect on bits in system registers as they would if the bits were available. The same is true for *mtspr* and *mfspr* unless the preceding item applies.

When the PCR makes a facility unavailable in problem state, the facility is treated as not defined in problem state; any Hypervisor Facility Unavailable interrupt that would occur if the facility were not made unavailable by the PCR does not occur as a result of problem state access. See Section 2.5 for additional information.

When a Hypervisor Facility Unavailable interrupt occurs, the facility that was accessed is indicated in the most-significant byte of the HFSCR.

**Figure 68. Hypervisor Facility Status and Control Register**

The contents of the HFSCR are specified below.

**Value Meaning**

0:7 **Interruption Cause (IC)**

When a Hypervisor Facility Unavailable interrupt occurs, the IC field contains a binary number indicating the access that was attempted. The values and their meanings are specified below.

- 00 Access to a Floating Point register or execution of a Floating Point instruction
- 01 Access to a Vector or VSX register or execution of a Vector or VSX instruction
- 02 Access to the DSCR at SPRs 3 or 17
- 03 Read or write access of a Performance Monitor SPR in group A, or read access of a Performance Monitor SPR in group B. (See Section 11.4.1 for a definition of groups A and B.)
- 04 Execution of a BHRB Instruction

- 07 Access to an Event-Based Branch SPR or execution of an Event-Based Branch instruction
- 08 Access to the Target Address Register
- 09 Access to the **stop** instruction in privileged non-hypervisor state when one or more of the following conditions exist.

PSSCR<sub>EC</sub>=1  
 PSSCR<sub>ESL</sub>=1  
 PSSCR<sub>MTL</sub>>PSSCR<sub>PSSL</sub>  
 PSSCR<sub>RL</sub>>PSSCR<sub>PSSL</sub>

- 0A Access to the *msgsndp* or *msgclrp* instructions, the TIR or the DPDES Register
- 0D Execution of a prefixed instruction

All other values are reserved.

8:63 **Facility Enable (FE)**

The FE field controls the availability of various facilities in problem and privileged non-hypervisor states as specified below.

8:49 Reserved

50 **Prefixed Instruction**

- 0 Prefixed instructions are not available in problem and privileged non-hypervisor states.
- 1 Prefixed instructions are available in problem and privileged non-hypervisor states unless made unavailable by another register.

51:52 Reserved

**Programming Note**

There is no bit in this register controlling the availability of the **stop** instruction because the availability of **stop** in privileged non-hypervisor state is controlled by the PSSCR. See Section 4.2.2.

53 **msgsndp instructions and SPRs (MSGP)**

- 0 The *msgsndp* and *msgclrp* instructions and the TIR and DPDES registers are not available in privileged non-hypervisor state.
- 1 The *msgsndp* and *msgclrp* instructions and the TIR and DPDES registers are available in privileged non-hypervisor state unless made unavailable by another register.
- 54 Reserved
- 55 **Target Address Register (TAR)**
- 0 The TAR and *bctar* instruction are not available in problem and privileged non-hypervisor state.
- 1 The TAR and *bctar* instruction are available in problem and privileged states unless made unavailable by another register.
- 56 **Event-Based Branch Facility (EBB)**
- 0 The Event-Based Branch facility SPRs and instructions are not available in problem and privileged non-hypervisor states, and event-based exceptions and branches do not occur.
- 1 The Event-Based Branch facility SPRs and instructions are available in problem and privileged states unless made unavailable by another register, and event-based exceptions and branches are allowed to occur if enabled by other bits.
- 57 Reserved
- 58 Reserved
- 59 **BHRB Instructions (BHRB)**
- 0 The BHRB instructions (*clrbhrb*, *mfbhrbe*) are not available in problem and privileged non-hypervisor states.
- 1 The BHRB instructions (*clrbhrb*, *mfbhrbe*) are available in problem and privileged states unless made unavailable by another register.
- 60 **Performance Monitor Facility SPRs (PM)**
- 0 Read and write operations of Performance Monitor SPRs in group A and read operations of Performance Monitor SPRs in group B are not available in problem and privileged non-hypervisor states; read and write operations to privileged Performance Monitor registers (SPRs 752-754, 784-792, 795-798) are not available in privileged non-hypervisor state. (See Section 11.4.1 for a definition of groups A and B.) Performance Monitor exceptions do not cause Performance Monitor interrupts to occur when the thread is in problem or privileged states.
- 1 Read and write operations of Performance Monitor SPRs in group A and read operations of Performance Monitor SPRs in group B are available in problem and privileged states unless made unavailable by another register; read and write operations to privileged Performance Monitor registers (SPRs 752-754, 784-792, 795-798) are available in privileged state; Performance Monitor interrupts to occur if  $MSR_{EE}=1$  and  $MMCR0_{EBE}=0$ . See Section 11.2 for additional information
- 61 **Data Stream Control Register (DSCR)**
- 0 SPR 3 is not available in problem or privileged non-hypervisor states and SPR 17 is not available in privileged non-hypervisor state.
- 1 SPR 3 is available in problem and privileged states and SPR 17 is available in privileged state unless made unavailable by another register.
- 62 **Vector and VSX Facilities (VECVSX)**
- 0 The facilities whose availability is controlled by either  $MSR_{VEC}$  or  $MSR_{VSX}$  are not available in problem and privileged non-hypervisor states.
- 1 The facilities whose availability is controlled by either  $MSR_{VEC}$  or  $MSR_{VSX}$  are available in problem and privileged states unless made unavailable by another register.
- 63 **Floating Point Facility (FP)**
- 0 The facilities whose availability is controlled by  $MSR_{FP}$  are not available in problem and privileged non-hypervisor states.
- 1 The facilities whose availability is controlled by  $MSR_{FP}$  are available in problem and privileged states unless made unavailable by another register.

#### Programming Note

The FSCR can be used to determine whether a particular facility is being used by an application, and the HFSCR can be used to determine whether a particular facility is being used by either an application or by an operating system. This is done by disabling the facility initially, and enabling it in the interrupt handler upon first usage. The information about the usage of a particular facility can be used to determine whether that facility's state must be saved and restored when changing program context.

### Programming Note

The following tables summarize the interrupts that occur as a result of accessing the non-privileged Performance Monitor registers in problem state when  $MMCR0_{PMCC}$ , PCR, and HFSCR are set to various values. (Accesses to privileged Performance Monitor SPRs (SPRs 784-792, 795-798) in problem state result in Privileged Instruction type Program interrupts.)

		<i>mfspr</i>				<i>mtspr</i>			
		PMCC				PMCC

Notes:

- Terminology:  
FU: Facility Unavailable interrupt  
HE: Hypervisor Emulation Assistance interrupt  
HU: Hypervisor Facility Unavailable interrupt
- This SPR is read-only, and cannot be written in any privilege state. (See the *mtspr* instruction description in Section 5.4.4 for additional information.) FU or HU interrupts do not occur regardless of the value of  $MMCR0_{PMCC}$  or  $HFSCR_{PM}$ .
- When the PCR indicates a version of the architecture prior to V 2.07, this SPR is treated as undefined in problem state; no FU or HU interrupts occur regardless of the value of  $MMCR0_{PMCC}$  or  $HFSCR_{PM}$ .
- An HU interrupt occurs if  $HFSCR_{PM}=0$  when this SPR is accessed in either problem state or privileged non-hypervisor state.
- An FU interrupt occurs only if PCR indicates a version of the architecture subsequent to V 3.0. and  $MMCR0_{PMCC_{EXT}}$  is set.
- When the PCR indicates a version of the architecture prior to V 3.1, this SPR is treated as undefined in problem state; no FU or HU interrupts occur regardless of the value of  $MMCR0_{PMCC}$  or  $HFSCR_{PM}$ .

**Programming Note**

When an MSR bit makes a facility unavailable, the facility is made unavailable in all privilege states. Examples of this include the Floating Point, Vector, and VSX facilities. The FSCR and HFSCR affect the availability of facilities only in privilege states that are lower than the privilege of the register (FSCR or HFSCR).

## 7.3 Interrupt Synchronization

When an interrupt occurs, SRR0, HSRR0, or USRR0 is set to point to an instruction such that all preceding instructions have completed execution, no subsequent instruction has begun execution, and the instruction addressed by SRR0, HSRR0, or USRR0 may or may not have completed execution, depending on the interrupt type.

With the exception of System Reset and Machine Check interrupts, all interrupts are context synchronizing as defined in Section 1.5.1. System Reset and Machine Check interrupts are context synchronizing if they are recoverable (i.e., if bit 62 of SRR1 is set to 1 by the interrupt). If a System Reset or Machine Check interrupt is not recoverable (i.e., if bit 62 of SRR1 is set to 0 by the interrupt), it acts like a context synchronizing operation with respect to subsequent instructions. That is, a non-recoverable System Reset or Machine Check interrupt need not satisfy items 1 through 3 of Section 1.5.1, but does satisfy items 4 and 5.

## 7.4 Interrupt Classes

Interrupts are classified by whether they are directly caused by the execution of an instruction or are caused by some other system exception. Those that are “system-caused” are:

- System Reset
- Machine Check
- External
- Decrementer
- Directed Privileged Doorbell
- Hypervisor Decrementer
- Hypervisor Maintenance
- Hypervisor Virtualization
- Directed Hypervisor Doorbell
- Directed Ultravisor Doorbell
- Performance Monitor

External, Decrementer, Hypervisor Decrementer, Directed Privileged Doorbell, Directed Hypervisor Doorbell, Directed Ultravisor Doorbell, Hypervisor Maintenance, and Hypervisor Virtualization interrupts are maskable interrupts. Therefore, software may delay the generation of these interrupts. System Reset and Machine Check interrupts are not maskable.

“Instruction-caused” interrupts are further divided into two classes, *precise* and *imprecise*.

### 7.4.1 Precise Interrupt

Except for the Imprecise Mode Floating-Point Enabled Exception type Program interrupt, all instruction-caused interrupts are precise.

When the fetching or execution of an instruction causes a precise interrupt, the following conditions exist at the interrupt point.

1. SRR0, HSRR0, and USRR0 addresses either the instruction causing the exception or the immediately following instruction. Which instruction is addressed can be determined from the interrupt type and status bits.
2. An interrupt is generated such that all instructions preceding the instruction causing the exception appear to have completed with respect to the executing thread.
3. The instruction causing the exception may appear not to have begun execution (except for causing the exception), may have been partially executed, or may have completed, depending on the interrupt type.
4. Architecturally, no subsequent instruction has begun execution.

### 7.4.2 Imprecise Interrupt

This architecture defines one imprecise interrupt, the Imprecise Mode Floating-Point Enabled Exception type Program interrupt.

When an Imprecise Mode Floating-Point Enabled Exception type Program interrupt occurs, the following conditions exist at the interrupt point.

1. SRR0 addresses either the instruction causing the exception or some instruction following that instruction; see Section 7.5.9, “Program Interrupt” on page 1287.
2. An interrupt is generated such that all instructions preceding the instruction addressed by SRR0 appear to have completed with respect to the executing thread.
3. The instruction addressed by SRR0 may appear not to have begun execution (except, in some cases, for causing the interrupt to occur), may have been partially executed, or may have completed; see Section 7.5.9.
4. No instruction following the instruction addressed by SRR0 appears to have begun execution.

All Floating-Point Enabled Exception type Program interrupts are maskable using the MSR bits FE0 and FE1. Although these interrupts are maskable, they differ significantly from the other maskable interrupts in that the masking of these interrupts is usually controlled by the application program, whereas the masking of all other maskable interrupts is controlled by either the operating system or the hypervisor.

### 7.4.3 Interrupt Processing

Associated with each kind of interrupt is an *interrupt vector*, which contains the initial sequence of instructions that is executed when the corresponding interrupt occurs.

Interrupt processing consists of saving a small part of the thread's state in certain registers, identifying the cause of the interrupt in other registers, and continuing execution at the corresponding interrupt vector location. When an exception exists that will cause an interrupt to be generated and it has been determined that the interrupt will occur, the following actions are performed. The handling of Machine Check interrupts (see Section 7.5.2) and System Call Vectored interrupts (see Section 7.5.27) differs from the description given below in several respects.

1. SRR0, HSRR0, or USRR0 is loaded with an instruction address that depends on the type of interrupt; see the specific interrupt description for details.
2. Bits 33:36 and 42:47 of SRR1, HSRR1, or USRR1 are loaded with information specific to the interrupt type.
3. Bits 0:32, 37:41, and 48:63 of SRR1, HSRR1, or USRR1 are loaded with a copy of the corresponding bits of the MSR.
4. The MSR is set as shown in Figure 69 on page 1275. In particular, MSR bits IR and DR are set as specified by  $LPCR_{AIL}$  or  $LPCR_{HAIL}$  as appropriate (see Section 2.2), and MSR bit SF is set to 1, selecting 64-bit mode. The new values take effect beginning with the first instruction executed following the interrupt.
5. Instruction fetch and execution resumes, using the new MSR value, at the effective address specific to the interrupt type. These effective addresses are shown in Figure 70 on page 1276. An offset may be applied to get the effective addresses, as specified by  $LPCR_{AIL}$  or  $LPCR_{HAIL}$  as appropriate (see Section 2.2).

Interrupts do not clear reservations obtained with *lbarx*, *lharx*, *lwarx*, *ldarx*, or *lqarx*.

#### Programming Note

In general, when an interrupt occurs, the following instructions should be executed by the interrupt handler before dispatching a “new” program on the thread.

- *stbcx.*, *sthcx.*, *stwcx.*, *stdcx.*, or *stqcx.* to clear the reservation if one is outstanding, to ensure that a *lbarx*, *lharx*, *lwarx*, *ldarx*, or *lqarx* in the interrupted program is not paired with a *stbcx.*, *sthcx.*, *stwcx.*, *stdcx.*, *stqcx.*, or *waitrsv* on the “new” program.
- “*eieio*, *tbsync*, *sbsync*, *ptesync*,” to complete any outstanding translation table modification sequence and ensure that all storage accesses caused by the interrupted program will be performed with respect to another thread before the program is resumed on that other thread. (If software conventions are such that there is no possibility of a translation table modification sequence being in progress on the thread, a *phwsync* instruction suffices. If software conventions are also such that there is no possibility of a *dcbstps* or *dcbfps* instruction having been executed on the thread since the preceding execution of *phwsync* or *ptesync* on the thread, an *hwsync* suffices.)

If dispatching the “new” program includes changing the contents of LPIDR and/or PIDR, the *ptesync* or *[p]hwsync* just described can, if placed properly, also serve as the *ptesync* or *hwsync* that is part of the software synchronization requirements for *mtlpidr* and *mtpidr*; see note 20 in Chapter 13. If advantage is taken of this commonality, the stronger of the two required sync variants must be used. E.g., if the current Programming Note requires *phwsync* and note 20 requires *hwsync*, *phwsync* must be used.

- *isync* or *rfid*, to ensure that the instructions in the “new” program execute in the “new” context.
- *cpabort*, to clear state from any previous use of the Copy-Paste Facility.

### Programming Note

For instruction-caused interrupts, in some cases it may be desirable for the operating system to emulate the instruction that caused the interrupt, while in other cases it may be desirable for the operating system not to emulate the instruction. The following list, while not complete, illustrates criteria by which decisions regarding emulation should be made. The list applies to general execution environments; it does not necessarily apply to special environments such as program debugging, bring-up, etc.

In general, the instruction should be emulated if:

- The interrupt is caused by a condition for which the instruction description (including related material such as the introduction to the section describing the instruction) implies that the instruction works correctly. Example: Alignment interrupt caused by ***lmw*** for which the storage operand is not aligned, or by ***dcbz*** for which the storage operand is in storage that is Write Through Required or Caching Inhibited.
- The instruction is an illegal instruction that should appear, to the program executing it, as if it were supported by the implementation. Example: A Hypervisor Emulation Assistance interrupt is caused by an instruction that has been phased out of the architecture but is still used by some programs that the operating system supports.

If the instruction is a *Storage Access* instruction, the emulation must satisfy the atomicity requirements described in Section 1.4 of Book II.

In general, the instruction should not be emulated if:

- The purpose of the instruction is to cause an interrupt. Example: System Call interrupt caused by ***sc***.
- The interrupt is caused by a condition that is stated, in the instruction description, potentially to cause the interrupt. Example: Alignment interrupt caused by ***lwarx*** for which the storage operand is not aligned.
- The program is attempting to perform a function that it should not be permitted to perform. Example: Data Storage interrupt caused by ***lwz*** for which the storage operand is in storage that the program should not be permitted to access. (If the function is one that the program should be permitted to perform, the conditions that caused the interrupt should be corrected and the program re-dispatched such that the instruction will be re-executed. Example: Data Storage interrupt caused by ***lwz*** for which the storage operand is in storage that the program should be permitted to access but for which there currently is no PTE that satisfies the Page Table search.)

### Programming Note

If a program modifies an instruction that it or another program will subsequently execute and the execution of the instruction causes an interrupt, the state of storage and the content of some registers may appear to be inconsistent to the interrupt handler program. For example, this could be the result of one program executing an instruction that causes a Hypervisor Emulation Assistance interrupt just before another instance of the same program stores an *Add Immediate* instruction in that storage location. To the interrupt handler code, it would appear that a hardware generated the interrupt as the result of executing a valid instruction.

**Programming Note**

Hardware reports system integrity problems via Machine Check and System Reset interrupts that set  $SRR1_{62}$  to 0. All other interrupts that set the SRRs, including Machine Check and System Reset interrupts that do not themselves report integrity problems, copy  $MSR_{RI}$  to  $SRR1_{62}$ . (All interrupts that set the SRRs set  $MSR_{RI}$  to 0.) To interact correctly with this behavior, interrupt handlers for interrupts that set the SRRs should do as follows.

- In each such interrupt handler, interpret  $SRR1_{62}$  as:
  - 0: interrupt is not recoverable
  - 1: interrupt is recoverable
- In each such interrupt handler, when enough state has been saved that another interrupt that sets the SRRs can be recovered from, set  $MSR_{RI}$  to 1.
- In each such interrupt handler, do the following (in order) just before returning.
  1. Set  $MSR_{RI}$  to 0.
  2. Set  $SRR0$  and  $SRR1$  to the values to be used by *rfid*. The new value of  $SRR1$  should have bit 62 set to 1 (which will happen naturally if  $SRR1$  is restored to the value saved there by the interrupt, because the interrupt handler will not be executing this sequence unless the interrupt is recoverable).
  3. Execute *rfid*.

**Programming Note**

Because interrupts that set the HSRRs preserve  $MSR_{RI}$  instead of setting it to 0 as is done by interrupts that set the SRRs, handlers for interrupts that set the HSRRs must prevent additional such interrupts from occurring until enough state has been saved that another such interrupt can be recovered from, and also when the HSRRs have been restored prior to executing *hrfid*. Required behavior during those intervals includes the following.

- Keep  $MSR_{HV\ PR\ EE}=0b100$ . (This state prevents many such interrupts from occurring.)
- Execute only defined instructions that are not in invalid form.
- Pin the first page of the hypervisor's Process Table
- Ensure that the PTE mapping the first page of the hypervisor's Process Table has the Reference bit set and has no other reason to cause an exception.

Similarly, because the Directed Ultravisor Doorbell interrupt preserves  $MSR_{RI}$  instead of setting it to 0, the Directed Ultravisor Doorbell interrupt handler must prevent additional such interrupts from occurring until enough state has been saved that another such interrupt can be recovered from, and also when the USRRs have been restored prior to executing *urfid*. This can be accomplished by keeping  $MSR_{S\ HV\ PR\ EE}=0b1100$  during those intervals.

## 7.4.4 Implicit alteration of HSRR0 and HSRR1

Executing some of the more complex instructions may have the side effect of altering the contents of HSRR0 and HSRR1. The instructions listed below are guaranteed not to have this side effect. Any omission of instruction suffixes is significant; e.g., *add* is listed but *add.* is excluded.

1. *Branch* instructions

*b[l][a]*, *bc[l][a]*, *bclr[l]*, *bcctr[l]*

2. *Fixed-Point Load and Store* Instructions

*lbz*, *lbzx*, *lhz*, *lhzx*, *lwz*, *lwzx*, *ld*, *ldx*, *stb*, *stbx*, *sth*, *sthx*, *stw*, *stwx*, *std*, *stdx*

Execution of these instructions is guaranteed not to have the side effect of altering HSRR0 and HSRR1 only if the storage operand is aligned and  $MSR_{HV\ DR}=0b10$ .

3. *Arithmetic* instructions

*addi*, *addis*, *add*, *subf*, *neg*

4. *Compare* instructions

*cmpi*, *cmp*, *cmpli*, *cmpl*

5. *Logical and Extend Sign* instructions

***ori, oris, xori, xoris, and, or, xor, nand, nor, eqv, andc, orc, extsb, extsh, extsw***

6. *Rotate and Shift* instructions

***rdicl, rldicr, rldic, rlwinm, rldcl, rldcr, rlwnm, rldimi, rlwimi, sld, slw, srd, srw***

## 7. Other instructions

***isync***

***rfid, urfid***

***hrfid*** in hypervisor state

***mtspr, mfspr, mtmsrd, mfmsr***

**Programming Note**

Instructions excluded from the list include the following.

- instructions that set or use XER<sub>CA</sub>
- instructions that set XER<sub>OV</sub> or XER<sub>SO</sub>
- ***andi, andis.***, and fixed-point instructions with Rc=1 (Fixed-point instructions with Rc=1 can be replaced by the corresponding instruction with Rc=0 followed by a *Compare* instruction.)
- all floating-point instructions
- ***mftb***

These instructions, and the other excluded instructions, may be implemented with the assistance of the Hypervisor Emulation Assistance interrupt, or of implementation-specific interrupts that modify HSRR0 and HSRR1. The included instructions are guaranteed not to be implemented thus. (The included instructions are sufficiently simple as to be unlikely to need such assistance. Moreover, they are likely to be needed in interrupt handlers before HSRR0 and HSRR1 have been saved or after HSRR0 and HSRR1 have been restored.)

Similarly, fetching instructions may have the side effect of altering the contents of HSRR0 and HSRR1 unless MSR<sub>HV IR</sub> = 0b10.

## 7.5 Interrupt Definitions

Figure 69 shows all the types of interrupts and the values assigned to the MSR for each. Figure 70 shows the effective address of the interrupt vector for each interrupt type. (Section 6.7.5 on page 1196 summarizes all architecturally defined uses of effective addresses, including those implied by Figure 70.)

Interrupt Type	MSR Bit									
	IR	DR	FE0	FE1	EE	RI	ME	HV	S

Interrupt Type	MSR Bit
	IR DR FE0 FE1 EE RI ME HV S
0	bit is set to 0
1	bit is set to 1
-	bit is not altered
r	for interrupts for which $LPCR_{AIL}$ applies, if $LPCR_{AIL}=3$ , set to 1; for interrupts for which $LPCR_{HAIL}$ applies, if $LPCR_{HAIL}=1$ , set to 1; otherwise set to 0
p	if the interrupt occurred while the thread was in power-saving mode, set to 1; otherwise not altered
e	if $LPES=0$ , set to 1; otherwise not altered
h	if $LPES=1$ , set to 0; otherwise not altered
s	if $LEV=1$ or $LEV=2$ , set to 1; otherwise not altered
t	if the interrupt caused exit from a state-losing power-saving mode and $SMFCTRL_E=1$ , set to 1; if the interrupt caused exit from a state-losing power-saving mode and $SMFCTRL_E=0$ , set to 0; otherwise not altered
u	if $SMFCTRL_E=1$ and $LEV=2$ , set to 1; otherwise not altered
<u>Settings for Other Bits</u>	
Bits PR and PMM are set to 0.	
The TE field is set to 0b00.	
FP, VEC, VSX, and bits 5 and 31 are set to 0.	
If the interrupt results in $MSR_{S_{HV}}$ being equal to 0b11, the LE bit is copied from the UILE bit; otherwise, if the interrupt results in $MSR_{S_{HV}}$ being equal to 0b01, the LE bit is copied from the HILE bit; otherwise the LE bit is copied from the $LPCR_{ILE}$ bit.	
The SF bit is set to 1.	
Reserved bits are set as if written as 0.

**Figure 70. Effective address of interrupt vector by interrupt type**

**Programming Note**

When address translation is disabled, use of any of the effective addresses that are shown as reserved in Figure 70 risks incompatibility with future implementations.

### 7.5.1 System Reset Interrupt

If a System Reset exception causes an interrupt that is not context synchronizing or causes the loss of a Machine Check exception or a Direct External exception, or if the state of the thread has been corrupted, the interrupt is not recoverable.

When the thread is in any power-saving level, a System Reset interrupt occurs when a System Reset exception exists. When the thread is in a power-saving level that was entered when PSSCR<sub>EC</sub>=1, a System Reset interrupt also occurs when any of the following events occurs provided that the event is enabled to cause exit from power-saving mode (see Section 2.2). When the thread is in a power-saving level that allows the state of the LPCR to be lost, it is implementation-specific

whether the following events, when enabled, cause exit, or whether only a system-reset exception causes exit.

- External
- Decrementer
- Directed Privileged Doorbell
- Directed Hypervisor Doorbell
- Directed Ultravisor Doorbell
- Hypervisor Maintenance
- Hypervisor Virtualization exception
- Implementation-specific

SRR1 indicates the exception that caused exit from power-saving mode as specified below.

The following registers are set:

**SRR0** If the interrupt did not occur when the thread was in power-saving mode, set to the effective address of the instruction that the thread would have attempted to execute next if no interrupt conditions were present; if the interrupt occurred when the thread was in a power-saving mode that was entered with PSSCR bit ESL=0, and fields RL, MTL, and PSLI set to values that do not allow state loss, set to the effective address of the instruction following the stop instruction; otherwise, set to an undefined value.

If the interrupt occurred while the thread was in power-saving mode, set to the effective address of the instruction following the **stop** instruction when **stop** is executed with PSSCR bit ESL=0 and fields RL, MTL, and PSLI set to values that do not allow state loss; otherwise, set to an undefined value.

#### Programming Note

Whenever **stop** is executed in privileged non-hypervisor state, the hypervisor typically sets both PSSCR<sub>ESL</sub> and PSSCR<sub>EC</sub> to 0, and sets RL and MTL to values that do not cause state loss. If an interrupt causes exit to power-saving mode (either because the interrupt was a System Reset or Machine Check interrupt or MSR<sub>EE</sub>=1), then SRR0 for that interrupt contains the effective address of the instruction immediately following **stop**.

**33** Implementation-dependent.

**34:36** Set to 0.

**42:45** If the interrupt did not occur when the thread was in power-saving mode, set to an implementation-specific value. If the interrupt occurred when the thread was in power-saving mode, set to indicate the exception that caused exit from power-saving mode as shown below:

#### SRR1<sub>42:45</sub> Exception

0000	Reserved
0001	Directed Ultravisor Doorbell
0010	Implementation specific
0011	Directed Hypervisor Doorbell
0100	System Reset
0101	Directed Privlgd Doorbell
0110	Decrementer
0111	Reserved
1000	External
1001	Hypervisor Virtualization
1010	Hypervisor Maintenance
1011	Reserved
1100	Implementation specific
1101	Reserved
1110	Implementation specific
1111	Reserved

If multiple events that cause exit from power-saving mode exist, the event reported is the exception corresponding to the interrupt that would have occurred if the same conditions existed and the thread was not in power-saving mode.

**46:47** Set to indicate whether the interrupt occurred when the thread was in power-saving mode and, if so, the extent to which resource state was maintained while the thread was in power-saving mode, as follows:

00	The interrupt did not occur when the thread was in power-saving mode.
01	The interrupt occurred when the thread was in power-saving mode. The state of all resources was maintained as if the thread was not in power-saving mode.

## SRR1

- 10 The interrupt occurred when the thread was in power-saving mode. The state of some resources was not maintained, but the state of all hypervisor resources, including the DEC, HDEC, TB, PURR, SPURR, and VTB, was maintained as if the thread was not in power-saving mode and the state of all other resources is such that the hypervisor can resume execution. (See Section 2.6 for the list of hypervisor resources.)
- 11 The interrupt occurred when the thread was in power-saving mode. The state of some resources was not maintained, and the state of some hypervisor resources was not maintained or the state of some resources is such that the hypervisor cannot resume execution.

#### Programming Note

Although the resources that are maintained in power-saving levels that allow loss of state are implementation-dependent, the hypervisor can avoid implementation-dependence in the portion of the System Reset and Machine Check interrupt handlers that recover from having been in power-saving mode by using the contents of SRR1<sub>46:47</sub>, to determine what state to restore. (To avoid implementation-dependence, the hypervisor must assume that only the resources indicated in SRR1<sub>46:47</sub> have been preserved.)

- 62 If the interrupt did not occur while the thread was in a power-saving level that was entered when PSSCR<sub>EC</sub>=1, loaded from bit 62 of the MSR if the thread is in a recoverable state; otherwise set to 0. If the interrupt occurred while the thread was in a power-saving level that was entered when PSSCR<sub>EC</sub>=1, set to 1 if the thread is in a recoverable state; otherwise set to 0.

**Others** Loaded from the MSR.

**MSR** See Figure 69 on page 1275.

In addition, if the interrupt occurs when the thread is in a power-saving level that was entered when PSSCR<sub>EC</sub>=1 and is caused by an exception other than a System Reset exception, all other registers, except HSRR0 and HSRR1, that would be set by the corresponding interrupt if the exception occurred when the

thread was not in power-saving mode are set by the System Reset interrupt, and are set to the values to which they would be set if the exception occurred when the thread was not in power-saving mode.

Execution resumes at effective address 0x0000\_0000\_0000\_0100.

The means for software to distinguish between power-on Reset and other types of System Reset are implementation-dependent.

## 7.5.2 Machine Check Interrupt

The causes of Machine Check interrupts are implementation-dependent. For example, a Machine Check interrupt may be caused by a reference to a storage location that contains an uncorrectable error or does not exist (see Section 6.6), or by an error in the storage subsystem. In some cases, processor designers may choose to present what would normally be considered a storage exception, and reported as an [H]DSI or [H]ISI, as a Machine Check interrupt instead, often because of the perceived severity of the programming error or the difficulty of the verification and testing associated with reporting the error as an [H]DSI or [H]ISI. If the decision to report the exception as a Machine Check interrupt is made when the scenario is first added to the architecture, the exception may never be documented in a storage interrupt description. One such case is an attempt to access control memory as anything other than an operand of *copy* or *paste*.

When the thread is not in power-saving mode, Machine Check interrupts are enabled when MSR<sub>ME</sub>=1; if MSR<sub>ME</sub>=0 and a Machine Check exception occurs, the thread enters the Checkstop state. When the thread is in a power-saving level that does not allow loss of hypervisor state, Machine Check interrupts are treated as enabled when LPCR<sub>51</sub>=1 and cannot occur when LPCR<sub>51</sub>=0. When the thread is in a power-saving level that allows loss of hypervisor state, it is implementation-specific whether Machine Check interrupts are treated as enabled LPCR<sub>51</sub>=1 or if they cannot occur. If a Machine Check exception occurs while the thread is in power-saving mode and the Machine Check exception is not enabled to cause exit from power-saving mode, the result is implementation specific.

The Checkstop state may also be entered if an access is attempted to a storage location that does not exist (see Section 6.6), or if an implementation-dependent hardware error occurs that prevents continued operation.

### Disabled Machine Check (Checkstop State)

When a thread is in Checkstop state, instruction processing is suspended and generally cannot be restarted without resetting the thread. Some implementations may preserve some or all of the internal state of the thread when entering Checkstop state, so that the

state can be analyzed as an aid in problem determination.

### Enabled Machine Check

If a Machine Check exception causes an interrupt that is not context synchronizing or causes the loss of a Direct External exception, or if the state of the thread has been corrupted, the interrupt is not recoverable.

The following registers are set:

**SRR0** If the interrupt occurred when the thread was not in a power-saving mode, or was in a power-saving mode that was entered with PSSCR bit ESL=0, and fields RL, MTL, and PSL set to values that do not allow state loss, set on a "best effort" basis to the effective address of some instruction that was executing or was about to be executed when the Machine Check exception occurred; otherwise set to an undefined value.

**SRR1**  
**34** If SRR0 is set to the effective address of an instruction for which the instruction length can easily be reported, set to 0 if the instruction is a word instruction and to 1 if the instruction is a prefixed instruction; otherwise set to an undefined value.

**46:47** Set to indicate whether the interrupt occurred when the thread was in power-saving mode and, if so, the extent to which resource state was maintained while the thread was in power-saving mode, as follows.

00 The interrupt did not occur when the thread was in power-saving mode.

01 The interrupt occurred when the thread was in power-saving mode. The state of all resources was maintained as if the thread was not in power-saving mode.

10 The interrupt occurred when the thread was in power-saving mode. The state of some resources was not maintained, but the state of all hypervisor resources, including the DEC, HDEC, TB, PURR, SPURR, and VTB, was maintained as if the thread was not in power-saving mode and the state of all other resources is such that the hypervisor can resume execution. (See Section 2.6 for the list of hypervisor resources.)

11 The interrupt occurred when the thread was in power-saving mode. The state of some resources was not maintained, and the state of some hypervisor resources was not maintained or the state of some resources is such that the hypervisor cannot resume execution.

### Programming Note

Although the resources that are maintained in power-saving mode (except when all resources are maintained) are implementation-dependent, the hypervisor can avoid implementation-dependence in the portion of the System Reset and Machine Check interrupt handlers that recover from having been in power-saving mode by using the contents of SRR1<sup>46:47</sup>, to determine what state to restore. (To avoid implementation-dependence in the portion of the hypervisor that enters power-saving mode, the hypervisor must use the specification of the four instructions to determine what state to save.)

**62** If the interrupt did not occur while the thread was in a power-saving level that was entered when PSSCR<sub>EC</sub>=1, loaded from bit 62 of the MSR if the thread is in a recoverable state; otherwise set to 0. If the interrupt occurred while the thread was in a power-saving level that was entered when PSSCR<sub>EC</sub>=1, set to 1 if the thread is in a recoverable state; otherwise set to 0.

**Others** Set to an implementation-dependent value.

**MSR** See Figure 69.

**DSISR** Set to an implementation-dependent value.

**DAR** Set to an implementation-dependent value.

**ASDR** Set to an implementation-dependent value.

Execution resumes at effective address 0x0000\_0000\_0000\_0200.

A Machine Check interrupt caused by the existence of multiple SLB entries or TLB entries (or similar entries in implementation-specific translation caches) which translate a given effective or virtual address (see Sections 6.7.8.2 and 6.7.9.2.) must occur while still in the context of the partition that caused it. The interrupt must be presented in a way that permits continuing execution, with damage limited to the causing partition. Treating the exception as instruction-caused will achieve these requirements.

**Programming Note**

If a Machine Check interrupt is caused by an error in the storage subsystem, the storage subsystem may return incorrect data, which may be placed into registers. This corruption of register contents may occur even if the interrupt is recoverable.

### 7.5.3 Data Storage Interrupt (DSI)

A Data Storage interrupt occurs when no higher priority exception exists and a data access cannot be performed for any of the reasons listed below, under the conditions described immediately below.

In general, a Data Storage interrupt can occur only under the following conditions.

- The value of the expression  $(MSR_{HV\ PR}=0b10) \& (MSR_{DR}=0)$  is 1.
- $HR=0$ ,  $MSR_{DR}=1$ , and the value of the expression  $(MSR_{HV\ PR}=0b10) \mid \neg VPM$  is 1.
- $HR=1$ ,  $MSR_{DR}=1$ , and either of the following prevents the data access from being performed.
  - process-scoped translation
  - partition-scoped translation for the Process Table Entry when  $effLPID=0$

The exceptions to the preceding general statement are as follows.

- If  $HR=0$  and  $MSR_{HV\ PR}\neq 0b10$ , a security violation in accessing the PTEG during address translation causes a Hypervisor Data Storage interrupt regardless of the rest of the translation state.
- If  $HR=0$ ,  $MSR_{DR}=1$ , and an invalid Process Table Entry stops the translation process, a Data Storage interrupt occurs regardless of the rest of the translation state. (This can happen only when  $UPRT=1$ , the needed translation is not found in the SLB, and either  $MSR_{HV}=0$  or  $LPID=0$ .)
- If  $HR=0$ ,  $MSR_{HV\ PR}\neq 0b10$ ,  $MSR_{DR}=1$ ,  $VPM=0$ , and  $LPCR_{KBV}=1$ , a Virtual Page Class Key Storage Protection exception causes a Hypervisor Data Storage interrupt instead of a Data Storage interrupt, as described in more detail below.
- If  $HR=1$ ,  $MSR_{HV\ PR}=0b10$ , and  $MSR_{DR}=1$ , an attempt to execute a *Fixed-Point Load or Store Caching Inhibited* instruction causes a Data Storage interrupt regardless of the rest of the translation state.
- If  $HR=1$ ,  $MSR_{DR}=1$ ,  $effLPID=0$ , and either (a) an unsupported radix tree configuration is found in the Partition Table Entry, or (b) the effective address of the Process Table Entry cannot be translated to a host real address because no valid PTE is found that translates the effective address, a Hypervisor Data Storage interrupt occurs regardless of the rest of the translation state.

- If  $HR=1$  and either  $MSR_{HV\ PR}\neq 0b10$  or  $MSR_{DR}=1$ , any of the following causes a Data Storage interrupt regardless of the rest of the translation state.
  - a Data Address Watchpoint match
  - an attempt to execute an AMO with a reserved function code
  - an attempt to copy from control memory, or to paste to control memory that is not properly configured

Under the conditions described above, a Data Storage interrupt may occur for any of the following reasons.

- The effective or virtual address of any byte of the storage location specified by a *Load* or *Store* instruction, or by an instruction that is treated as a *Load* or *Store* other than a *Cache Block Touch* instruction, cannot be translated to a host real address ( $HR=0$ ; or  $HR=1$  and  $effLPID=0$ ) or to a guest real address ( $HR=1$  and  $effLPID\neq 0$ ) because no valid PTE was found that translates the effective or virtual address.
- $HR=0$  and either (a) the virtual address of the Process Table Entry or Segment Table Entry Group cannot be translated because no valid PTE was found that translates the virtual address, or (b) the Process Table Entry is invalid.
- $HR=1$  and a Reference or Change bit update cannot be performed atomically in the process-scoped PTE, or in the partition-scoped PTE if  $effLPID=0$ .
- The effective address specified by a *lq*, *stq*, *lwat*, *ldat*, *lbarx*, *lharx*, *lwarx*, *ldarx*, *lqarx*, *stwat*, *stdat*, *stbcx.*, *sthcx.*, *stwcx.*, *stdcx.*, or *stqcx.* instruction refers to storage that is Write Through Required or Caching Inhibited; or the effective address specified by a *copy* or *paste* instruction refers to storage that is Caching Inhibited; or the effective address specified by a *lwat*, *ldat*, *stwat*, or *stdat* instruction refers to storage that is Guarded.

**Programming Note**

When nested Radix Tree translation is used to translate the effective address, these combinations of instruction and storage control attribute never cause a Hypervisor Data Storage interrupt (see Section 6.7.10.3).

- Control memory is specified as the source of a *copy* instruction or an attempt is made to paste to control memory that is not properly configured.
- The access violates Basic Storage Protection.
- The access violates Virtual Page Class Key Storage Protection.
- The access violates Radix Tree Translation Storage Protection.
- The access violates Secure Memory Protection.

**Programming Note**

A storage protection violation may be for the data access or for an associated implicit access to a table entry, other than the PATE, during address translation or when updating Reference and Change bits. (“Table entry” here includes STEGs, PTEGs, and PDEs. For data and table entries for which the host real address is not the result of address translation, the only possible storage protection violation is a Secure Memory Protection violation.) Note that when nested Radix Tree Translation is being performed, a violation of Radix Tree Translation Storage Protection causes a DSI when the process-scoped access authority does not permit the access, regardless of whether the partition-scoped access authority permits it.

- The process- and partition-scoped page attributes (ATT values) conflict.

**Programming Note**

The only case of such conflict is the attribute mismatch in which the process-scoped PTE specifies  $l=0$  and the partition-scoped PTE specifies  $l=1$ .

- An unsupported radix tree configuration is found in the Process Table Entry, in the process-scoped tables, or, if  $effLPID=0$ , in the partition-scoped tables. (Note that this condition may not be detected until the associated values are about to cause a functional problem for the processor.)
- A Data Address Watchpoint match occurs.
- An attempt is made to execute a *Load Atomic* or *Store Atomic* instruction with a reserved function code.
- An attempt is made to execute a *Fixed-Point Load* or *Store Caching Inhibited* instruction with  $MSR_{DR}=1$  or specifying a storage location that is specified by the Hypervisor Real Mode Storage Control facility to be treated as non-Guarded.

**Programming Note**

A *Load Atomic* or *Store Atomic* instruction containing a reserved function code (see Figures 3 and 4 in Book II) is an invalid form of the instruction. Attempting to execute such a *Load Atomic* or *Store Atomic* instruction causes a DSI (or HDSI), rather than causing a Hypervisor Emulation Assistance interrupt or yielding boundedly undefined results, to permit the function code to be handled entirely by the memory agent, thereby facilitating the definition of additional function codes in the future if that proves desirable. Consistent with the usual handling of invalid instruction forms, this instance of [H]DSI occurs very early in the execution of the instruction, with the result that [hypervisor] data storage exceptions associated with computing and translating the EA do not occur and Reference and Change bits are not updated.

If a *stbcx.*, *stbcx.*, *stwcx.*, *stdcx.*, or *stqcx.* would not perform its store in the absence of a Data Storage interrupt, and either (a) the specified effective address refers to storage that is Write Through Required or Caching Inhibited, or (b) a non-conditional *Store* to the specified effective address would cause a Data Storage interrupt, it is implementation-dependent whether a Data Storage interrupt occurs.

If the XER specifies a length of zero for an indexed *Move Assist* instruction, a Data Storage interrupt does not occur.

The following registers are set:

**SRR0** Set to the effective address of the instruction that caused the interrupt.

**SRR1**

**33** Set to 0.

**34** Set to 0 if the instruction that caused the interrupt is a word instruction and to 1 if the instruction that caused the interrupt is a prefixed instruction.

**35:36** Set to 0.

**42:47** Set to 0.

**Others** Loaded from the MSR.

**MSR** See Figure 69.

**DSISR**

**32** Set to 0.

**33** Set to 1 if the translation for an attempted access is not found in the Page Table; otherwise set to 0..

**34** Set to 1 if the process- and partition-scoped page attributes conflict; otherwise set to 0.

**35** Set to 0.

**36** Set to 1 if the access is not permitted by Figure 47 or the Privilege, Read, or Read/Write bits in Figure 48 as appropriate; otherwise set to 0.

- 37 Set to 1 if the access is due to a *lq*, *stq*, *lwat*, *ldat*, *lbarx*, *lharx*, *lwax*, *ldarx*, *lqarx*, *stwat*, *stdat*, *stbcx.*, *sthcx.*, *stwcx.*, *stdcx.*, or *stqcx.* instruction that addresses storage that is Write Through Required or Caching Inhibited; or if the access is due to a *copy* or *paste* instruction that addresses storage that is Caching Inhibited; or if the access is due to a *lwat*, *ldat*, *stwat*, or *stdat* instruction that addresses storage that is Guarded; otherwise set to 0.
- 38 Set to 1 for an explicit access for a *Store*, *dcbz*, or *Load/Store Atomic* instruction; set to 1 when an implicit update of the Change bit in the process-scoped PTE fails; otherwise set to 0.
- 39:40 Set to 0.
- 41 Set to 1 if a Data Address Watchpoint match occurs; otherwise set to 0.
- 42 Set to 1 if the access is not permitted by Virtual Page Class Key Protection; otherwise set to 0.
- 43 Set to 1 if the access is not permitted by Secure Memory Protection; otherwise set to 0.
- 44 Set to 1 if an unsupported radix tree configuration is found during the translation process; otherwise set to 0.
- 45 Set to 1 if an attempt to atomically set a Reference or Change bit fails; otherwise set to 0.

#### Programming Note

The number of attempts hardware makes to atomically set Reference and Change bits before triggering this exception is implementation dependent. For example, the POWER9 processor makes no attempt. Software may still support the atomic update programming model to get performance benefits such as those described in Section 6.7.12.

- 46 Set to 1 if the address of the appropriate Process Table Entry or Segment Table Entry Group cannot be translated, or the Process Table Entry is invalid.
- 47:59 Set to 0.
- 60 Set to 1 if control memory is specified as the source of a *copy* instruction or an attempt is made to paste to control memory that is not properly configured; otherwise set to 0. These exceptions are presented differently from most instruction-caused exceptions. See Section 4.4, “Copy-Paste Facility”, in Book II for details. Additional information may be retained by the platform

- if the control memory is not properly configured.
- 61 Set to 1 if an attempt is made to execute a *Load Atomic* or *Store Atomic* instruction specifying a reserved function code; otherwise set to 0.
- 62 Set to 1 if an attempt is made to execute a *Fixed-Point Load* or *Store Caching Inhibited* instruction with  $MSR_{DR}=1$  or specifying a storage location that is specified by the Hypervisor Real Mode Storage Control facility to be treated as non-Guarded.
- 63 Set to 0.
- DAR Set to the effective address of a storage element, or undefined, as described in the following list. The list should be read from the top down; the DAR is set as described by the first item that corresponds to an exception that is reported in the DSISR. For example, if a *Load Word* instruction causes a storage protection violation and a Data Address Watchpoint match (and both are reported in the DSISR), the DAR is set to the effective address of a byte in the first aligned doubleword for which access was attempted in the page that caused the exception.
- undefined, for *Load Atomic* or *Store Atomic* instruction specifying a reserved function code
  - 
  - undefined, when  $DSISR_{60}=1$
  - a Data Storage exception occurs for reasons other than a Data Address Watchpoint match
    - a byte in the block that caused the exception, for a *Cache Management* instruction
    - a byte in the first aligned doubleword for which access was attempted in the page that caused the exception, for a *Load* or *Store* instruction or an instruction that is treated as a *Load* or *Store* (“first” refers to address order: see Section 7.7).
  - the first byte of overlap between the operand and the matching watched range, for a Data Address Watchpoint match

For the cases in which the DAR is specified above to be set to a defined value, if the interrupt occurs in 32-bit mode the high-order 32 bits of the DAR are set to 0.

If a Data Storage exception occurs due to an attempt to execute a *Fixed-Point Load* or *Store Caching Inhibited* instruction when  $MSR_{DR}=1$  or a *Load Atomic* or *Store Atomic* instruction with a reserved function code, the

only exception bit that is set in the DSISR is bit 62 or 61 respectively and the remainder of this paragraph does not apply. Otherwise, if multiple Data Storage exceptions occur for a given effective address, any one or more of the bits corresponding to these exceptions may be set to 1 in the DSISR. However, if one or more Data Storage exceptions are to be reported together with a VirtualPage Class Key Storage Protection exception that occurs when the thread is not in hypervisor state ( $MSR_{HV\_PR} \neq 0b10$ ),  $LPCR_{KBV}=1$ , and Virtualized Partition Memory is disabled by  $VPM=0$ , an HDSI results, and all of the exceptions are reported in the HDSISR.

Execution resumes at effective address  $0x0000\_0000\_0000\_0300$ , possibly offset as specified in Figure 70.

## 7.5.4 Data Segment Interrupt

For Paravirtualized HPT Translation, a Data Segment interrupt occurs when no higher priority exception exists and a data access cannot be performed because data address translation is enabled and the effective address of any byte of the storage location specified by a *Load* or *Store* instruction, or by an instruction that is treated as a *Load* or *Store* other than a *Cache Block Touch* instruction, cannot be translated to a virtual address because the SLB search fails and, if  $UPRT=1$ , the Segment Table search fails after the STEG has been accessed.

For Radix Tree Translation, a Data Segment interrupt occurs when no higher priority exception exists and a data access cannot be performed because for the effective address specified by a *Load* or *Store* instruction, or by an instruction that is treated as a *Load* or *Store* other than a *Cache Block Touch* instruction, one of the following conditions is satisfied.

- Data address translation is enabled and  $EA_{0:1}=0b01$  or  $0b10$  when  $MSR_{HV\_PR} \neq 0b10$ .
- Data address translation is enabled and  $EA_{0:1}=0b11$  when  $MSR_{PR}=1$ .
- Data address translation is enabled and  $EA_{0:1}=0b00$  when  $MSR_{HV\_PR}=0b10$  and  $LPIDR \neq 0$ .
- $EA_{2:63}$  is outside the range translated by the appropriate Radix Tree.

If a *stbcx.*, *sthcx.*, *stwcx.*, *stdcx.*, or *stqcx.* would not perform its store in the absence of a Data Segment interrupt and a non-conditional *Store* to the specified effective address would cause a Data Segment interrupt, it is implementation-dependent whether a Data Segment interrupt occurs.

If the XER specifies a length of zero for an indexed *Move Assist* instruction, a Data Segment interrupt does not occur.

The following registers are set:

**SRR0** Set to the effective address of the instruction that caused the interrupt.

### SRR1

- 33** Set to 0.
- 34** Set to 0 if the instruction that caused the interrupt is a word instruction and to 1 if the instruction that caused the interrupt is a prefixed instruction.
- 35:36** Set to 0.
- 42:47** Set to 0.
- Others** Loaded from the MSR.

**MSR** See Figure 69.

**DSISR** Set to an undefined value.

**DAR** Set to the effective address of a storage element as described in the following list.

- a byte in the block that caused the exception, for a *Cache Management* instruction
- a byte in the first aligned doubleword for which access was attempted in the segment that caused the exception, for a *Load* or *Store* instruction, or for an instruction that is treated as a *Load* or *Store* other than a *Cache Management* instruction (“first” refers to address order: see Section 7.7).

If the interrupt occurs in 32-bit mode the high-order 32 bits of the DAR are set to 0.

Execution resumes at effective address  $0x0000\_0000\_0000\_0380$ , possibly offset as specified in Figure 70.

#### Programming Note

A Data Segment interrupt occurs if  $MSR_{DR}=1$  and the translation of the effective address of any byte of the specified storage location is not found in the SLB (or in any implementation-specific address translation lookaside information).

## 7.5.5 Instruction Storage Interrupt (ISI)

An Instruction Storage interrupt occurs when no higher priority exception exists and the next instruction to be executed cannot be fetched for any of the reasons listed below, under the conditions described immediately below.

In general, an Instruction Storage interrupt can occur only under the following conditions.

- The value of the expression  $(MSR_{HV\_PR}=0b10) \& (MSR_{IR}=0)$  is 1.
- $HR=0$ ,  $MSR_{IR}=1$ , and the value of the expression  $(MSR_{HV\_PR}=0b10) \mid \neg VPM$  is 1.

- HR=1, MSR<sub>IR</sub>=1, and either of the following prevents the next instruction to be executed from being fetched.
  - process-scoped translation
  - partition-scoped translation for the Process Table Entry when effLPID=0

The exceptions to the preceding general statement are as follows.

- If HR=0 and MSR<sub>HV PR</sub>≠0b10, a security violation in accessing the PTEG during address translation causes a Hypervisor Instruction Storage interrupt regardless of the rest of the translation state.
- If HR=0, MSR<sub>IR</sub>=1, and an invalid Process Table Entry stops the translation process, an Instruction Storage interrupt occurs regardless of the rest of the translation state. (This can happen only when UPRT=1, the needed translation is not found in the SLB, and either MSR<sub>HV</sub>=0 or LPID=0.)
- If HR=1, MSR<sub>IR</sub>=1, effLPID=0, and either (a) an unsupported radix tree configuration is found in the Partition Table Entry, or (b) the effective address of the Process Table Entry cannot be translated to a host real address because no valid PTE is found that translates the effective address, a Hypervisor Instruction Storage interrupt occurs regardless of the rest of the translation state.
- If the instruction is a prefixed instruction and is in storage that is Caching Inhibited, attempting to fetch it causes an Instruction Storage interrupt regardless of the rest of the translation state.

Under the conditions described above, an Instruction Storage interrupt may occur for any of the following reasons.

- The effective or virtual address of the next instruction to be executed cannot be translated to a host real address (HR=0; or HR=1 and effLPID=0) or to a guest real address (HR=1 and effLPID≠0) because no valid PTE was found that translates the effective or virtual address.
- HR=0 and either (a) the virtual address of the Process Table Entry or Segment Table Entry Group cannot be translated because no valid PTE was found that translates the virtual address, or (b) the Process Table Entry is invalid.
- HR=1 and a Reference bit update cannot be performed atomically in the process-scoped PTE, or in the partition-scoped PTE if effLPID=0.
- The instruction is a prefixed instruction and is in storage that is Caching Inhibited.
- The access violates Basic Storage Protection.
- The access violates Virtual Page Class Key Storage Protection.
- The access violates Radix Tree Translation Storage Protection.
- The access violates Secure Memory Protection.

#### Programming Note

A storage protection violation may be for the instruction fetch or for an associated implicit access to a table entry, other than the PATE, during address translation or when updating Reference bits. (“Table entry” here includes STEGs, PTEGs, and PDEs. For instructions and table entries for which the host real address is not the result of address translation, the only possible storage protection violation is a Secure Memory Protection violation.) Note that when nested Radix Tree Translation is being performed, a violation of Radix Tree Translation Storage Protection causes an ISI when the process-scoped access authority does not permit the access, regardless of whether the partition-scoped access authority permits it.

- The process- and partition-scoped page attributes (ATT values) conflict.

#### Programming Note

The only case of such conflict is the attribute mismatch in which the process-scoped PTE specifies I=0 and the partition-scoped PTE specifies I=1.

- An unsupported radix tree configuration is found in the Process Table Entry, in the process-scoped tables, or, if effLPID=0, in the partition-scoped tables. (Note that this condition may not be detected until the associated values are about to cause a functional problem for the processor.)

The following registers are set:

- SRR0** Set to the effective address of the instruction that the thread would have attempted to execute next if no interrupt conditions were present (if the interrupt occurs on attempting to fetch a branch target, SRR0 is set to the branch target address).
- SRR1**
- |           |   |
|-----------|---|
| <b>33</b> | Set to 1 if the translation for an attempted access is not found in the Page Table; otherwise set to 0.   |
| <b>34</b> | Set to 1 if the process- and partition-scoped page attributes conflict; otherwise set to 0.   |
| <b>35</b> | Set to 1 if the access is to No-execute (as indicated by the N bit in the Segment Table Entry or the N bit in the HPT PTE or the Execute and Privilege bits in the EAA field of the Radix PTE and IAMR key 0) or Guarded storage, or is to Caching Inhibited storage and is for a prefixed instruction; otherwise set to 0. |
| <b>36</b> | Set to 1 if the access is not permitted by Figure 47 or the Privilege or Execute bits in  |

- Figure 48 as appropriate; otherwise set to 0.
- 42** Set to 1 if the access is not permitted by Virtual Page Class Key Protection; otherwise set to 0.
- 43** Set to 1 if the access is not permitted by Secure Memory Protection; otherwise set to 0.
- 44** Set to 1 if an unsupported radix tree configuration is found during the translation process; otherwise set to 0.
- 45** Set to 1 if an attempt to atomically set a Reference bit fails; otherwise set to 0.

#### Programming Note

The number of attempts hardware makes to atomically set Reference and Change bits before triggering this exception is implementation dependent. For example, the POWER9 processor makes no attempt. Software may still support the atomic update programming model to get performance benefits such as those described in Section 6.7.12.

- 46** Set to 1 if the address of the appropriate Process Table Entry or Segment Table Entry Group cannot be translated, or the Process Table Entry is invalid.
- 47** Set to 0.
- Others** Loaded from the MSR.

**MSR** See Figure 69.

If multiple Instruction Storage exceptions occur due to attempting to fetch a single instruction, any one or more of the bits corresponding to these exceptions may be set to 1 in SRR1.

Execution resumes at effective address 0x0000\_0000\_0000\_0400, possibly offset as specified in Figure 70.

## 7.5.6 Instruction Segment Interrupt

For Paravirtualized HPT Translation, an Instruction Segment interrupt occurs when no higher priority exception exists and the next instruction to be executed cannot be fetched because instruction address translation is enabled and the effective address cannot be translated to a virtual address because the SLB search fails and, if UPRT=1, the Segment Table search fails after the STEG has been accessed.

For Radix Tree Translation, an Instruction Segment interrupt occurs when no higher priority exception exists and the next instruction to be executed cannot

be fetched because one of the following conditions is satisfied.

- Instruction address translation is enabled and  $EA_{0:1}=0b01$  or  $0b10$  when  $MSR_{HVPR} \neq 0b10$ .
- Instruction address translation is enabled and  $EA_{0:1}=0b11$  when  $MSR_{PR}=1$ .
- Instruction address translation is enabled and  $EA_{0:1}=0b00$  when  $MSR_{HVPR}=0b10$  and  $LPIDR \neq 0$ .
- $EA_{2:63}$  is outside the range translated by the appropriate Radix Tree.

The following registers are set:

**SRR0** Set to the effective address of the instruction that the thread would have attempted to execute next if no interrupt conditions were present (if the interrupt occurs on attempting to fetch a branch target, SRR0 is set to the branch target address).

**SRR1**

**33:36** Set to 0.

**42:47** Set to 0.

**Others** Loaded from the MSR.

**MSR** See Figure 69 on page 1275.

Execution resumes at effective address 0x0000\_0000\_0000\_0480, possibly offset as specified in Figure 70.

#### Programming Note

An Instruction Segment interrupt occurs if  $MSR_{IR}=1$  and the translation of the effective address of the next instruction to be executed is not found in the SLB (or in any implementation-specific address translation lookaside information).

## 7.5.7 External Interrupt

An External interrupt is classified as being either a Direct External interrupt or a Mediated External interrupt. Throughout this Book, usage of the phrase “External interrupt”, without further classification, refers to both a Direct External interrupt and a Mediated External interrupt.

### 7.5.7.1 Direct External Interrupt

A Direct External interrupt occurs when no higher priority exception exists, a Direct External exception exists, and the value of the expression

$$MSR_{EE} \& \neg(MSR_{HV} \& \neg MSR_{PR} \& LPCR_{HEIC}) \mid (\neg(LPES) \& (\neg(MSR_{HV}) \mid MSR_{PR}))$$

is one. The occurrence of the interrupt does not cause the exception to cease to exist.

**Programming Note**

When HEIC=1, Direct External exceptions will not result in external interrupts when the processor is in hypervisor state even if  $MSR_{EE}=1$ . This enables the Hypervisor Virtualization interrupt handler to prevent External interrupts from occurring during the Hypervisor Virtualization interrupt handler.

When LPES=0, the following registers are set:

**HSRR0** Set to the effective address of the instruction that the thread would have attempted to execute next if no interrupt conditions were present.

**HSRR1**

**33:36** Set to 0.

**42:47** Set to 0.

**Others** Loaded from the MSR.

**MSR** See Figure 69 on page 1275.

When LPES=1, the following registers are set:

**SRR0** Set to the effective address of the instruction that the thread would have attempted to execute next if no interrupt conditions were present.

**SRR1**

**33:36** Set to 0.

**42:47** Set to 0.

**Others** Loaded from the MSR.

**MSR** See Figure 69 on page 1275.

Execution resumes at effective address 0x0000\_0000\_0000\_0500, possibly offset as specified in Figure 70.

**Programming Note**

Because the value of  $MSR_{EE}$  is always 1 when the thread is in problem state, the simpler expression

$$MSR_{EE} \& \neg(MSR_{HV} \& \neg MSR_{PR} \& LPCR_{HEIC}) \mid \neg(LPES \mid MSR_{HV})$$

is equivalent to the expression given above.

**Programming Note**

The Direct External exception has the same meaning as the External exception in versions of the architecture prior to Version 2.05.

**7.5.7.2 Mediated External Interrupt**

A Mediated External interrupt occurs when no higher priority exception exists, a Mediated External exception exists (see the definition of  $LPCR_{MER}$  in Section 2.2), and the value of the expression

$$MSR_{EE} \& (\neg(MSR_{HV}) \mid MSR_{PR})$$

is one. The occurrence of the interrupt does not cause the exception to cease to exist.

When LPES=0, the following registers are set:

**HSRR0** Set to the effective address of the instruction that the thread would have attempted to execute next if no interrupt conditions were present.

**HSRR1**

**33:36** Set to 0.

**42** Set to 1.

**43:47** Set to 0.

**Others** Loaded from the MSR.

**MSR** See Figure 69 on page 1275.

When LPES=1, the following registers are set:

**SRR0** Set to the effective address of the instruction that the thread would have attempted to execute next if no interrupt conditions were present.

**SRR1**

**33:36** Set to 0.

**42:47** Set to 0.

**Others** Loaded from the MSR.

**MSR** See Figure 69 on page 1275.

Execution resumes at effective address 0x0000\_0000\_0000\_0500, possibly offset as specified in Figure 70.

**7.5.8 Alignment Interrupt**

Most causes of Alignment interrupt involve storage operands, and many of those causes involve the alignment thereof. Storage operand alignment is defined in Section 1.10.1 of Book I. Another cause of Alignment interrupt is attempt to execute a prefixed instruction that crosses a 64-byte address boundary.

An Alignment interrupt occurs when no higher priority exception exists and an attempt is made to execute an instruction in a manner that is required, by the instruction description, to cause an Alignment interrupt, or to execute a prefixed instruction that crosses a 64-byte boundary. These cases are as follows.

- A *Load/Store Multiple* instruction that is executed in Little-Endian mode
- A *Move Assist* instruction that is executed in Little-Endian mode, unless the string length is zero
- A *copy, paste., lwat, ldat, lharx, lwarx, ldarx, lqarx, stwat, stdat, sthcx., stwcx., stdcx., or stqcx., hashst, hashchk, hashstp* or *hashchkp* instruction that has an unaligned storage operand, unless execution of the instruction yields bounded undefined results

- The operand(s) of a *Load Atomic* or *Store Atomic* instruction cross(es) a 32-byte boundary.
- A prefixed instruction that is at an effective address equal to 60 modulo 64.

An Alignment interrupt may occur when no higher priority exception exists and a data access cannot be performed for any of the following reasons.

- The storage operand of *lfdp*, *lfdpx*, *stfdp*, *stfdpx*, *lxsihzx*, or *stxsihx* is unaligned.
- The storage operand of *lq* or *stq* is unaligned.
- The storage operand of a Floating-Point *Storage Access* or *VSX Storage Access* instruction other than *lfdp*, *lfdpx*, *stfdp*, *stfdpx*, *lxsihzx*, *lxsibzx*, *stxsihx*, or *stxsibx* is not word-aligned.
- The storage operand of a *Load/Store Multiple* instruction is not aligned and the thread is in Big-Endian mode.
- The storage operand of a *Load/Store Multiple*, *lfdp*, *lfdpx*, *lxvl*, *lxvll*, *stfdp*, *stfdpx*, *stxvl*, *stxvll*, or *dcbz* instruction is in storage that is Write Through Required or Caching Inhibited. The storage operand of a *Move Assist* instruction is in storage that is Write Through Required or Caching Inhibited and has length greater than zero.
- The storage operand of a *Load* or *Store* instruction is unaligned and is in storage that is Write Through Required or Caching Inhibited.
- The storage operand of a *Storage Access* instruction crosses a segment boundary, or crosses a boundary between virtual pages that have different storage control attributes.

The following registers are set:

<b>SRR0</b>	Set to the effective address of the instruction that caused the interrupt.
<b>SRR1</b>	
<b>33</b>	Set to 0.
<b>34</b>	Set to 0 if the instruction that caused the interrupt is a word instruction and to 1 if the instruction that caused the interrupt is a prefixed instruction.
<b>35</b>	Set to 1 if the instruction that caused the interrupt is a prefixed instruction that is at an effective address equal to 60 modulo 64; otherwise set to 0.
<b>36</b>	Set to 0.
<b>42:47</b>	Set to 0.
<b>Others</b>	Loaded from the MSR.
<b>MSR</b>	See Figure 69.
<b>DAR</b>	Set to the effective address computed by the instruction, unless the instruction is a prefixed instruction at an effective address equal to 60 modulo 64, in which case set to an undefined value except as described in the next sentence. If the interrupt occurs in 32-bit mode the high-order 32 bits of the DAR are set to 0.

Execution resumes at effective address 0x0000\_0000\_0000\_0600, possibly offset as specified in Figure 70.

#### Programming Note

If an Alignment interrupt occurs for a case in the second bulleted list above, the Alignment interrupt handler should emulate the instruction. The emulation must satisfy the atomicity requirements described in Section 1.4 of Book II.

If an Alignment interrupt occurs for a case in the first bulleted list above, the Alignment interrupt handler must not attempt to emulate the instruction, but instead should treat the instruction as a programming error.

## 7.5.9 Program Interrupt

A Program interrupt occurs when no higher priority exception exists and one of the following exceptions arises during execution of an instruction:

#### Floating-Point Enabled Exception

A Floating-Point Enabled Exception type Program interrupt is generated when the value of the expression

$$(\text{MSR}_{\text{FE0}} \mid \text{MSR}_{\text{FE1}}) \& \text{FPSCR}_{\text{FEX}}$$

is 1.  $\text{FPSCR}_{\text{FEX}}$  is set to 1 by the execution of a floating-point instruction that causes an enabled exception, including the case of a *Move To FPSCR* instruction that causes an exception bit and the corresponding enable bit both to be 1.

#### Privileged Instruction

The following applies if the instruction is executed when  $\text{MSR}_{\text{PR}} = 1$ .

A Privileged Instruction type Program interrupt is generated when execution is attempted of a privileged instruction, or of an *mtspr* or *mfspr* instruction with an SPR field that contains a value having  $\text{spr}_0 = 1$ .

The following applies if the instruction is executed when  $\text{MSR}_{\text{HV PR}} = 0\text{b}00$  and  $\text{LPCR}_{\text{EVIRT}} = 0$ .

A Privileged Instruction type Program interrupt is generated when execution is attempted of a hypervisor privileged instruction, or of an *mtspr* or *mfspr* instruction that specifies an SPR that is hypervisor privileged for the operation or that specifies  $\text{PTCR}$ ,  $\text{DAWR}_n$ ,  $\text{DAWRX}_n$ , or  $\text{CIABR}$  when those SPRs are ultravisor privileged for the operation.

The following applies if the instruction is executed when  $\text{MSR}_{\text{HV PR}} = 0\text{b}00$  or when  $\text{MSR}_{\text{S HV PR}} = 0\text{b}010$ .

A Privileged Instruction type Program interrupt is generated when execution is attempted of an ultravisor privileged instruction, or of an *mtspr* or *mfspr* instruction that specifies an SPR, other than PTCR, DAWRn, DAWRXn, and CIABR, that is ultravisor privileged for the operation.

#### Programming Note

These are the only cases in which a Privileged Instruction type Program interrupt can be generated when  $MSR_{PR}=0$ . They can be distinguished from other causes of Privileged Instruction type Program interrupts by examining  $SRR1_{49}$  (the bit in which  $MSR_{PR}$  was saved by the interrupt).

#### Trap

A Trap type Program interrupt is generated when any of the conditions specified in a *Trap* instruction is met, or when the two values compared by a *hashchk* or *hashchkp* instruction are unequal.

The following registers are set:

**SRR0** For all Program interrupts except a Floating-Point Enabled Exception type Program interrupt, set to the effective address of the instruction that caused the corresponding exception.

For a Floating-Point Enabled Exception type Program interrupt, set as described in the following list.

- If  $MSR_{FE0\ FE1} = 0b00$ ,  $FPSCR_{FEX} = 1$ , and an instruction is executed that changes  $MSR_{FE0\ FE1}$  to a nonzero value, set to the effective address of the instruction that the thread would have attempted to execute next if no interrupt conditions were present.

#### Programming Note

Recall that all instructions that can alter  $MSR_{FE0\ FE1}$  are context synchronizing, and therefore are not initiated until all preceding instructions have reported all exceptions they will cause.

- If  $MSR_{FE0\ FE1} = 0b11$ , set to the effective address of the instruction that caused the Floating-Point Enabled Exception.
- If  $MSR_{FE0\ FE1} = 0b01$  or  $0b10$ , set to the effective address of the first instruction that caused a Floating-Point Enabled Exception since the most recent time

$FPSCR_{FEX}$  was changed from 1 to 0 or of some subsequent instruction.

#### Programming Note

If  $SRR0$  is set to the effective address of a subsequent instruction, that instruction will not be beyond the first such instruction at which synchronization of floating-point instructions occurs. (Recall that such synchronization is caused by *Floating-Point Status and Control Register* instructions, as well as by execution synchronizing instructions and events.)

#### SRR1

**33**

Set to 0.

**34**

Except for the cases in which  $SRR0$  is not necessarily set to the effective address of the instruction that caused the exception (first and third bullets in the description of how  $SRR0$  is set), set to 0 if the instruction that caused the interrupt is a word instruction and to 1 if the instruction that caused the interrupt is a prefixed instruction; for the cases in which  $SRR0$  is not necessarily set to the effective address of the instruction that caused the exception, set to an undefined value.

**35:36**

Set to 0.

**42**

Set to 0.

**43**

Set to 1 for a Floating-Point Enabled Exception type Program interrupt; otherwise set to 0.

**44**

Set to 0.

#### Programming Note

Bit 44 will not be assigned a meaning. In versions of the architecture that precede Version 2.05 this bit was set to 1 (and bits 42:43 and 45:46 were set to 0) to indicate that an "Illegal Instruction type Program interrupt" had occurred. Hypervisors may set this bit to 1 as part of simulating an Illegal Instruction type Program interrupt to the operating system, as described in a subsequent Programming Note.

**45**

Set to 1 for a Privileged Instruction type Program interrupt; otherwise set to 0.

**46**

Set to 1 for a Trap type Program interrupt; otherwise set to 0.

**47**

Set to 0 if  $SRR0$  contains the address of the instruction causing the exception and there is only one such instruction; otherwise set to 1.

**Programming Note**

SRR1<sub>47</sub> can be set to 1 only if the exception is a Floating-Point Enabled Exception and either MSR<sub>FE0 FE1</sub> = 0b01 or 0b10 or MSR<sub>FE0 FE1</sub> has just been changed from 0b00 to a nonzero value. (SRR1<sub>47</sub> is always set to 1 in the last case.)

**Others** Loaded from the MSR.

Exactly one of bits 43, 45, and 46 is set to 1.

**MSR** See Figure 69 on page 1275.

Execution resumes at effective address 0x0000\_0000\_0000\_0700, possibly offset as specified in Figure 70.

**Programming Note**

In versions of the architecture that precede V. 2.05, the conditions that now cause a Hypervisor Emulation Assistance interrupt with HSRR1<sub>45</sub>=0 instead caused an “Illegal Instruction type Program interrupt”. This was a Program interrupt for which registers (SRR0, SRR1, and the MSR) were set as described above for the Privileged Instruction type Program interrupt, except that SRR1<sub>44</sub> was set to 1 and SRR1<sub>45</sub> was set to 0. Thus older operating systems have code to handle these conditions, at the Program interrupt vector location. For this reason, if a Hypervisor Emulation Assistance interrupt occurs with HSRR1<sub>45</sub>=0 when the thread is not in hypervisor state, for an instruction that the hypervisor determines should be handled by the operating system, the hypervisor is expected to pass control to the operating system at the operating system’s Program interrupt vector location, with all registers (SRR0, SRR1, MSR, GPRs, etc.) set as if the instruction had caused a Privileged Instruction type Program interrupt, except with SRR1<sub>44:45</sub> set to 0b10. (The Hypervisor Emulation Assistance interrupt was added to the architecture in V. 2.05, and the Illegal Instruction type Program interrupt was removed from the architecture in V. 2.06. In V. 2.05 the Hypervisor Emulation Assistance interrupt was optional: implementations that supported it generated it as described in V. 2.06, and never generated an Illegal Instruction type Program interrupt; implementations that did not support it generated an Illegal Instruction type Program interrupt as described above.)

**Programming Note**

When LPCR<sub>EVRT</sub>=1, some of the conditions that cause a Privileged Instruction type Program interrupt when LPCR<sub>EVRT</sub>=0 (attempted execution, in privileged but non-hypervisor state, of a hypervisor privileged instruction or of an *mtspr* or *mfspr* instruction specifying an SPR that is hypervisor privileged for the operation or PTCR, DAWRn, DAWRXn, or CIABR when they are ultravisor privileged for the operation) instead cause a Hypervisor Emulation Assistance interrupt with HSRR1<sub>45</sub>=1. Having these conditions cause a Hypervisor Emulation Assistance interrupt permits support of nested hypervisors through virtualization of hypervisor resources, and simplifies creation of a common kernel for the OS and the hypervisor. In versions of the architecture that precede V. 3.0, LPCR<sub>EVRT</sub> did not exist and these conditions always caused a Privileged Instruction type Program interrupt. Thus older operating systems have code to handle these conditions, at the Program interrupt vector location. For this reason, if a Hypervisor Emulation Assistance interrupt occurs with HSRR1<sub>45</sub>=1 for an instruction that the hypervisor determines should be handled by the operating system, the hypervisor is expected to pass control to the operating system at the operating system’s Program interrupt vector location, with all registers (SRR0, SRR1, MSR, GPRs, etc.) set as if the instruction had caused a Privileged Instruction type Program interrupt.

## 7.5.10 Floating-Point Unavailable Interrupt

A Floating-Point Unavailable interrupt occurs when no higher priority exception exists, an attempt is made to execute a floating-point instruction (including floating-point loads, stores, and moves), and MSR<sub>FP</sub>=0.

The following registers are set:

**SRR0** Set to the effective address of the instruction that caused the interrupt.

**SRR1**

**33** Set to 0.

**34** Set to 0 if the instruction that caused the interrupt is a word instruction and to 1 if the instruction that caused the interrupt is a prefixed instruction.

**35:36** Set to 0.

**42:47** Set to 0.

**Others** Loaded from the MSR.

**MSR** See Figure 69 on page 1275.

Execution resumes at effective address 0x0000\_0000\_0000\_0800, possibly offset as specified in Figure 70.

### 7.5.11 Decrementer Interrupt

A Decrementer interrupt occurs when no higher priority exception exists, a Decrementer exception exists, and  $MSR_{EE}=1$ .

The following registers are set:

**SRR0** Set to the effective address of the instruction that the thread would have attempted to execute next if no interrupt conditions were present.

**SRR1**

**33:36** Set to 0.

**42:47** Set to 0.

**Others** Loaded from the MSR.

**MSR** See Figure 69 on page 1275.

Execution resumes at effective address 0x0000\_0000\_0000\_0900, possibly offset as specified in Figure 70.

### 7.5.12 Hypervisor Decrementer Interrupt

A Hypervisor Decrementer interrupt occurs when no higher priority exception exists, a Hypervisor Decrementer exception exists, and the value of the following expression is 1.

$(MSR_{EE} | \neg(MSR_{HV}) | MSR_{PR}) \& HDICE$

The following registers are set:

**HSRR0** Set to the effective address of the instruction that the thread would have attempted to execute next if no interrupt conditions were present.

**HSRR1**

**33:36** Set to 0.

**42:47** Set to 0.

**Others** Loaded from the MSR.

**MSR** See Figure 69 on page 1275.

Execution resumes at effective address 0x0000\_0000\_0000\_0980, possibly offset as specified in Figure 70.

#### Programming Note

Because the value of  $MSR_{EE}$  is always 1 when the thread is in problem state, the simpler expression

$(MSR_{EE} | \neg(MSR_{HV})) \& HDICE$

is equivalent to the expression given above.

### 7.5.13 Directed Privileged Doorbell Interrupt

A Directed Privileged Doorbell interrupt occurs when no higher priority exception exists, a Directed Privileged Doorbell exception is present, and  $MSR_{EE}=1$ . Directed Privileged Doorbell exceptions are generated when Directed Privileged Doorbell messages (see Chapter 12) are received and accepted by the thread.

The following registers are set:

**SRR0** Set to the effective address of the instruction that the thread would have attempted to execute next if no interrupt conditions were present.

**SRR1**

**33:36** Set to 0.

**42:47** Set to 0.

**Others** Loaded from the MSR.

**MSR** See Figure 69 on page 1275.

Execution resumes at effective address 0x0000\_0000\_0000\_0A00, possibly offset as specified in Figure 70.

### 7.5.14 System Call Interrupt

A System Call interrupt occurs when a *System Call* instruction is executed.

The following registers are set:

**SRR0** Set to the effective address of the instruction following the System Call instruction.

**SRR1**

**33:36** Set to 0.

**42:43** Set to indicate the LEV value specified by the *System Call* instruction that caused the interrupt, as follows.

LEV	SRR1 <sub>42:43</sub>
0	00
1	01
2	10
3*	undefined
* reserved LEV value	

**44:47** Set to 0.

**Others** Loaded from the MSR.

**MSR** See Figure 69 on page 1275.

Execution resumes at effective address 0x0000\_0000\_0000\_0C00, possibly offset as specified in Figure 70.

**Programming Note**

An attempt to execute an **sc** instruction with LEV=1 or LEV=2 in problem state, or an attempt to execute an **sc** instruction with LEV=2 in privileged non-hypervisor state, should be treated as a programming error.

An attempt to execute an **sc** instruction with LEV=2 when SMFCTRL<sub>E</sub>=0 should be treated as a programming error.

## 7.5.15 Trace Interrupt

A Trace interrupt occurs when no higher priority exception exists and any instruction except **rfd**, **hrfid**, **urfid**, **rfscv**, or a *Power-Saving Mode* instruction is successfully completed, provided any of the following is true:

- the instruction is **mtmsr[d]** and MSR<sub>TE</sub>=0b10 when the instruction was initiated,
- the instruction is not **mtmsr[d]** and MSR<sub>TE</sub>=0b10,
- the instruction is a *Branch* instruction and MSR<sub>TE</sub>=0b01, or
- a CIABR match occurs.

Successful completion for an instruction means that the instruction caused no other interrupt. Thus a Trace interrupt never occurs for a *System Call* or *System Call Vectored* instruction, or for a *Trap* instruction that traps. The instruction that causes a Trace interrupt is called the “traced instruction”.

The following registers are set:

<b>SRR0</b>	Set to the effective address of the instruction that the thread would have attempted to execute next if no interrupt conditions were present.
<b>SRR1</b>	
<b>33</b>	Set to 1.
<b>34</b>	Set to 0 if the traced instruction is a word instruction and to 1 if the traced instruction is a prefixed instruction.
<b>35</b>	Set to 1 if the the Trace interrupt is not the result of a CIABR match and the traced instruction is a <i>Load</i> instruction other than a <i>Load String</i> instruction with string length of 0 or is specified to be treated as a <i>Load</i> instruction; otherwise set to 0.
<b>36</b>	Set to 1 if the the Trace interrupt is not the result of a CIABR match and the traced instruction is a <i>Store</i> instruction other than a <i>Store String</i> instruction with string length of 0 or is specified to be treated as a <i>Store</i> instruction; otherwise set to 0.
<b>42</b>	Set to 0.

<b>43</b>	Set to 1 if the Trace interrupt is the result of a CIABR match.
<b>44:47</b>	Set to 0.
<b>Others</b>	Loaded from the MSR.

**Programming Note**

Bit 33 is set to 1 for historical reasons.

**SIAR** For all Trace interrupts other than those caused by a CIABR match, set to the effective address of the traced instruction; for Trace interrupts caused by a CIABR match, not modified if MSR<sub>TE</sub>=0b00; otherwise undefined.

**SDAR** For all Trace interrupts other than those caused by a CIABR match, set to the effective address of the storage operand (if any) of the traced instruction; for Trace interrupts caused by a CIABR match, not modified if MSR<sub>TE</sub>=0b00; otherwise undefined.

If the state of the Performance Monitor is such that the Performance Monitor may be altering the SIAR and SDAR (i.e., if MMCR0<sub>PMAE</sub>=1), the contents of the SIAR and SDAR are undefined for the Trace interrupt and may change even when no Trace interrupt occurs.

**MSR** See Figure 69 on page 1275.

Execution resumes at effective address 0x0000\_0000\_0000\_0D00, possibly offset as specified in Figure 70. For a Trace interrupt resulting from execution of an instruction that modifies the value of MSR<sub>IR</sub>, MSR<sub>DR</sub>, MSR<sub>HV</sub>, LPCR<sub>AIL</sub>, or LPCR<sub>HAIL</sub>, the Trace interrupt vector location is based on the modified values.

**Programming Note**

The following instructions are not traced.

- **rfd**
- **hrfid**
- **urfid**
- **rfscv**
- **sc**, **scv**, and *Trap* instructions that trap
- *Power-Saving Mode* instructions
- other instructions that cause interrupts (other than Trace interrupts)
- the first instructions of any interrupt handler (applies to Branch and Single Step tracing; CIABR matches may still occur)
- instructions that are emulated by software

In general, interrupt handlers can achieve the effect of tracing these instructions.

**Programming Note**

If a *wait* instruction is executed when  $MSR_{TE}=0b10$  or when the instruction causes a CIABR match, a Trace interrupt occurs immediately, with no suspension of instruction fetching or execution. (Architecturally, the suspension of instruction fetching and execution begins but is terminated immediately by the Trace interrupt.)

## 7.5.16 Hypervisor Data Storage Interrupt (HDSI)

A Hypervisor Data Storage interrupt occurs when no higher priority exception exists and a data access cannot be performed for any of the reasons listed below, under the conditions described immediately below.

In general, a Hypervisor Data Storage interrupt can occur only under the following conditions.

- $HR=0$ ,  $MSR_{HV\_PR}\neq 0b10$ , and the value of the expression  $(\neg MSR_{DR}) \mid VPM$  is 1.
- $HR=1$  and partition-scoped translation, other than for the Process Table Entry when  $effLPID=0$ , prevents the data access from being performed.

The exceptions to the preceding general statement are as follows.

- If  $HR=0$  and  $MSR_{HV\_PR}\neq 0b10$ , a security violation in accessing the PTEG during address translation causes a Hypervisor Data Storage interrupt regardless of the rest of the translation state.
- If  $MSR_{HV\_PR}\neq 0b10$  or  $MSR_{DR}=1$ , a translation mode mismatch causes a Hypervisor Data Storage interrupt regardless of the rest of the translation state.
- If  $HR=0$ ,  $MSR_{HV\_PR}\neq 0b10$ ,  $MSR_{DR}=1$ ,  $VPM=0$ , and  $LPCR_{KBV}=1$ , a Virtual Page Class Key Storage Protection exception causes a Hypervisor Data Storage interrupt, with HDSISR set according to the bit definitions for DSISR as set by a Data Storage interrupt, as described in more detail below.
- If  $HR=1$ ,  $MSR_{DR}=1$ ,  $effLPID=0$ , and either (a) an unsupported radix tree configuration is found in the Partition Table Entry, or (b) the effective address of the Process Table Entry cannot be translated to a host real address because no valid PTE is found that translates the effective address, a Hypervisor Data Storage interrupt occurs regardless of the rest of the translation state.
- If  $HR=1$  and either  $MSR_{HV\_PR}\neq 0b10$  or  $MSR_{DR}=1$ , any of the following causes a Data Storage interrupt regardless of the rest of the translation state.
  - a Data Address Watchpoint match
  - an attempt to execute an AMO with a reserved function code

- an attempt to copy from control memory, or to paste to control memory that is not properly configured

Under the conditions described above, a Hypervisor Data Storage interrupt may occur for any of the following reasons.

- The virtual or guest real address of any byte of the storage location specified by a *Load* or *Store* instruction, or by an instruction that is treated as a *Load* or *Store* other than a *Cache Block Touch* instruction, cannot be translated to a host real address because no valid PTE was found that translates the virtual or guest real address.
- $HR=0$  and the virtual address of the Process Table Entry or Segment Table Entry Group cannot be translated because no valid PTE was found that translates the virtual address; or  $HR=1$  and the effective address of the Process Table Entry ( $effLPID=0$ ), or the guest real address of the Process Table Entry, a Page Directory Entry, or the Page Table Entry ( $effLPID\neq 0$ ), cannot be translated because no valid PTE was found that translates the effective or guest real address.
- $HR=1$  and a Reference or Change bit update cannot be performed atomically in a partition-scoped PTE (including for the Process Table Entry, process-scoped PDE, or process-scoped PTE for a radix guest).
- The effective address specified by a *lq*, *stq*, *lwat*, *ldat*, *lbarx*, *lharx*, *lwarx*, *ldarx*, *lqarx*, *stwat*, *stdat*, *stbcx*, *sthcx*, *stwcx*, *stdcx*, or *stqcx* instruction refers to storage that is Write Through Required or Caching Inhibited; or the effective address specified by a *copy* or *paste* instruction refers to storage that is Caching Inhibited; or the effective address specified by a *lwat*, *ldat*, *stwat*, or *stdat* instruction refers to storage that is Guarded.

**Programming Note**

When nested Radix Tree translation is used to translate the effective address, these combinations of instruction and storage control attribute never cause a Hypervisor Data Storage interrupt (see Section 6.7.10.3 of Book III).

- Control memory is specified as the source of a *copy* instruction or an attempt is made to paste to control memory that is not properly configured.
- The access violates Basic Storage Protection.
- The access violates Virtual Page Class Key Storage Protection.
- The access violates Radix Tree Translation Storage Protection.
- The access violates Secure Memory Protection.

**Programming Note**

A storage protection violation may be for the data access or for an associated implicit access to a table entry, other than the PATE, during address translation or when updating Reference and Change bits. (“Table entry” here includes STEGs, PTEGs, and PDEs. For data and table entries for which the host real address is not the result of address translation, the only possible storage protection violation is a Secure Memory Protection violation.) Note that when nested Radix Tree Translation is being performed, a violation of Radix Tree Translation Storage Protection causes an HDSI only when the process-scoped access authority permits the access but the partition-scoped access authority does not.

- Any of the following unsupported MMU configurations is found. (Note that these conditions may not be detected until the associated values are about to cause a functional problem for the processor.)
  - an unsupported radix tree configuration in the Partition Table Entry or in the partition-scoped tables, excluding the Process Table
  - a translation mode mismatch:
    - UPRT=0 when HR=1
    - LPID=0 and MSR<sub>HV</sub>=0 when HR=1
    - HR=0 for LPID=0 when HR=1 for a non-zero LPID
- A Data Address Watchpoint match occurs.
- An attempt is made to execute a *Load Atomic* or *Store Atomic* instruction with a reserved function code.
- 

**Programming Note**

A *Load Atomic* or *Store Atomic* instruction containing a reserved function code (see Figures 3 and 4 in Book II) is an invalid form of the instruction. Attempting to execute such a *Load Atomic* or *Store Atomic* instruction causes an HDSI (or DSI), rather than causing a Hypervisor Emulation Assistance interrupt or yielding boundedly undefined results, to permit the function code to be handled entirely by the memory agent, thereby facilitating the definition of additional function codes in the future if that proves desirable. Consistent with the usual handling of invalid instruction forms, this instance of [H]DSI occurs very early in the execution of the instruction, with the result that [hypervisor] data storage exceptions associated with computing and translating the EA do not occur and Reference and Change bits are not updated.

If a *stbcx.*, *sthcx.*, *stwcx.*, *stdcx.*, or *stqcx.* would not perform its store in the absence of a Hypervisor Data

Storage interrupt, and either (a) the specified effective address refers to storage that is Write Through Required or Caching Inhibited, or (b) a non-conditional *Store* to the specified effective address would cause a Hypervisor Data Storage interrupt, it is implementation-dependent whether a Hypervisor Data Storage interrupt occurs.

If the XER specifies a length of zero for an indexed *Move Assist* instruction, a Hypervisor Data Storage interrupt does not occur.

The following registers are set:

<b>HSRR0</b>	Set to the effective address of the instruction that caused the interrupt.
<b>HSRR1</b>	
<b>33</b>	Set to 0.
<b>34</b>	Set to 0 if the instruction that caused the interrupt is a word instruction and to 1 if the instruction that caused the interrupt is a prefixed instruction.
<b>35:36</b>	Set to 0.
<b>42:47</b>	Set to 0.
<b>Others</b>	Loaded from the MSR.
<b>MSR</b>	See Figure 69.
<b>HDSISR</b>	
<b>32</b>	Set to 0.
<b>33</b>	Set to 1 if the translation for an attempted access is not found in the Page Table; otherwise set to 0.
<b>34:35</b>	Set to 0.
<b>36</b>	Set to 1 if the access is not permitted by Figure 47 or the Read or Read/Write bits in Figure 48 as appropriate; otherwise set to 0.
<b>37</b>	Set to 1 if the access is due to a <i>lq</i> , <i>stq</i> , <i>lwat</i> , <i>ldat</i> , <i>lbarx</i> , <i>lharx</i> , <i>lwarx</i> , <i>ldarx</i> , <i>lqarx</i> , <i>stwat</i> , <i>stdat</i> , <i>stbcx.</i> , <i>sthcx.</i> , <i>stwcx.</i> , <i>stdcx.</i> , or <i>stqcx.</i> instruction that addresses storage that is Write Through Required or Caching Inhibited; or if the access is due to a <i>copy</i> or <i>paste</i> instruction that addresses storage that is caching inhibited; or if the access is due to a <i>lwat</i> , <i>ldat</i> , <i>stwat</i> , or <i>stdat</i> instruction that addresses storage that is Guarded; otherwise set to 0.
<b>38</b>	Set to 1 for an explicit access for a <i>Store</i> , <i>dcbz</i> , or <i>Load/Store Atomic</i> instruction; set to 1 when an implicit update of a process-scoped PTE fails due to lack of write authority or when an implicit update of the Change bit in the partition-scoped PTE fails; otherwise set to 0.
<b>39:40</b>	Set to 0.
<b>41</b>	Set to 1 if a Data Address Watchpoint match occurs; otherwise set to 0.
<b>42</b>	Set to 1 if the access is not permitted by Virtual Page Class Key Protection; otherwise set to 0.

- 43** Set to 1 if the access is not permitted by Secure Memory Protection; otherwise set to 0.
- 44** Set to 1 if an unsupported MMU configuration is found during the translation process; otherwise set to 0.
- 45** Set to 1 if an attempt to atomically set a Reference or Change bit fails; otherwise set to 0.

#### Programming Note

The number of attempts hardware makes to atomically set Reference and Change bits before triggering this exception is implementation dependent. For example, the POWER9 processor makes no attempt. Software may still support the atomic update programming model to get performance benefits such as those described in Section 6.7.12.

- 46** Set to 1 if the guest real address of a page directory entry, page table entry, or process table entry cannot be translated; or the virtual address of a Process Table Entry or Segment Table Entry Group cannot be translated; otherwise set to 0.

**47:59** Set to 0.

- 60** Set to 1 if control memory is specified as the source of a *copy* instruction or an attempt is made to paste to control memory that is not properly configured; otherwise set to 0. These exceptions are presented differently from most instruction-caused exceptions. See Section 4.4, “Copy-Paste Facility”, in Book II for details. Additional information may be retained by the platform if the control memory is not properly configured.

- 61** Set to 1 if an attempt is made to execute a *Load Atomic* or *Store Atomic* instruction specifying a reserved function code; otherwise set to 0.

**62:63** Set to 0.

- HDAR** Set to the effective address or portion of the VPN of a storage element, or undefined, as described in the following list. The list should be read from the top down; the HDAR is set as described by the first item that corresponds to an exception that is reported in the HDSISR. For example, if a *Load Word* instruction causes a storage protection violation and a Data Address Watchpoint match (and both are reported in the HDSISR), the HDAR is set to the effective address of a byte in the first aligned doubleword for which access was

attempted in the page that caused the exception.

- undefined, for *Load Atomic* or *Store Atomic* instruction specifying a reserved function code
- undefined, when  $HDSISR_{60}=1$
- least significant 64 bits of the VA of the table entry or group when a process table entry or segment table entry group virtual address cannot be translated.
- EA, when a Hypervisor Data Storage exception occurs for reasons other than a Data Address Watchpoint match, of
  - a byte in the block that caused the exception, for a *Cache Management* instruction
  - a byte in the first aligned doubleword for which access was attempted in the page that caused the exception, for a *Load* or *Store* instruction or an instruction that is treated as a *Load* or *Store* (“first” refers to address order: see Section 7.7).
- EA of the first byte of overlap between the operand and the matching watched range, for a Data Address Watchpoint match

For the cases in which the HDAR is specified above to be set to an effective address, if the interrupt occurs in 32-bit mode the high-order 32 bits of the HDAR are set to 0.

#### Programming Note

Note that for HPT translation, the full EA is a superset of the bits required to construct the full VA, when also provided with the VSID in the ASDR.

- ASDR** When  $HR=0$ , loaded with VSID, B,  $K_s$ ,  $K_p$ , N, C, L, and LP values from the segment descriptor that translated the access or indicated the base of the table, or undefined, as described in the following list. When  $HR=1$  and nested translation is taking place, loaded with the guest real address down to bit 51 of a storage element or table entry, or undefined, as described in the following list. The list should be read from the top down; the ASDR is set as described by the first item that corresponds to an exception that is reported in the HDSISR.
- undefined, for *Load Atomic* or *Store Atomic* instruction specifying a reserved function code
  -

- undefined, when  $HDSISR_{60}=1$
- the guest real address of the table entry when a Process Table or process-scoped Page Directory or Page Table Entry guest real address cannot be translated or the VSID of the table entry (group) when a Process Table Entry or Segment Table Entry Group virtual address cannot be translated (the rest of the segment descriptor is implied, or, for the base page size, comes from the Partition Table Entry or Process Table Entry, respectively).
- the guest real address of the process-scoped PDE or PTE or Process Table Entry when a Reference or Change bit in the partition-scoped PTE mapping the process-scoped PDE or PTE or Process Table Entry cannot be set atomically
- the guest real address of the storage element when a Reference or Change bit in the partition-scoped PTE cannot be set atomically
- the guest real address of the storage element, Process Table Entry, Page Directory Entry, or Page Table Entry (depending on which partition-scoped table has the flaw) for an unsupported radix tree configuration for the partition-scoped tables (the effective address for other cases of the unsupported MMU configuration exception is found in the HDAR)
- the guest real address of the process-scoped PTE when an attempt is made to set a Reference or Change bit without write authority in the partition-scoped PTE that maps it
- the guest real address or segment descriptor associated with the specified storage element when a Hypervisor Data Storage exception occurs for reasons other than a Data Address Watchpoint match, unsupported MMU configuration, or accesses to storage that is Caching Inhibited or Write Through Required by the instructions that are prohibited from making such accesses
- undefined, for a Data Address Watchpoint match, unsupported MMU configuration, or accesses to storage that is Caching Inhibited or Write Through Required by the instructions that are prohibited from making such accesses.

If a Hypervisor Data Storage exception occurs due to an attempt to execute a *Load Atomic* or *Store Atomic* instruction with a reserved function code, the only

exception bit that is set in the HDSISR is bit 61 and the remainder of this paragraph does not apply. Otherwise, if multiple Hypervisor Data Storage exceptions occur for a given effective address, any one or more of the bits corresponding to these exceptions may be set to 1 in the HDSISR. If the HDSISR reports other exceptions together with a Virtual Page Class Key Storage Protection exception that occurs when the thread is not in hypervisor state ( $MSR_{HV\_PR} \neq 0b10$ ),  $LPCR_{KBY}=1$ , and Virtualized Partition Memory is disabled by  $VPM=0$ , the other exceptions are actually Data Storage exceptions, and HDSISR is set according to the bit definitions for DSISR as set by a Data Storage interrupt.

#### Programming Note

A Virtual Page Class Key Storage Protection exception that occurs when the thread is not in hypervisor state ( $MSR_{HV\_PR} \neq 0b10$ ),  $LPCR_{KBY}=1$ , and Virtualized Partition Memory is disabled by  $VPM=0$  identifies an access that must be emulated by the hypervisor. When it is reported together with other exceptions in the HDSISR, the hypervisor should service the Virtual Page Class Key Storage Protection exception first. This is in part because the operating system may be using some PTE fields for non-architected purposes, which could in turn cause spurious exceptions to be reported.

Execution resumes at effective address  $0x0000\_0000\_0000\_0E00$ , possibly offset as specified in Figure 70.

## 7.5.17 Hypervisor Instruction Storage Interrupt (HISI)

A Hypervisor Instruction Storage interrupt occurs when no higher priority exception exists and the next instruction to be executed cannot be fetched for any of the reasons listed below, under the conditions described immediately below.

In general, a Hypervisor Instruction Storage interrupt can occur only under the following conditions.

- $HR=0$ ,  $MSR_{HV\_PR} \neq 0b10$ , and the value of the expression  $(\neg MSR_{IR}) \mid VPM$  is 1.
- $HR=1$  and partition-scoped translation, other than for the Process Table Entry when  $effLPID=0$ , prevents the next instruction to be executed from being fetched.

The exceptions to the preceding general statement are as follows.

- If  $HR=0$  and  $MSR_{HV\_PR} \neq 0b10$ , a security violation in accessing the PTEG during address translation causes a Hypervisor Instruction Storage interrupt regardless of the rest of the translation state.

- If  $MSR_{HV} PR \neq 0b10$  or  $MSR_{IR}=1$ , a translation mode mismatch causes a Hypervisor Instruction Storage interrupt regardless of the rest of the translation state.
- If  $HR=1$ ,  $MSR_{IR}=1$ ,  $effLPID=0$ , and either (a) an unsupported radix tree configuration is found in the Partition Table Entry, or (b) the effective address of the Process Table Entry cannot be translated to a host real address because no valid PTE is found that translates the effective address, a Hypervisor Instruction Storage interrupt occurs regardless of the rest of the translation state.
- If the instruction is a prefixed instruction and is in storage that is Caching Inhibited, attempting to fetch it causes an Instruction Storage interrupt regardless of the rest of the translation state.

Under the conditions described above, a Hypervisor Instruction Storage interrupt may occur for any of the following reasons.

- The virtual or guest real address of the next instruction to be executed cannot be translated to a host real address because no valid PTE was found that translates the virtual or guest real address.
- $HR=0$  and the virtual address of the Process Table Entry or Segment Table Entry Group cannot be translated because no valid PTE was found that translates the virtual address; or  $HR=1$  and the effective address of the Process Table Entry ( $effLPID=0$ ), or the guest real address of the Process Table Entry, a Page Directory Entry, or the Page Table Entry ( $effLPID \neq 0$ ), cannot be translated because no valid PTE was found that translates the effective or guest real address.
- $HR=1$  and a Reference or Change bit update cannot be performed atomically in a partition-scoped PTE (including for the Process Table Entry, process-scoped PDE, or process-scoped PTE for a radix guest).

#### Programming Note

When failure to set a Reference or Change bit is reported, whether the Change bit must be set is indicated by whether  $HSRR1_{47}$  is set to 1. Whether an access authority failure was caused by absence of write authority is determined similarly.

- The access violates Basic Storage Protection.
- The access violates Virtual Page Class Key Storage Protection.
- The access violates Radix Tree Translation Storage Protection.
- The access violates Secure Memory Protection.

#### Programming Note

A storage protection violation may be for the instruction fetch or for an associated implicit access to a table entry, other than the PATE, during address translation or when updating Reference and Change bits. (“Table entry” here includes STEGs, PTEGs, and PDEs. For instructions and table entries for which the host real address is not the result of address translation, the only possible storage protection violation is a Secure Memory Protection violation.) Note that when nested Radix Tree Translation is being performed, a violation of Radix Tree Translation Storage Protection causes an HISI only when the process-scoped access authority permits the access but the partition-scoped access authority does not.

- Any of the following unsupported MMU configurations is found. (Note that these conditions may not be detected until the associated values are about to cause a functional problem for the processor.)
  - an unsupported radix tree configuration in the Partition Table Entry or in the partition-scoped tables, excluding the Process Table
  - a translation mode mismatch:
    - $UPRT=0$  when  $HR=1$
    - $LPID=0$  and  $MSR_{HV}=0$  when  $HR=1$
    - $HR=0$  for  $LPID=0$  when  $HR=1$  for a non-zero  $LPID$

The following registers are set:

**HSRR0** Set to the effective address of the instruction that the thread would have attempted to execute next if no interrupt conditions were present (if the interrupt occurs on attempting to fetch a branch target, **HSRR0** is set to the branch target address).

#### HSRR1

- 33** Set to 1 if the translation for an attempted access is not found in the Page Table; otherwise set to 0.
- 34** Set to 0.
- 35** Set to 1 if the access is to No-execute (as indicated by the N bit in the Segment Table Entry and HPT PTE or the Execute bit in the EAA field of the Radix PTE) or Guarded storage; otherwise set to 0.
- 36** Set to 1 if the access is not permitted by Figure 47 or the Execute bit in Figure 48 as appropriate; otherwise set to 0.
- 42** Set to 1 if the access is not permitted by Virtual Page Class Key Protection; otherwise set to 0.
- 43** Set to 1 if the access is not permitted by Secure Memory Protection; otherwise set to 0.

- 44** Set to 1 if an unsupported MMU configuration is found during the translation process; otherwise set to 0.
- 45** Set to 1 if an attempt to atomically set a Reference or Change bit fails; otherwise set to 0.

#### Programming Note

The number of attempts hardware makes to atomically set Reference and Change bits before triggering this exception is implementation dependent. For example, the POWER9 processor makes no attempt. Software may still support the atomic update programming model to get performance benefits such as those described in Section 6.7.12.

- 46** Set to 1 if the guest real address of a Page Directory Entry, Page Table Entry, or Process Table Entry cannot be translated; or the virtual address of a Process Table Entry or Segment Table Entry Group cannot be translated; otherwise set to 0.
- 47** Set to 1 if the operation that caused the exception is attempting to update storage; otherwise set to 0. This bit may be set as a modifier to bit 45 to indicate that a Change bit must be set. It may also be set as a modifier to bits 36 and 42, to indicate that write authority is required to complete the operation.

**Others** Loaded from the MSR.

**HDAR** Set to the least significant 64 bits of the VA of a table entry or group when a Process Table Entry or Segment Table Entry Group virtual address cannot be translated. May be set spuriously in other cases.

**ASDR** When HR=0, loaded with VSID, B, K<sub>s</sub>, K<sub>p</sub>, N, C, L, and LP values from the segment descriptor that translated the access or indicated the base of the table, or undefined, as described in the following list. When HR=1 and nested translation is taking place, loaded with the guest real address down to bit 51 of the instruction or table entry, or undefined, as described in the following list. The list should be read from the top down; the ASDR is set as described by the first item that corresponds to an exception that is reported in HSRR1.

- the guest real address of the table entry when a Process Table or process-scoped Page Directory or Page Table Entry guest real address cannot be translated or the VSID of the table entry (group) when a Process Table

Entry or Segment Table Entry Group virtual address cannot be translated (the rest of the segment descriptor is implied, or, for the base page size, comes from the Partition Table Entry or Process Table Entry, respectively).

- the guest real address of the process-scoped PDE or PTE or Process Table Entry when a Reference or Change bit in the partition-scoped PTE mapping the process-scoped PDE or PTE or Process Table Entry cannot be set atomically
- the guest real address of the instruction when a Reference or Change bit in the partition-scoped PTE cannot be set atomically
- the guest real address of the instruction, Process Table Entry, Page Directory Entry, or Page Table Entry (depending on which partition-scoped table has the flaw) for an unsupported radix tree configuration for the partition-scoped tables (the effective address for other cases of the unsupported MMU configuration exception will be found in HSRR0)
- the guest real address of the process-scoped PTE when an attempt is made to set a Reference bit without write authority in the partition-scoped PTE that maps it
- the guest real address or segment descriptor associated with the instruction that the thread would have attempted to execute next if no interrupt conditions were present (partition-scoped page fault or protection exception)
- undefined for unsupported MMU configuration

**MSR** See Figure 69.

If multiple Hypervisor Instruction Storage exceptions occur due to attempting to fetch a single instruction, any one or more of the bits corresponding to these exceptions may be set to 1 in HSRR1.

Execution resumes at effective address 0x0000\_0000\_0000\_0E10, possibly offset as specified in Figure 70.

## 7.5.18 Hypervisor Emulation Assistance Interrupt

A Hypervisor Emulation Assistance interrupt is generated when execution is attempted of an illegal instruction, or of a reserved instruction or an instruction that is not provided by the implementation. It is also generated under the following conditions.

- When  $MSR_{HV\ PR}=0b00$  and  $LPCR_{EVIRT}=1$ , execution is attempted of a hypervisor privileged instruction, or of an *mtspr* or *mfspir* instruction that specifies an SPR that is hypervisor privileged for the operation or that specifies PTCR, DAWRn, DAWRXn, or CIABR when those SPRs are ultravisor privileged for the operation.
- When  $MSR_{S\ HV\ PR} = 0b010$ , execution is attempted of an *mtspr* or *mfspir* instruction that specifies PTCR, DAWRn, DAWRXn, or CIABR when those SPRs are ultravisor privileged for the operation.
- When  $MSR_{PR}=1$ , execution is attempted of an *mtspr* or *mfspir* instruction that specifies an SPR with  $spr_0=0$  that is not provided by the implementation.
- When  $MSR_{PR}=0$ , execution is attempted of an *mtspr* or *mfspir* instruction that specifies SPR 0, 4, 5, or 6.
- When  $MSR_{PR}=0$  and  $LPCR_{EVIRT}=1$ , execution is attempted of an *mtspr* or *mfspir* instruction that specifies an SPR other than 0, 4, 5, or 6 that is not provided by the implementation.

A Hypervisor Emulation Assistance interrupt may be generated when execution is attempted of an instruction that is in invalid form or that is treated as if the instruction form were invalid.

The following registers are set:

**HSRR0** Set to the effective address of the instruction that caused the interrupt.

#### HSRR1

- 33** Set to 0.
- 34** Set to 0 if the instruction that caused the interrupt is a word instruction (or a prefixed instruction when prefixed instructions are unavailable based on the PCR setting) and to 1 if the instruction that caused the interrupt is a prefixed instruction.
- 35:36** Set to 0.
- 42:44** Set to 0.
- 45** Set to 1 for an attempt, when  $MSR_{HV\ PR} = 0b00$  and  $LPCR_{EVIRT}=1$ , to execute a hypervisor privileged instruction or an *mtspr* or *mfspir* instruction that specifies an SPR that is hypervisor privileged for the operation or that specifies PTCR, DAWRn, DAWRXn, or CIABR when they are ultravisor privileged for the operation, or for an attempt when  $MSR_{S\ HV\ PR} = 0b010$  to execute an *mtspr* or *mfspir* instruction that specifies PTCR, DAWRn, DAWRXn, or CIABR when they are ultravisor privileged for the operation; otherwise set to 0.
- 46:47** Set to 0.
- Others** Loaded from the MSR.

**MSR** See Figure 69 on page 1275.

**HEIR** Set to a copy of the instruction that caused the interrupt

If the interrupt is caused by an attempt to execute an invalid form of a hypervisor privileged instruction when  $MSR_{HV\ PR} = 0b00$  and  $LPCR_{EVIRT}=1$ , it is implementation dependent whether  $HSRR1_{45}$  is set to 0 (reflecting the invalid instruction form) or to 1 (reflecting the privilege violation).

Execution resumes at effective address  $0x0000\_0000\_0000\_0E40$ , possibly offset as specified in Figure 70.

## Programming Note

This Programming Note illustrates how Hypervisor Emulation Assistance interrupts should be handled by software, including in environments that support nested hypervisors. For simplicity, this Programming Note ignores effects of the SMF facility (equivalently, assumes that  $SMFCTRL_E=0$ ).

In this Note, “the hypervisor” may be the hypervisor to which hardware passes control when a Hypervisor Emulation Assistance interrupt occurs or, in an environment that supports nested hypervisors, may be a nested hypervisor. The hypervisor to which hardware passes control when a Hypervisor Emulation Assistance interrupt occurs is here called the “level 0 hypervisor,” and is the only level of hypervisor that runs with  $MSR_{HV\_PR}=0b10$  and that can access hypervisor resources directly; nested hypervisors run with  $MSR_{HV\_PR}=0b00$  and their attempts to access hypervisor resources are virtualized by a higher-level hypervisor as described below. In this Note, the hypervisor receiving the Hypervisor Emulation Assistance interrupt (which may have been passed from a higher-level hypervisor as described below) is called the “level N hypervisor.” This Note assumes that  $LPCR_{EVIRT}=1$  if nested hypervisors are used. (A Hypervisor Emulation Assistance interrupt can set  $HSRR_{145}$  to 1 only when  $LPCR_{EVIRT}=1$ .) Higher level numbers correspond to lower level hypervisors.

In the description immediately below, it is assumed that nested hypervisors (if any) are new versions of the existing hypervisor, and that the purpose of the nesting is to test the nested hypervisors before using them as level 0 hypervisors.

When a Hypervisor Emulation Assistance interrupt is received by the level N hypervisor, the cases and their suggested handling are as follows.

- The program that caused the interrupt is the level N hypervisor itself.
  - $HSRR_{145}=0$ : Emulate the instruction, recover from the error, or terminate this hypervisor, as appropriate.
  - $HSRR_{145}=1$ : Cannot occur for  $N=0$ ; will not occur for  $N>0$  if the hypervisor nesting software is written correctly.
- The program that caused the interrupt is not the level N hypervisor.
  - The program most recently dispatched by the level N hypervisor is a level N+1 hypervisor.
    - $HSRR_{145}=0$ : Pass control to the level N+1 hypervisor as if the instruction had caused a Hypervisor Emulation Assistance interrupt (with  $HSRR_{145}=0$ ) to that hypervisor.
    - $HSRR_{145}=1$ :
      - The program that caused the interrupt is the level N+1 hypervisor: Virtualize the instruction.
      - The program that caused the interrupt is not the level N+1 hypervisor: Pass

control to the level N+1 hypervisor as if the instruction had caused a Hypervisor Emulation Assistance interrupt (with  $HSRR_{145}=1$ ) to that hypervisor.

- The program most recently dispatched by the level N hypervisor is an operating system.
  - $HSRR_{145}=0$ : Emulate the instruction if appropriate (rather than pass control to the operating system to do the emulation); otherwise pass control to the operating system as if the instruction had caused an “Illegal Instruction type Program interrupt” as described in a Programming Note near the end of Section 7.5.9.
  - $HSRR_{145}=1$ : Either terminate the operating system or pass control to the operating system as if the instruction had caused a Privileged Instruction type Program interrupt as described in a Programming Note near the end of Section 7.5.9.
- The program most recently dispatched by the level N hypervisor is an application program.
  - $HSRR_{145}=0$ : Emulate the instruction if appropriate; otherwise terminate the application program.
  - $HSRR_{145}=1$ : Cannot occur.

The preceding description implicitly assumes that any nested hypervisors being tested will, when run at level 0, be run on processors that support the same version of the architecture as the processor on which they are being tested. If instead they will be run on processors that support a newer version of the architecture, the level 0 hypervisor should behave as described above if the interrupt is caused by an instruction that is unchanged between the two architecture versions. However, if the interrupt is caused by an instruction that differs between the two architecture versions (e.g., an instruction that is added by the newer version of the architecture), the level 0 hypervisor should emulate the behavior of the newer processor, rather than, for example, passing the interrupt to a level 1 hypervisor.

Other uses of nested hypervisors are also possible. For example, software that is designed to interact, nearly simultaneously, with the hypervisor instance that is running on each of many processors could be tested on a single processor by running multiple level 1 hypervisors under a single level 0 hypervisor.

It is expected that in practice there will be at most two levels of nested hypervisor (i.e.,  $N \leq 2$ ). (For example, two levels are needed in the case described in detail above, to test the ability of the nested hypervisors at level 1 to support nested hypervisors.)

**Programming Note**

If a Hypervisor Emulation Assistance interrupt occurs with  $\text{HSRR}_{145}=0$  when the thread is not in hypervisor state, for an instruction that the hypervisor does not emulate, the hypervisor should pass control to the operating system as if the instruction had caused an "Illegal Instruction type Program interrupt", as described in a Programming Note near the end of Section 7.5.9, "Program Interrupt" on page 1287.

Similarly, if a Hypervisor Emulation Assistance interrupt occurs with  $\text{HSRR}_{145}=1$  when the thread is in privileged non-hypervisor state, for an instruction that the hypervisor does not virtualize, the hypervisor should pass control to the operating system as if the instruction had caused a Privileged Instruction type Program interrupt, as described in another Programming Note near the end of Section 7.5.9, "Program Interrupt" on page 1287.

**Programming Note**

In versions of the architecture that precede V. 3.1B, an attempt when  $\text{MSR}_{\text{PR}}=0$  to execute an *mtspr* or *mfspir* instruction specifying an SPR that was not implemented (with the exception of SPR 0 for *mtspr* and SPRs 0, 4, 5, and 6 for *mfspir*) was treated as a no-op. These former no-op cases now cause a Hypervisor Emulation Assistance interrupt (with  $\text{HSRR}_{145}=0$ ) when  $\text{LPCR}_{\text{EVIRT}}=1$  to enable future functions to be emulated on older implementations. (An attempt when  $\text{MSR}_{\text{PR}}=0$  to execute an *mtspr* instruction specifying SPRs 4, 5, and 6 now causes a Hypervisor Emulation Assistance interrupt regardless of the value of  $\text{LPCR}_{\text{EVIRT}}$ .) If there is no future function emulation to be performed, hypervisor software must choose a policy from the following.

- treat the instruction as an error
- emulate the legacy no-op behavior
- give control to the operating system

## 7.5.19 Hypervisor Maintenance Interrupt

A Hypervisor Maintenance interrupt occurs when no higher priority exception exists, a Hypervisor Maintenance exception exists (a bit in the HMER is set to one), the exception is enabled in the HMEER, and the value of the following expression is 1.

$$(\text{MSR}_{\text{EE}} \mid \neg(\text{MSR}_{\text{HV}}) \mid \text{MSR}_{\text{PR}})$$

The following registers are set:

**HSRR0** Set to the effective address of the instruction that the thread would have attempted to execute next if no interrupt conditions were present.

**HSRR1**

**33:36** Set to 0.  
**42:47** Set to 0.  
**Others** Loaded from the MSR.

**MSR** See Figure 69 on page 1275.

**HMER** See Section 7.2.10 on page 1263.

The exception bits in the HMER are sticky; that is, once set to 1 they remain set to 1 until they are set to 0 by an *mtmmer* instruction.

Execution resumes at effective address  $0x0000\_0000\_0000\_0E60$ .

**Programming Note**

Because the value of  $\text{MSR}_{\text{EE}}$  is always 1 when the thread is in problem state, the simpler expression

$$(\text{MSR}_{\text{EE}} \mid \neg(\text{MSR}_{\text{HV}}))$$

is equivalent to the expression given above.

**Programming Note**

If an implementation uses the HMER to record that a readable resource, such as the Time Base, has been corrupted, then, because the HMI is disabled in the hypervisor state, it is necessary for the hypervisor to check HMER after reading that resource to be sure an error has not occurred.

## 7.5.20 Directed Hypervisor Doorbell Interrupt

A Directed Hypervisor Doorbell interrupt occurs when no higher priority exception exists, a Directed Hypervisor Doorbell exception is present, and the value of the following expression is 1.

$$(\text{MSR}_{\text{EE}} \mid \neg(\text{MSR}_{\text{HV}}) \mid \text{MSR}_{\text{PR}})$$

Directed Hypervisor Doorbell exceptions are generated when Directed Hypervisor Doorbell messages (see Chapter 12) are received and accepted by the thread.

The following registers are set:

**HSRR0** Set to the effective address of the instruction that the thread would have attempted to execute next if no interrupt conditions were present.

**HSRR1**

**33:36** Set to 0.  
**42:47** Set to 0.  
**Others** Loaded from the MSR.

**MSR** See Figure 69 on page 1275.

Execution resumes at effective address 0x0000\_0000\_0000\_0E80, possibly offset as specified in Figure 70.

#### Programming Note

Because the value of  $MSR_{EE}$  is always 1 when the thread is in problem state, the simpler expression

$$(MSR_{EE} \mid \neg(MSR_{HV}))$$

is equivalent to the expression given above.

## 7.5.21 Hypervisor Virtualization Interrupt

A Hypervisor Virtualization interrupt occurs when no higher priority exception exists, a Hypervisor Virtualization exception exists, and the value of the following equation is 1.

$$(MSR_{EE} \mid \neg(MSR_{HV}) \mid MSR_{PR}) \& HVICE$$

The occurrence of the interrupt does not cause the exception to cease to exist.

**HSRR0** Set to the effective address of the instruction that the thread would have attempted to execute next if no interrupt conditions were present.

#### HSRR1

**33:36** Set to 0.

**42:47** Set to 0.

**Others** Loaded from the MSR.

**MSR** See Figure 69 on page 1275.

Execution resumes at effective address 0x0000\_0000\_0000\_0EAO, possibly offset as specified in Figure 70.

## 7.5.22 Performance Monitor Interrupt

A Performance Monitor interrupt occurs when no higher priority exception exists, a Performance Monitor exception exists, event-based branches are disabled ( $MMCR0_{EBE}=0$ ), and  $MSR_{EE}=1$ , and either  $HFSCR_{PM}=1$  or the thread is in hypervisor state.

If multiple Performance Monitor exceptions occur before the first causes a Performance Monitor interrupt, the interrupt reflects the most recent Performance Monitor exception and the preceding Performance Monitor exceptions are lost.

The following registers are set:

**SRR0** Set to the effective address of the instruction that would have been attempted to be

execute next if no interrupt conditions were present.

#### SRR1

**33:36** Set to 0.

**42:47** Set to 0.

**Others** Loaded from the MSR.

**MSR** See Figure 69 on page 1275.

Execution resumes at effective address 0x0000\_0000\_0000\_0F00, possibly offset as specified in Figure 70.

## 7.5.23 Vector Unavailable Interrupt

A Vector Unavailable interrupt occurs when no higher priority exception exists, an attempt is made to execute a Vector instruction (including Vector loads, stores, and moves), and  $MSR_{VEC}=0$ .

The following registers are set:

**SRR0** Set to the effective address of the instruction that caused the interrupt.

#### SRR1

**33** Set to 0.

**34** Set to 0 if the instruction that caused the interrupt is a word instruction and to 1 if the instruction that caused the interrupt is a prefixed instruction.

**35:36** Set to 0.

**42:47** Set to 0.

**Others** Loaded from the MSR.

**MSR** See Figure 69 on page 1275.

Execution resumes at effective address 0x0000\_0000\_0000\_0F20, possibly offset as specified in Figure 70.

## 7.5.24 VSX Unavailable Interrupt

A VSX Unavailable interrupt occurs when no higher priority exception exists, an attempt is made to execute a VSX instruction (including VSX loads, stores, and moves), and  $MSR_{VSX}=0$ .

The following registers are set:

**SRR0** Set to the effective address of the instruction that caused the interrupt.

#### SRR1

**33** Set to 0.

**34** Set to 0 if the instruction that caused the interrupt is a word instruction and to 1 if the instruction that caused the interrupt is a prefixed instruction.

**35:36** Set to 0.

**42:47** Set to 0.

**Others** Loaded from the MSR.

**MSR** See Figure 69 on page 1275.

Execution resumes at effective address 0x0000\_0000\_0000\_0F40, possibly offset as specified in Figure 70.

## 7.5.25 Facility Unavailable Interrupt

A Facility Unavailable interrupt occurs when no higher priority exception exists, and one of the following occurs.

- a facility is accessed in problem state when it has been made unavailable by the FSCR
- a Performance Monitor register is accessed or a *clrbhrb* or *mfbhrbe* instruction is executed in problem state when it has been made unavailable by MMCR0.

The following registers are set:

**SRR0** Set to the effective address of the instruction that caused the interrupt.

### SRR1

- 33** Set to 0.
- 34** Set to 0 if the instruction that caused the interrupt is a word instruction and to 1 if the instruction that caused the interrupt is a prefixed instruction.
- 35:36** Set to 0.
- 42:47** Set to 0.
- Others** Loaded from the MSR.

**MSR** See Figure 69 on page 1275.

### FSCR

- 0:7** See Section 7.2.12 on page 1264.
- Others** Not changed.

Execution resumes at effective address 0x0000\_0000\_0000\_0F60, possibly offset as specified in Figure 70.

## 7.5.26 Hypervisor Facility Unavailable Interrupt

A Hypervisor Facility Unavailable interrupt occurs when no higher priority exception exists, and one of the following occurs.

- a facility is accessed in problem or privileged non-hypervisor states when it has been made unavailable by the HFSCR.
- The *stop* instruction is executed in privileged non hypervisor state when any of the following conditions exist.
  - PSSCR<sub>EC</sub>=1
  - PSSCR<sub>ESL</sub>=1

PSSCR<sub>MTL</sub>>PSSCR<sub>PSLL</sub>  
PSSCR<sub>RL</sub>>PSSCR<sub>PSLL</sub>

The following registers are set:

**HSRR0** Set to the effective address of the instruction that caused the interrupt.

### HSRR1

- 33** Set to 0.
- 34** Set to 0 if the instruction that caused the interrupt is a word instruction and to 1 if the instruction that caused the interrupt is a prefixed instruction.
- 35:36** Set to 0.
- 42:47** Set to 0.
- Others** Loaded from the MSR.

**MSR** See Figure 69 on page 1275.

### HFSCR

- 0:7** See Section 7.2.13 on page 1265.
- Others** Not changed.

Execution resumes at effective address 0x0000\_0000\_0000\_0F80, possibly offset as specified in Figure 70.

## Programming Note

The Hypervisor Facility Unavailable interrupt handler should either (a) make the facility, the attempted use of which caused the interrupt, available, or (b) pass control to the operating system as if the instruction that caused the interrupt had instead caused an “Illegal Instruction type Program interrupt”, as described in a Programming Note near the end of Section 7.5.9. Specifically, for choice (b) the hypervisor should pass control to the operating system at the operating system's Program interrupt vector location, with all registers (SRR0, SRR1, MSR, GPRs, etc.) set as if the instruction had caused a Privileged Instruction type Program interrupt, except with SRR1<sub>44:45</sub> set to 0b10. (This behavior is the same as that provided by the Hypervisor Emulation Assistance interrupt handler when that interrupt is caused by an illegal instruction or by *mt/fspr* specifying an undefined SPR number.) In general this behavior by the Hypervisor Facility Unavailable interrupt handler provides to the operating system the appearance that the instructions in the facility are illegal instructions and that the SPRs in the facility correspond to undefined SPR numbers. The cases in which it does not provide this appearance are as follows.

### 1. privileged instruction executed in problem state

Because Privileged Instruction type Program interrupt has higher priority than Hypervisor Facility Unavailable interrupt, an attempt in problem state to execute a privileged instruction made unavail-

able by the HFSCR will cause a Privileged Instruction type Program interrupt to the operating system, rather than a Hypervisor Facility Unavailable interrupt, so the hypervisor will not have opportunity to make the instruction appear to be illegal. (It may be useful to note that the handling described in choice (b) above together with the behavior of this case provides behavior, in problem state, that is equivalent to the behavior that would be obtained by making the facility unavailable by means of the PCR.)

### 2. *mt/fspr* executed in privileged non-hypervisor state when LPCR<sub>EVRT=0</sub>

*mt/fspr* specifying an undefined SPR number (other than 0, 4, 5, 6) and executed in privileged non-hypervisor state when LPCR<sub>EVRT=0</sub> will be treated as a no-op. If instead the SPR number is defined and the SPR is made unavailable by the HFSCR a Hypervisor Facility Unavailable interrupt will occur, and there is no easy way for the interrupt handler to determine that the interrupting instruction is *mt/fspr* and hence should be treated as a no-op. (Hypervisor Facility Unavailable interrupt does not set HEIR.) Passing control to the operating system's Program interrupt handler in the manner described above is preferable to incurring the software complexity and performance cost of emulating the no-op behavior.

## 7.5.27 System Call Vectored Interrupt

A System Call Vectored interrupt occurs when a *System Call Vectored* instruction is executed.

The following registers are set:

<b>LR</b>	Set to the effective address of the instruction following the System Call Vectored instruction.
<b>CTR</b>	
<b>33:36</b>	undefined
<b>42:47</b>	undefined
<b>Others</b>	Loaded from corresponding bits of the MSR.
<b>MSR</b>	See Figure 69 on page 1275.

Execution resumes at the effective address specified in Figure 70

### Programming Note

When the System Call Vectored interrupt results in MSR<sub>IR</sub> being 1 or MSR<sub>HV</sub> being 0, the effective address described above is translated to a real address before being used to access storage. If the effective address cannot be translated, or if instructions cannot be fetched from the addressed storage location (e.g., the access would violate storage protection, or would be to No-execute storage), an [Hypervisor] Instruction Storage interrupt occurs before the first instruction at the effective address is executed.

Because the System Call Vectored interrupt uses save/restore registers that differ from those used by other interrupts, the System Call Vectored interrupt handler can run with address translation enabled and External interrupts enabled. Similarly, the Programming Note about managing MSR<sub>RI</sub> at the end of Section 7.4.3 does not apply to the System Call Vectored interrupt handler (the System Call Vectored interrupt does not alter MSR<sub>RI</sub>).

## 7.5.28 Directed Ultravisor Doorbell Interrupt

A Directed Ultravisor Doorbell interrupt occurs when no higher priority exception exists,  $SMFCTRL_E=1$ , a Directed Ultravisor Doorbell exception is present, and the value of the following expression is 1.

$$(MSR_{EE} \mid \neg(MSR_{S_{HVPR}}=0b110))$$

Directed Ultravisor Doorbell exceptions are generated when Directed Ultravisor Doorbell messages (see Chapter 12) are received and accepted by the thread.

The following registers are set:

**USRR0** Set to the effective address of the instruction that the thread would have attempted to execute next if no interrupt conditions were present.

### USRR1

**33:36** Set to 0.

**42:47** Set to 0.

**Others** Loaded from the MSR.

**MSR** See Figure 69 on page 1275.

Execution resumes at effective address  $0x0000\_0000\_0000\_0FA0$ .

## 7.6 Partially Executed Instructions

If a Data Storage, Data Segment, Alignment, system-caused, or imprecise exception occurs while a *Load* or *Store* instruction is executing, the instruction may be aborted. In such cases the instruction is not completed, but may have been partially executed in the following respects.

- Some of the bytes of the storage operand may have been accessed, except that if access to a given byte of the storage operand would violate storage protection, that byte is neither copied to a register by a *Load* instruction nor modified by a *Store* instruction. Also, the rules for storage accesses given in Section 6.8.1, “Guarded Storage” and in Section of Book II are obeyed.
- Some registers may have been altered as described in the Book II section cited above.
- Reference and Change bits may have been updated as described in Section 6.7.12.
- For a *stbcx.*, *sthcx.*, *stwcx.*, *stdcx.*, or *stqcx.* instruction that is executed in-order, CR0 may have been set to an undefined value and the reservation may have been cleared.
- 

The architecture does not support continuation of an aborted instruction but intends that the aborted instruction be re-executed if appropriate.

### Programming Note

An exception may result in the partial execution of a *Load* or *Store* instruction. For example, if the Page Table Entry that translates the address of the storage operand is altered, by a program running on another thread, such that the new contents of the Page Table Entry preclude performing the access, the alteration could cause the *Load* or *Store* instruction to be aborted after having been partially executed.

As stated in the Book II section cited above, if an instruction is partially executed the contents of registers are preserved to the extent that the instruction can be re-executed correctly. The consequent preservation is described in the following list. For any given instruction, zero, one, or two items in the list apply.

- For a fixed-point *Load* instruction that is not a multiple or string form, if  $RT=RA$  or  $RT=RB$  then the contents of register  $RT$  are not altered.
- For an *lq* instruction, if  $RT+1 = RA$  then the contents of register  $RT+1$  are not altered.
- For an update form *Load* or *Store* instruction, the contents of register  $RA$  are not altered.

## 7.7 Exception Ordering

Since multiple exceptions can exist at the same time and the architecture does not provide for reporting more than one interrupt at a time, the generation of more than one interrupt is prohibited. Some exceptions, such as the Mediated External exception, persist and can be deferred. However, other exceptions would be lost if they were not recognized and handled when they occur. For example, if an External interrupt was generated when a Data Storage exception existed, the Data Storage exception would be lost. If the Data Storage exception was caused by a *Store Multiple* instruction for which the storage operand crosses a virtual page boundary and the exception was a result of attempting to access the second virtual page, the store could have modified locations in the first virtual page even though it appeared that the *Store Multiple* instruction was never executed.

For the above reasons, all exceptions are prioritized with respect to other exceptions that may exist at the same instant to prevent the loss of any exception that is not persistent. Some exceptions cannot exist at the same instant as some others.

Data Storage, Hypervisor Data Storage, Data Segment, and Alignment exceptions occur as if the storage operand were accessed one byte at a time in order of increasing effective address (with the obvious caveat if the operand includes both the maximum effective address and effective address 0). (The required ordering of exceptions on components of non-atomic accesses does not extend to the performing of the component accesses in the event of an exception. For example, if byte *n* causes a data storage exception, it is not necessarily true that the access to byte *n*-1 has been performed.)

### 7.7.1 Unordered Exceptions

With one exception, the exceptions listed here are unordered, meaning that they may occur at any time regardless of the state of the interrupt processing mechanism. These exceptions are recognized and processed when presented. The exception is that a Machine Check caused by an attempt to access control memory as other than an operand of *copy* or *paste*. is ordered similarly to the corresponding type of storage access exception. (Note that this results in two different orderings. The one for instruction fetch occurs early, as item 2 in the “Instruction-Caused and Precise” list. The one for data access appears later, within case 3 of the appropriate “Function-Dependent” listings.)

1. System Reset
2. Machine Check except for those caused by an invalid attempt to access control memory

### 7.7.2 Ordered Exceptions

The exceptions listed here are ordered with respect to the state of the interrupt processing mechanism. With one exception, in the following list the hypervisor forms of the Data Storage and Instruction Storage exceptions can be substituted for the non-hypervisor forms since the hypervisor forms cannot be caused by the same instruction and have the same ordering. The exception is that Virtual Page Class Key Storage Protection exceptions that occur when  $LPCR_{KBV}=1$  and Virtualized Partition Memory is disabled by  $VPM=0$  cause only a Hypervisor Data Storage exception (and never a Data Storage exception).

In the list below for Instruction-Caused and Precise exceptions, for prefixed instructions items 1, 2, and 6 apply to the first word of the instruction, and determination of whether the exceptions of items 3-5 and 7 occur is based on the first word of the instruction. (Items 3-7 can occur only for prefixed instructions.)

#### Programming Note

For a prefixed instruction there is no need to determine whether the exceptions of items 1, 2, and 6 can be caused by the second word of the instruction.

- If the instruction is correctly aligned (i.e., is at an effective address that is not equal to 60 modulo 64), the determination would be the same for the second word as for the first word.
- If the instruction is not correctly aligned, an exception will occur due to one of items 1-7 applied to the first word, and the corresponding interrupt obviates the need for hardware to access the second word.

#### System-Caused or Imprecise

1. Program
  - Imprecise Mode Floating-Point Enabled Exception
2. Directed Ultravisor Doorbell
3. Hypervisor Maintenance
4. Hypervisor Virtualization, External, [Hypervisor] Decrementer, Performance Monitor, Directed Privileged Doorbell, Directed Hypervisor Doorbell

#### Instruction-Caused and Precise

1. Instruction Segment
2. [Hypervisor] Instruction Storage other than case described in item 6
3. Hypervisor Emulation Assistance due to PCR making all prefixed instructions unavailable
4. Hypervisor Facility Unavailable due to HFSCR making all prefixed instructions unavailable
5. Facility Unavailable due to HFSCR making all prefixed instructions unavailable
6. [Hypervisor] Instruction Storage for prefixed instruction in Caching Inhibited storage
7. Alignment for incorrectly aligned prefixed instruction

- 8. Machine Check for invalid control memory access
- 9. Other Hypervisor Emulation Assistance or Program (Privileged Instruction)
- 10. Function-Dependent
  - 10.a Fixed-Point and Branch
    - 1 Hypervisor Facility Unavailable
    - 2 Facility Unavailable
    - 3a Program
      - Trap
    - 3b System Call or System Call Vectored
    - 3c.1 Data Storage for the case of *Fixed-Point Load or Store Caching Inhibited* instructions with  $MSR_{DR}=1$  or the case of a reserved function code for an Atomic Memory Operation
    - 3c.2 all other Data Storage, Hypervisor Data Storage, [Hypervisor] Data Segment, Machine Check for invalid control memory access, or Alignment
      - 4 Trace
  - 10.b Floating-Point
    - 1 Hypervisor Facility Unavailable
    - 2 Floating Point Unavailable
    - 3a Program
      - Precise Mode Floating-Pt Enabled Excep'n
    - 3b [Hypervisor] Data Storage, [Hypervisor] Data Segment, Machine Check for invalid control memory access, or Alignment
      - 4 Trace
  - 10.c Vector
    - 1 Hypervisor Facility Unavailable
    - 2 Vector Unavailable
    - 3a [Hypervisor] Data Storage, [Hypervisor] Data Segment, Machine Check for invalid control memory access, or Alignment
      - 4 Trace
  - 10.d VSX
    - 1 Hypervisor Facility Unavailable
    - 2 VSX Unavailable
    - 3a Program
      - Precise Mode Floating-Pt Enabled Excep'n
    - 3b [Hypervisor] Data Storage, [Hypervisor] Data Segment, Machine Check for invalid control memory access, or Alignment
      - 4 Trace
  - 10.e Other Instructions
    - 1 Hypervisor Facility Unavailable
    - 2 Facility Unavailable
    - 3a [Hypervisor] Data Storage, [Hypervisor] Data Segment, Machine Check for invalid control memory access, or Alignment
      - 4 Trace

For implementations that execute multiple instructions in parallel using pipeline or superscalar techniques, or combinations of these, it can be difficult to understand the ordering of exceptions. To understand this ordering it is useful to consider a model in which each instruction is fetched, then decoded, then executed, all before the next instruction is fetched. In this model, the exceptions a single instruction would generate are in the order shown in the list of instruction-caused exceptions. Exceptions with different numbers have different ordering. Exceptions with the same numbering but different lettering are mutually exclusive and cannot be caused by the same instruction. The Hypervisor Virtualization, External, [Hypervisor] Decrementer, Performance Monitor, Directed Privileged Doorbell, and Directed Hypervisor Doorbell interrupts have equal ordering. Similarly, where Data Storage, Data Segment, and Alignment exceptions are listed in the same item, and where Hypervisor Emulation Assistance and Privileged Instruction exceptions are listed in the same item, they have equal ordering.

Even on threads that are capable of executing several instructions simultaneously, or out of order, instruction-caused interrupts (precise and imprecise) occur in program order.

#### Programming Note

Despite that debug address matches are EA based, the exceptions they cause are not necessarily ordered before translation-caused exceptions. For example, it may be considered advantageous to take a page fault that would have prevented an access rather than a DAWR match exception

## 7.8 Event-Based Branch Exception Ordering

Event-based exceptions are not ordered because they can occur simultaneously. Whenever an event-based exception occurs and the exception is enabled, the corresponding "exception occurred" bit in the BESCR is set to 1. See Section 6.2.1 of Book II.

## 7.9 Interrupt Priorities

This section describes the relationship of nonmaskable, maskable, precise, and imprecise interrupts. In the following descriptions, the interrupt mechanism waiting for all possible exceptions to be reported includes only exceptions caused by previously initiated instructions (e.g., it does not include waiting for the Decrementer to step through zero). The exceptions are listed in order of highest to lowest priority. The phrase "corresponding interrupt" means the interrupt

having the same name as the exception unless the thread is in power-saving mode, in which case the phrase means the System Reset interrupt.

Unless otherwise stated or obvious from context, it is assumed below that one of the following conditions is satisfied.

- The thread is not in power-saving mode and the interrupt, unless it is the Machine Check interrupt, is not disabled. (For the Machine Check interrupt no assumption is made regarding enablement.)
- The thread is in power-saving mode and the exception is enabled to cause exit from the mode.

With one exception, in the following list the hypervisor forms of the Data Storage and Instruction Storage exceptions can be substituted for the non-hypervisor forms since the hypervisor forms cannot be caused by the same instruction and have the same priority. The exception is that exceptions caused by Virtual Page Class Key Storage Protection exceptions that occur when  $LPCR_{KBV}=1$  and Virtualized Partition Memory is disabled by  $VPM=0$  cause only a Hypervisor Data Storage exception (and never a Data Storage exception).

#### 1. System Reset

System Reset exception has the highest priority of all exceptions. If this exception exists, the interrupt mechanism ignores all other exceptions and generates a System Reset interrupt.

Once the System Reset interrupt is generated, no nonmaskable interrupts are generated due to exceptions caused by instructions issued prior to the generation of this interrupt.

#### 2. Machine Check

With one exception, the Machine Check exception is the second highest priority exception. If this exception exists and a System Reset exception does not exist, the interrupt mechanism ignores all other exceptions and generates a Machine Check interrupt. The exception is that a Machine Check caused by an attempt to access control memory as other than an operand of *copy* or *paste*. is prioritized similarly to the corresponding type of storage access exception. (Note that this results in two different priorities. The one for data access is higher, appearing as item e or f in the listings for different types of *Load* and *Store* instructions. The one for instruction fetch is lower, in category K.)

Once the Machine Check interrupt is generated, no nonmaskable interrupts are generated due to exceptions caused by instructions issued prior to the generation of this interrupt.

#### 3. Instruction-Caused and Precise

This exception is the third highest priority exception. When this exception is created, the interrupt mechanism waits for all possible Imprecise exceptions to be reported. It then generates the appropriate ordered interrupt if no higher priority exception exists when the interrupt is to be generated. Within this category a particular instruction may present more than a single exception. When this occurs, those exceptions are ordered in priority as indicated in the following lists. Where [Hypervisor] Data Storage, Data Segment, and Alignment exceptions are listed in the same item they have equal priority (i.e., the hardware may generate any one of the three interrupts for which an exception exists).

##### A. Fixed-Point Loads and Stores

- a. These exceptions are mutually exclusive and have the same priority:
  - Hypervisor Emulation Assistance
  - Program - Privileged Instruction
- b. Hypervisor Facility Unavailable
- c. Facility Unavailable
- d. Data Storage for the case of *Fixed-Point Load or Store Caching Inhibited* instructions with  $MSR_{DR}=1$  or the case of a reserved function code for an Atomic Memory Operation
- e. all other Data Storage, Hypervisor Data Storage, [Hypervisor] Data Segment, Machine Check for invalid control memory access, or Alignment (other than for incorrectly aligned prefixed instruction)
- f. Trace

##### B. Floating-Point Loads and Stores

- a. Hypervisor Emulation Assistance

    - a. These exceptions or groups of exceptions are mutually exclusive and have the same priority (the members of a group are not mutually exclusive, but have the same priority):
      - Program - Trap
      - System Call
      - System Call Vectored
      - Hypervisor Emulation Assistance or Program (Privileged Instruction)
    - b. Hypervisor Facility Unavailable
    - c. Facility Unavailable
    - d. Trace
  - J. [Hypervisor] Instruction Storage, Instruction Segment, Alignment for incorrectly aligned prefixed instruction, and Machine Check for invalid control memory access
- These exceptions have the lowest priority in this category. They are recognized only when

all instructions prior to the instruction causing one of these exceptions appear to have completed and that instruction is the next instruction to be executed. The four exceptions are mutually exclusive.

The priority of these exceptions is specified for completeness and to ensure that they are not given more favorable treatment. It is acceptable for an implementation to treat these exceptions as though they had a lower priority.

4. Program - Imprecise Mode Floating-Point Enabled Exception

This exception is the fourth highest priority exception. When this exception is created, the interrupt mechanism waits for all other possible exceptions to be reported. It then generates this interrupt if no higher priority exception exists when the interrupt is to be generated.

5. Directed Ultravisor Doorbell

This exception is the fifth highest priority exception. When this exception is created, the interrupt mechanism waits for all other possible exceptions to be reported. It then generates this interrupt if no higher priority exception exists when the interrupt is to be generated.

#### Programming Note

Some platform implementations may depend on timely servicing of Hypervisor Maintenance interrupts, e.g. to prevent physical damage. The Directed Ultravisor Doorbell interrupt handler may test the HMER to identify such circumstances and take appropriate action.

6. Hypervisor Maintenance

This exception is the sixth highest priority exception. When this exception is created, the interrupt mechanism waits for all other possible exceptions to be reported. It then generates this interrupt if no higher priority exception exists when the interrupt is to be generated.

If a Hypervisor Maintenance exception exists and each attempt to execute an instruction when the Hypervisor Maintenance interrupt is enabled causes an exception (see the Programming Note below), the Hypervisor Maintenance interrupt is not delayed indefinitely.

7. Hypervisor Virtualization, Direct External, Mediated External, and [Hypervisor] Decrementer, Performance Monitor, Directed Privileged Doorbell, Directed Hypervisor Doorbell

These exceptions are the lowest priority exceptions. All have equal priority (i.e., the hardware may generate any one of the corresponding interrupts for which an exception exists). When one of

these exceptions is created, the interrupt processing mechanism waits for all other possible exceptions to be reported. It then generates the corresponding interrupt if no higher priority exception exists when the interrupt is to be generated.

If a Hypervisor Decrementer exception exists and each attempt to execute an instruction when the Hypervisor Decrementer interrupt is enabled causes an exception (see the Programming Note below), the Hypervisor Decrementer interrupt is not delayed indefinitely.

If LPES=0 and a Direct External exception exists and each attempt to execute an instruction when this interrupt is enabled causes an exception (see the Programming Note below), the Direct External interrupt is not delayed indefinitely.

#### Programming Note

An incorrect or malicious operating system could corrupt the first instruction in the interrupt vector location for an instruction-caused interrupt such that the attempt to execute the instruction causes the same exception that caused the interrupt (a looping interrupt; e.g., *Trap* instruction and Program interrupt). Similarly, the first instruction of the interrupt vector for one instruction-caused interrupt could cause a different instruction-caused interrupt, and the first instruction of the interrupt vector for the second instruction-caused interrupt could cause the first instruction-caused interrupt (e.g., Program interrupt and Floating-Point Unavailable interrupt). The looping caused by these and similar cases is terminated by the occurrence of a System Reset or Hypervisor Decrementer interrupt.

tions have completed execution, no subsequent instruction has begun execution, and the instruction addressed by EBBRR has not completed execution.

### 7.10.3 EBB Classes

Event-based branches are classified by whether they are directly caused by the execution of an instruction or are caused by some other system exception. Those that are “system-caused” are

- Performance Monitor
- External

## 7.10 Relationship of Event-Based Branches to Interrupts

### 7.10.1 EBB Exception Priority

Event-based branches have a priority lower than that of all interrupts. When an event-based exception is created, the Event-Based Branch facility waits for all possible exceptions that would cause interrupts to be reported. It then generates the event-based branch if no exception that would cause an interrupt exists when the event-based branch is to be generated.

### 7.10.2 EBB Synchronization

When an event-based branch occurs, EBBRR is set to point to an instruction such that all preceding instruc-

## Chapter 8. Timer Facilities

### 8.1 Overview

The Time Base, Decrementer, Hypervisor Decrementer, Processor Utilization of Resources, and Scaled Processor Utilization of Resources registers provide timing functions for the system. The remainder of this section describes these registers and related facilities.

### 8.2 Time Base (TB)

The Time Base (TB) is a 64-bit register (see Figure 71) containing a 64-bit unsigned integer that is incremented periodically.

Field	Description
TBU40	Upper 40 bits of Time Base
TBU	Upper 32 bits of Time Base
TBL	Lower 32 bits of Time Base

**Figure 71. Time Base**

The Time Base is a hypervisor resource; see Chapter 2.

The SPRs TBU40, TBU, and TBL provide access to the fields of the Time Base shown in Figure 71. When a *mtspr* instruction is executed specifying one of these SPRs, the associated field of the Time Base is altered and the remaining bits of the Time Base are not affected.

See Chapter 5 of Book II for information about the update frequency of the Time Base.

The Time Base is implemented such that:

1. Loading a GPR from the Time Base has no effect on the accuracy of the Time Base.

2. Copying the contents of a GPR to the Time Base replaces the contents of the Time Base with the contents of the GPR.

The Power ISA does not specify a relationship between the frequency at which the Time Base is updated and other frequencies, such as the CPU clock or bus clock in a Power ISA system. The Time Base update frequency is not required to be constant. What *is* required, so that system software can keep time of day and operate interval timers, is one of the following.

- The system provides an (implementation-dependent) interrupt to software whenever the update frequency of the Time Base changes, and a means to determine what the current update frequency is.
- The update frequency of the Time Base is under the control of the system software.

Implementations must provide a means for either preventing the Time Base from incrementing or preventing it from being read in problem state ( $MSR_{PR}=1$ ). If the means is under software control, it must be accessible only in hypervisor state ( $MSR_{HV\_PR} = 0b10$ ). There must be a method for getting all Time Bases in the system to start incrementing with values that are identical or almost identical.

**Programming Note**

If software initializes the Time Base on power-on to some reasonable value and the update frequency of the Time Base is constant, the Time Base can be used as a source of values that increase at a constant rate, such as for time stamps in trace entries.

Even if the update frequency is not constant, values read from the Time Base are monotonically increasing (except when the Time Base wraps from  $2^{64}-1$  to 0). If a trace entry is recorded each time the update frequency changes, the sequence of Time Base values can be post-processed to become actual time values.

Successive readings of the Time Base may return identical values.

If Time Base bits 60:63 are used as part of a random number generator, software must account for the fact that these bits are set to 0x0 only when bit 59 changes state regardless of whether or not they incremented to 0xF since they were previously set to 0x0.

See the description of the Time Base in Chapter 5 of Book II for ways to compute time of day in POSIX format from the Time Base.

## 8.2.1 Writing the Time Base

Writing the Time Base is privileged, and can be done only in hypervisor state. Reading the Time Base is not privileged; it is discussed in Chapter 5 of Book II.

It is not possible to write the entire 64-bit Time Base using a single instruction. The *mttbl* and *mttbu* extended mnemonics write the lower and upper halves of the Time Base (TBL and TBU), respectively, preserving the other half. These are extended mnemonics for the *mtspr* instruction; Figure 21.

The Time Base can be written by a sequence such as:

```
lwz    Rx,upper # load 64-bit value for
lwz    Ry,lower # TB into Rx and Ry
li     Rz,0
mttbl  Rz      # set TBL to 0
mttbu  Rx      # set TBU
mttbl  Ry      # set TBL
```

Provided that no interrupts occur while the last three instructions are being executed, loading 0 into TBL prevents the possibility of a carry from TBL to TBU while the Time Base is being initialized.

The preferred method of changing the Time Base utilizes the TBU40 facility. The following code sequence demonstrates the process. Assume the upper 40 bits of Rx contain the desired value upper 40 bits of the Time Base.

```
mftb  Ry# Read 64-bit Time Base value
clrldi Ry,Ry,40# lower 24 bits of old TB
mttbu40Rx# write upper 40 bits of TB
mftb  Rz# read TB value again
clrldi Rz,Rz,40# lower 24 bits of new TB
cmpld Rz,Ry# compare new and old lwr 24 bits
bge   done# no carry out of low 24 bits
addis Rx,Rx,0x0100
      #increment upper 40 bits
mttbu40 Rx# update to adjust for carry
```

**Programming Note**

The instructions for writing the Time Base are mode-independent. Thus code written to set the Time Base will work correctly in either 64-bit or 32-bit mode.

## 8.3 Virtual Time Base

The Virtual Time Base (VTB) is a 64-bit incrementing counter.

**Figure 72. Virtual Time Base**

Virtual Time Base increments at the same rate as the Time Base until its value becomes 0xFFFF\_FFFF\_FFFF\_FFFF ( $2^{64} - 1$ ); at the next increment its value becomes 0x0000\_0000\_0000\_0000. There is no interrupt or other indication when this occurs.

The operation of the Virtual Time Base has the following additional properties.

1. Loading a GPR from the Virtual Time Base has no effect on the accuracy of the Virtual Time Base.
2. Copying the contents of a GPR to the Virtual Time Base replaces the contents of the Virtual Time Base with the contents of the GPR.

**Programming Note**

In systems that change the Time Base update frequency for purposes such as power management, the Virtual Time Base input frequency will also change. Software must be aware of this in order to set interval timers.

**Programming Note**

In configurations in which the hypervisor allows multiple partitions to time-share a processor, the Virtual Time Base can be managed by the hypervisor such that it appears to each partition as if it counts only during the times that the partition is executing.

In order to do this, the hypervisor saves the value of the Virtual Time Base as part of the program context when removing a partition from the processor, and restores it to its previous value when initiating the partition again on the same or another processor.

## 8.4 Decrementer

The Decrementer (DEC) is a decrementing counter that provides a mechanism for causing a Decrementer interrupt after a programmable delay.

The Decrementer is driven at the same frequency as the Time Base.

**Figure 73. Decrementer**

The LPCR is used to enable and disable Large Decrementer mode, as defined below. (See Section 2.2.)

When the Decrementer is not in Large Decrementer mode, it behaves as a 32-bit signed integer and operates as follows.

The Decrementer counts down until its value becomes 0x0000\_0000\_0000\_0000; at the next decrement its value becomes 0x0000\_0000\_FFFF\_FFFF. When reading the Decrementer using *mtspr*, bits 0:31 always read back as 0s.

When the contents of DEC<sub>32</sub> change from 0 to 1, a Decrementer exception will come into existence within a reasonable period of time. When the contents of DEC<sub>32</sub> change from 1 to 0, the existing Decrementer exception, if any, will cease to exist within a reasonable period of time, but not later than the completion of the next context synchronizing instruction or event.

The preceding paragraph applies regardless of whether the change in the contents of DEC<sub>32</sub> is the result of decrementation of the Decrementer by the hardware or of modification of the Decrementer caused by execution of an *mtspr* instruction.

When the Decrementer is in Large Decrementer mode, it behaves as a d-bit decrementing counter which is sign-extended to 64 bits. The value of d is implementa-

tion dependent but at least 32. When the Decrementer is written, bits 0:63-d are ignored by the hardware.

**Programming Note**

In Large Decrementer mode, the maximum positive value supported by the Decrementer is  $2^{d-1}-1$ , represented with bits 0:64-d containing 0's and bits 65-d:63 containing 1's. The minimum value supported by the Decrementer is  $-2^{d-1}$ , represented as 0xFFFF\_FFFF\_FFFF\_FFFF.

When in Large Decrementer mode, the Decrementer operates as follows.

The binary value of the Decrementer counts down until its value becomes 0x0000\_0000\_0000\_0000; at the next decrement its value becomes the minimum value supported, which is represented as 0xFFFF\_FFFF\_FFFF\_FFFF.

When the contents of the DEC<sub>0</sub> change from 0 to 1, a Decrementer exception will come into existence within a reasonable period of time. When the contents of DEC<sub>0</sub> change from 1 to 0, the existing Decrementer exception, if any, will cease to exist within a reasonable period of time, but not later than the completion of the next context synchronizing instruction or event.

The preceding paragraph applies regardless of whether the change in the contents of DEC<sub>0</sub> is the result of decrementation of the Decrementer by the hardware or of modification of the Decrementer caused by execution of an *mtspr* instruction.

The operation of the Decrementer has the following additional properties.

1. Loading a GPR from the Decrementer has no effect on the accuracy of the Time Base.
2. Copying the contents of a GPR to the Decrementer replaces the contents of the Decrementer with the contents of the GPR.

**Programming Note**

In systems that change the Time Base update frequency for purposes such as power management, the Decrementer input frequency will also change. Software must be aware of this in order to set interval timers.

If Decrementer bits 60:63 are used as part of a random number generator, software must account for the fact that these bits are set to 0xF only when bit 59 changes state regardless of whether or not they were decremented to 0x0 since they were previously set to 0xF.

### 8.4.1 Writing and Reading the Decrementer

The contents of the Decrementer can be read or written using the *mf spr* and *mt spr* instructions, both of which are privileged when they refer to the Decrementer. Using an extended mnemonic (Figure 21), the Decrementer can be written from GPR Rx using:

```
mtdec Rx
```

The Decrementer can be read into GPR Rx using:

```
mfdec Rx
```

Copying the Decrementer to a GPR has no effect on the Decrementer contents or on the interrupt mechanism.

## 8.5 Hypervisor Decrementer

The Hypervisor Decrementer is a h-bit decrementing counter that is sign-extended to 64 bits. The value of h is implementation dependent, however the number of bits supported by the Hypervisor Decrementer must be greater than or equal to the number of bits supported by the Decrementer. When the Decrementer is written, bits 0:63-h are ignored by the hardware.

#### Programming Note

The maximum positive value supported by the Hypervisor Decrementer is  $2^{h-1}-1$ , represented with bits 0:64-h containing 0's and bits 65-h:63 containing 1's. The minimum value supported by the Hypervisor Decrementer is  $-2^{h-1}$ , represented as 0xFFFF\_FFFF\_FFFF\_FFFF.

The binary value of the Hypervisor Decrementer counts down until its value becomes 0x0000\_0000\_0000\_0000; at the next decrement its value becomes the minimum value supported, which is represented as 0xFFFF\_FFFF\_FFFF\_FFFF.

When the contents of HDEC<sub>0</sub> change from 0 to 1 and the thread is not in a power-saving mode, a Hypervisor Decrementer exception will come into existence within a reasonable period of time. When a Hypervisor Decrementer interrupt occurs, the existing Hypervisor Decrementer exception will cease to exist within a reasonable period of time, but not later than the completion of the next context synchronizing instruction or event. Even if multiple HDEC<sub>0</sub> change transitions from 0 to 1 occur before a Hypervisor Decrementer interrupt occurs, at most one Hypervisor Decrementer exception exists.

The preceding paragraph applies regardless of whether the change in the contents of HDEC<sub>0</sub> is the result of decrementation of the Hypervisor Decrementer by the

hardware or of modification of the Hypervisor Decrementer caused by execution of an *mt spr* instruction.

The operation of the Hypervisor Decrementer has the following additional properties.

1. Loading a GPR from the Hypervisor Decrementer has no effect on the accuracy of the Hypervisor Decrementer.
2. Copying the contents of a GPR to the Hypervisor Decrementer replaces the contents of the Hypervisor Decrementer with the contents of the GPR.

#### Programming Note

In systems that change the Time Base update frequency for purposes such as power management, the Hypervisor Decrementer update frequency will also change. Software must be aware of this in order to set interval timers.

If Hypervisor Decrementer bits 60:63 are used as part of a random number generator, software must account for the fact that these bits are set to 0xF only when bit 59 changes state regardless of whether or not they decremented to 0x0 since they were previously set to 0xF.

#### Programming Note

A Hypervisor Decrementer exception is not created if the thread is in a power-saving mode when HDEC<sub>0</sub> changes from 0 to 1 because having a Hypervisor Decrementer interrupt occur almost immediately after exiting the power-saving mode in this case is deemed unnecessary. The hypervisor already has control, and if a timed exit from the power-saving mode is necessary and possible, the hypervisor can use the Decrementer to exit the power-saving mode at the appropriate time. For some power-saving levels, the state of the Hypervisor Decrementer and Decrementer is not necessarily maintained and updated.

## 8.6 Processor Utilization of Resources Register (PURR)

The Processor Utilization of Resources Register (PURR) is a 64-bit counter, the contents of which provide an estimate of the resources used by the thread. The contents of the PURR are treated as a 64-bit unsigned integer.

**Figure 74. Processor Utilization of Resources Register**

The PURR is a hypervisor resource; see Chapter 2.

The contents of the PURR increase monotonically, unless altered by software, until the sum of the contents plus the amount by which it is to be increased exceed  $0xFFFF\_FFFF\_FFFF\_FFFF$  ( $2^{64} - 1$ ) at which point the contents are replaced by that sum modulo  $2^{64}$ . There is no interrupt or other indication when this occurs.

The rate at which the value represented by the contents of the PURR increases is an estimate of the portion of resources used by the thread per unit time with respect to other threads that share those resources monitored by the PURR. When the thread is idle, the rate at which the PURR value increases is implementation dependent.

Let the difference between the value represented by the contents of the Time Base at times  $T_a$  and  $T_b$  be  $T_{ab}$ . Let the difference between the value represented by the contents of the PURR at time  $T_a$  and  $T_b$  be the value  $P_{ab}$ . The ratio of  $P_{ab}/T_{ab}$  is an estimate of the percentage of shared resources used by the thread during the interval  $T_{ab}$ . For the set  $\{S\}$  of threads that share the resources monitored by the PURR, the sum of the usage estimates for all the threads in the set is 1.0.

The definition of the set of threads  $S$ , the shared resources corresponding to the set  $S$ , and specifics of the algorithm for incrementing the PURR are implementation-specific.

The PURR is implemented such that:

1. Loading a GPR from the PURR has no effect on the accuracy of the PURR.
2. Copying the contents of a GPR to the PURR replaces the contents of the PURR with the contents of the GPR.

#### Programming Note

Estimates computed as described above may be useful for purposes related to resource utilization, including utilization-based system management and planning.

Because the rate at which the PURR accumulates resource usage estimates is dependent on the frequency at which the Time Base is incremented, and the frequency of the oscillator that drives instruction execution may vary independently from that of the Time Base, the interpretation of the contents of the PURR may be inaccurate as a measurement of capacity consumption for accounting purposes. The SPURR should be used for accounting purposes.

## 8.7 Scaled Processor Utilization of Resources Register (SPURR)

The Scaled Processor Utilization of Resources Register (SPURR) is a 64-bit counter, the contents of which provide an estimate of the resources used by the thread. The contents of the SPURR are treated as a 64-bit unsigned integer.

**Figure 75. Scaled Processor Utilization of Resources Register**

The SPURR is a hypervisor resource; see Section 2.6.

The contents of the SPURR increase monotonically, unless altered by software, until the sum of the contents plus the amount by which it is to be increased exceed  $0xFFFF\_FFFF\_FFFF\_FFFF$  ( $2^{64} - 1$ ) at which point the contents are replaced by that sum modulo  $2^{64}$ . There is no interrupt or other indication when this occurs.

The rate at which the value represented by the contents of the SPURR increases is an estimate of the portion of resources used by the thread with respect to other threads that share those resources monitored by the SPURR, and relative to the computational capacity provided by those resources. The computational capacity provided by the shared resources may vary as a function of the frequency of the oscillator which drives the resources or as a result of deliberate delays in processing that are created to reduce power consumption. When the thread is idle, the rate at which the SPURR value increases is implementation dependent.

Let the difference between the value represented by the contents of the Time Base at times  $T_a$  and  $T_b$  be  $T_{ab}$ . Let the ratio of the effective and nominal frequencies of the oscillator driving instruction execution  $f_e/f_n$  be  $f_r$ . Let the ratio of delay cycles created by power reduction circuitry and total cycles  $c_d/c_t$  be  $c_r$ . Let the difference between the value represented by the contents of the SPURR at time  $T_a$  and  $T_b$  be the value  $S_{ab}$ . The ratio of  $S_{ab}/(T_{ab} \times f_r \times (1 - c_r))$  is an estimate of the percentage of shared resource capacity used by the thread during the interval  $T_{ab}$ . For the set  $\{S\}$  of threads that share the resources monitored by the SPURR, the sum of the usage estimates for all the threads in the set is 1.0.

The definition of the set of threads  $S$ , the shared resources corresponding to the set  $S$ , and specifics of the algorithm for incrementing the SPURR are implementation-specific.

The SPURR is implemented such that:

1. Loading a GPR from the SPURR has no effect on the accuracy of the SPURR.

2. Copying the contents of a GPR to the SPURR replaces the contents of the SPURR with the contents of the GPR.

**Programming Note**

Estimates computed as described above may be useful for purposes of resource use accounting, program dispatching, etc.

## 8.8 Instruction Counter

The Instruction Counter (IC) is a 64-bit incrementing counter that counts the number of instructions that the thread has completed (according to the sequential execution model; see Section 2.2 of Book I).

**Figure 76. Instruction Counter**

## Chapter 9. Dynamic Execution Control Facility

### 9.1 Overview

The dynamic execution control facility provides control over certain architectural and micro-architectural aspects of execution especially regarding out-of-order execution behavior. This facility provides a means by which software can request different dynamic execution behaviors in the hardware without the necessity of firmware updates. The facility consists of execution control instructions such as the execution serializing no-op instruction (*ori R31,R31,0*) (see Section 9.2) and three Special Purpose Registers for execution control, the Dynamic Execution Control Register (DEXCR) and the Hypervisor Dynamic Execution Control Register (HDEXCR), and the implementation dependent Ultraviolet Dynamic Execution Control Register (UDEXCR) (see Section 9.3). The control provided by these registers is described in Section 9.4.

The *mfspr* and *mtspr* instructions (see Section 5.4.4) provide access to these registers.

### 9.2 Dynamic Execution Control Instructions

Instructions described in this Section provides dynamic control over certain architectural and micro-architectural aspects of execution as a direct or side effect of their own execution.

#### 9.2.1 Execution Serializing No-op Instruction

*ori R31,R31,0* is a no-op instruction that is also execution serializing: that is, executing an *ori R31,R31,0* instruction ensures that all instructions preceding the *ori R31,R31,0* instruction have completed before the *ori R31,R31,0* instruction completes, and that no subsequent instructions are initiated, even out-of-order, until after the *ori R31,R31,0* instruction completes. The *ori R31,R31,0* instruction may complete before storage accesses associated with instructions preceding the *ori R31,R31,0* instruction have been performed.

#### Extended Mnemonics:

Additional extended mnemonic for the execution serializing form of *Or Immediate*:

Extended:	Equivalent to:
exser	ori 31,31,0

#### Programming Note

**Warning:** Other forms of *ori Rx,Rx,0* that are not described in this section may also have micro-architectural effects on program execution. Use of these forms should be avoided except when software needs the associated micro-architectural effects. If a no-op is needed, the preferred no-op (*ori 0,0,0*) should be used.

#### Programming Note

This no-op is intended to be used by software for providing protection against the Spectre class of transient execution attacks by restricting eventually discarded out-of-order execution effects with transient register values, which may compromise confidential data via other covert channels.

### 9.3 Dynamic Execution Control Registers

The Special Purpose Registers defined for dynamic execution control can control up to 32 unique dynamic execution aspects. The effective aspect value to be used for a particular aspect for each privilege state is defined by the equations in Section 9.4, as is the assignment of dynamic execution aspects to aspect numbers.

#### 9.3.1 Dynamic Execution Control Register (DEXCR)

The layout of the 64-bit Dynamic Execution Control Register (DEXCR) is shown in Figure 2 below. PNH

refers to privileged non-hypervisor state. PRO refers to problem state.

PNH0	PNH1	...	PNH31	PRO0	PRO1	...	PRO31
0	1	2	31	32	33	34	63

Bits	Name	Description
0	PNH0	PNH value for aspect number 0
1	PNH1	PNH value for aspect number 1
...	...	...
n	PNH[n]	PNH value for aspect number n
...	...	...
31	PNH31	PNH value for aspect number 31
32	PRO0	PRO value for aspect number 0
33	PRO1	PRO value for aspect number 1
...	...	...
m	PRO[m-32]	PRO value for aspect number m-32
...	...	...
63	PRO31	PRO value for aspect number 31

**Figure 77. Dynamic Execution Control Register (DEXCR)**

This register can be read and written in privileged state using SPR 828. Bits 32:63 of the register can only be read in problem state using SPR 812; *mf spr* 812 returns 0s for bits 0:31.

### 9.3.2 Hypervisor Dynamic Execution Control Register (HDEXCR)

The layout of the 64-bit Hypervisor Dynamic Execution Control Register (HDEXCR) is shown in Figure 3 below. HNU refers to hypervisor non-ultravisor state. ENF refers to enforcement of a value to lower privilege states by hypervisor state.

HNU0	HNU1	...	HNU31	ENF0	ENF1	...	ENF31
0	1	2	31	32	33	34	63

Bits	Name	Description
0	HNU0	HNU value for aspect number 0
1	HNU1	HNU value for aspect number 1
...	...	...
n	HNU[n]	HNU value for aspect number n
...	...	...
31	HNU31	HNU value for aspect number 31
32	ENF0	ENF value for aspect number 0
33	ENF1	ENF value for aspect number 1
...	...	...
m	ENF[m-32]	ENF value for aspect number m-32
...	...	...
63	ENF31	ENF value for aspect number 31

**Figure 78. Hypervisor Dynamic Execution Control Register (HDEXCR)**

This register can be read and written in hypervisor state using SPR 471. Bits 32:63 of the register can only be read in non-hypervisor state using SPR 455; *mf spr* 455 returns 0s for bits 0:31.

### 9.3.3 Ultravisor Dynamic Execution Control Register (UDEXCR)

The Ultravisor Dynamic Execution Control Register (UDEXCR) is an implementation-dependent register or similar mechanism containing bits ULT0 through ULT31, which are equivalent to HDEXCR bits HNU0 through HNU31 except applying in ultravisor state instead of in hypervisor non-ultravisor state. UDEXCR is set, by an implementation-dependent method, only during system initialization.

The contents of UDEXCR must be the same for all threads under the control of a given instance of the ultravisor; otherwise all results are undefined.

#### Programming Note

Note that there is no need for ENF bits in UDEXCR, since ultravisor is capable of intercepting entry of execution of a secure partition or process and can set the ENF bits of the HDEXCR register for enforcement purposes as described in Section 9.3. Hence these bits only control the aspects of execution in ultravisor state.

## 9.4 Dynamic Execution Control Operation

The effective aspect control value for a particular dynamic execution aspect and privilege state is determined by the bits from DEXCR and HDEXCR described in previous section using the following equations. Note that the ENF bit fields in HDEXCR provide a way for the hypervisor or ultravisor to enforce a value of 1 for a particular aspect, but it cannot enforce a value of 0. Hence, the hypervisor or ultravisor can only enforce the behavior determined by positive polarity.

Problem state ( $MSR_{PR}=1$ ):

effective value for aspect number  $k = ENF[k] \mid PRO[k]$

Privileged non-hypervisor state ( $MSR_{HV\ PR}=0b00$ ):

effective value for aspect number  $k = ENF[k] \mid PNH[k]$

Hypervisor non-ultravisor state ( $MSR_{S\ HV\ PR}=0b010$ ):

effective value for aspect number  $k = HNU[k]$

Ultravisor state ( $MSR_{S\ HV\ PR}=0b110$ ):

effective value for aspect number  $k = ULT[k]$

**Programming Note**

Operating systems should provide system call to allow application programs to request to set PRO[k] bits of DEXCR. Operating system software must save and restore DEXCR on context switches. Likewise, hypervisor software must save and restore HDEXCR when swapping partitions. The hypervisor can enforce certain execution aspects for a partition by setting the ENF[k] bits in HDEXCR. The hypervisor also maintains control of its own execution aspect value via the HNU[k] bits while the operating system maintains control of its own execution aspect value via the PRIV[k] bits unless overridden by the hypervisor.

**Programming Note**

Changing the value of HNU[k] while in hypervisor state or changing the value of PNH[k] while in privileged non-hypervisor state may not cause immediate change of execution behavior. See the other programming notes in this section.

The assignment of aspect numbers to dynamic execution aspects in the processor is described below, alongside the interpretation of the effective values for each aspect.

**Aspect Description**

0	<b>Speculative Branch Hint Enable (SBHE)</b>
0	The hints provided by BO field of Branch instructions may be ignored during speculative execution
1	The hints provided by BO field of Branch instructions are obeyed during speculative execution
1:2	<b>Reserved</b>
3	<b>Indirect Branch Recurrent Target Prediction Disable (IBRTPD)</b>
0	Target address prediction mechanisms may be enabled for indirect branches that are not regarded as subroutine returns for prediction purposes (target address is likely to be same as the target address used the preceeding time the branch was taken)
1	Target address prediction mechanisms do not record or predict branch target addresses for all indirect branches that are not regarded as subroutine returns for prediction purposes

4 **Subroutine Return Address Prediction Disable (SRAPD)**

- 0 Target address prediction mechanisms may be enabled for indirect branches that are regarded as subroutine returns for prediction purposes
- 1 Target address prediction mechanisms do not record or predict branch target addresses for all indirect branches that are regarded as subroutine returns for prediction purposes

5 **Non-Privileged Hash Instruction Enable (NPHIE)**

- 0 *hashst* and *hashchk* instructions are executed as no-ops (even when allowed by PCR)
- 1 *hashst* and *hashchk* instructions are executed normally (if allowed by PCR)

6 **Privileged Hash Instruction Enable (PHIE)**

- 0 *hashstp* and *hashchkp* instructions are executed as no-ops (even when allowed by PCR)
- 1 *hashstp* and *hashchkp* instructions are executed normally (if allowed by PCR)

7:31 **Reserved****Programming Note**

In some micro-architectures, the execution behavior controlled by aspect 0 is difficult to change with any degree of timing precision. The change may also bleed over into other threads on the same processor. Any environment that has a dependence on the more secure setting of aspect 0 should not change the value, and ideally should share a processor only with similar threads. For other environments, changes to the effective value of aspect 0 represent a relative risk tolerance for its aspect of execution behavior, with the understanding that there will be significant hysteresis in the execution behavior.

**Programming Note**

XL-form *Branch* instructions such as *bclr[]*, *bcctr[]* and *bctar[]* are referred to as indirect branches in this chapter. Aspect 3 is intended to control target prediction behavior of *bclr[]* with BH field value of 0b01, *bcctr[]* and *bctar[]* instructions. Aspect 4 is intended to control target prediction behavior of *bclr[]* with BH field value of 0b00. (See Figure 42 in Section 2.4)

**Programming Note**

Software synchronization is required when changing the effective control aspect value for aspects 3 through 4 to ensure that the execution behavior has changed. See Table 8 on page 1355.

**Programming Note**

In general, aspect values are assigned such that the 1 value may provide greater security. (The 0 value may provide better performance.) This is not strictly enforced.

## Chapter 10. Debug Facilities

### 10.1 Overview

Implementations provide debug facilities to enable hardware and software debug functions, such as control flow tracing, data address watchpoints, and program single-stepping. The debug facilities described in this section consist of the Come-From Address Register (see Section 10.2), Completed Instruction Address Breakpoint Register (see Section 10.3), and the Data Address Watchpoint Register (DAWRn) and Data Address Watchpoint Register Extension (DAWRXn) (see Section 10.4). The interrupt associated with the Data Address Breakpoint registers is described in Section 7.5.3. The interrupt associated with the Completed Instruction Address Breakpoint Register is described in Section 7.5.15. The Trace facility, which can be used for single-stepping as well as for control flow tracing, is described in Section 7.5.15.

The *mfspr* and *mtspr* instructions (see Section 5.4.4) provide access to the registers of the debug facilities.

In addition to the facilities mentioned above, implementations typically provide debug facilities, modes, and access mechanisms that are implementation-specific. For example, implementations typically provide facilities for instruction address tracing, and also access to certain debug facilities via a dedicated interface such as the IEEE 1149.1 Test Access Port (JTAG).

### 10.2 Come-From Address Register

The Come-From Address Register (CFAR) is a 64-bit register. When an *rfebb*, *rfid*, or *rfscv* instruction is executed, the register is set to the effective address of the instruction. When a *Branch* instruction is executed and the branch is taken, the register is set to the effective address of an instruction in the instruction cache block containing the *Branch* instruction, except that if the *Branch* instruction is a B-form *Branch* (i.e., *bc*, *bca*, *bcl*, or *bcla*) for which the target address is in the instruction cache block containing the *Branch* instruction or is in the previous or next cache block, the register is not necessarily set. For *Branch* instructions, the

setting need not occur until a subsequent context synchronizing operation has occurred.

**Figure 79. Come-From Address Register**

The contents of the CFAR can be read and written using the *mfspr* and *mtspr* instructions. Access to the CFAR is privileged.

#### Programming Note

This register can be used for purposes of debugging software. For example, often a software bug results in the program executing a portion of the code that it should not have reached or causing an unexpected interrupt. In the former case, a breakpoint can be placed in the portion of the code that was erroneously reached and the program reexecuted. In either case, the interrupt handler can save the contents of the CFAR (before executing the first instruction that would modify the register), and then make the saved contents available for a debugger to use in determining the control flow path by which the exception was reached.

In order to preserve the CFAR's contents for each partition and to prevent it from being used to implement a "covert channel" between partitions, the hypervisor should initialize/save/restore the CFAR when switching partitions on a given thread.

### 10.3 Completed Instruction Address Breakpoint

The Completed Instruction Address Breakpoint mechanism provides a means of detecting an instruction completion at a specific instruction address. The address comparison is done on an effective address (EA).

The Completed Instruction Address Breakpoint mechanism is controlled by the Completed Instruction Address Breakpoint Register (CIABR), shown in Figure 80, except that if  $SMFCTRL_D=1$  when  $PRIV \neq 0$ ,

the Privilege specification in the PRIV field is ignored and the facility detects instruction address matches in ultravisor state.

Bit(s)	Name	Description
0:61	CIEA	Completed Instruction Effective Address
62:63	PRIV	Privilege (PRIV > 0b00 ignored when SMFCTRL <sub>D</sub> =1) 00: Disable matching 01: Match in problem state 10: Match in privileged non-hypervisor state 11: Match in hypervisor non-ultravisor state

**Figure 80. Completed Instruction Address Breakpoint Register**

A Completed Instruction Address Breakpoint match occurs upon instruction completion if all of the following conditions are satisfied. The values of CIABR, SMFCTRL, and the MSR that are used for the comparisons are those that exist at the time the instruction is initiated.

- the completed instruction address is equal to CIEA<sub>0:61</sub> || 0b00. For prefixed instructions, the completed instruction address is the address of the prefix.
- SMFCTRL<sub>D</sub>=0 and the thread privilege matches that specified in PRIV or SMFCTRL<sub>D</sub>=1, PRIV≠0, and MSR<sub>S HV PR</sub>=0b110.

In 32-bit mode the high-order 32 bits of the EA are treated as zeros for the purpose of detecting a match.

A Completed Instruction Address Breakpoint match causes a Trace exception, which may cause a Trace interrupt as described in Section 7.5.15.

## 10.4 Data Address Watchpoint

The Data Address Watchpoint mechanism provides a means of detecting load and store accesses to multiple doubleword-aligned effective address (EA) ranges. At least two independent address ranges are provided.

### Programming Note

The Data Address Watchpoint mechanism employs a simple EA compare. It makes no attempt to take the radix table translation quadrants (keyed off EA<sub>0:1</sub>) into account to enable a single setting to work in all privilege levels.

Each Data Address Watchpoint range is controlled by a pair of SPRs: the Data Address Watchpoint Register (DAWR<sub>n</sub>), shown in Figure 81, and the Data Address

Watchpoint Register Extension (DAWRX<sub>n</sub>), shown in Figure 82, where n=0,1,... SMFCTRL<sub>D</sub> functions as an extension to the PRIVM field: when SMFCTRL<sub>D</sub>=1, the facility detects data address watchpoint matches in ultravisor state in addition to states enabled by the PRIVM field.

Bit(s)	Name	Description
0:60	DEAW	Data Effective Address Watchpoint

**Figure 81. Data Address Watchpoint Register**

Bit(s)	Name	Description
48:53	MRD	Match Range in Doublewords biased by -1. (0b000000 = 1 DW, 0b111111 = 64 DW)
56	HRAMMC	Hypervisor Real Addressing Mode Match Control 0: DEAW <sub>0</sub> and EA <sub>0</sub> are used during matching in ultravisor or hypervisor real addressing mode 1: DEAW <sub>0</sub> and EA <sub>0</sub> are ignored during matching in ultravisor or hypervisor real addressing mode
57	DW	Data Write
58	DR	Data Read
59	WT	Watchpoint Translation
60	WTI	Watchpoint Translation Ignore
61:63	PRIVM	Privilege Mask
61	HYP	Hypervisor non-ultravisor state
62	PNH	Privileged Non-Hypervisor state
63	PRO	Problem state

All other fields are reserved.

**Figure 82. Data Address Watchpoint Register Extension**

The supported PRIVM values are 0b000, 0b001, 0b010, 0b011, 0b100, and 0b111 when SMFCTRL<sub>D</sub>=0 and 0b000, 0b001, 0b010, and 0b011 when SMFCTRL<sub>D</sub>=1. If the combination of SMFCTRL<sub>D</sub> and the PRIVM field does not contain one of the supported values, then whether a match occurs for a given storage access is undefined. Elsewhere in this section it is assumed that the PRIVM field contains one of the supported values.

**Programming Note**

When  $SMFCTRL_D=0$ , PRIVM value 0b000 causes matches not to occur regardless of the contents of other DAWR<sub>n</sub> and DAWRX<sub>n</sub> fields. PRIVM values 0b101 and 0b110 are not supported because a storage location that is shared between the hypervisor and non-hypervisor software is unlikely to be accessed using the same EA by both the hypervisor and the non-hypervisor software. (PRIVM value 0b111 is supported primarily for reasons of software compatibility with respect to emulation of the DABR facility as described in a subsequent Programming Note.)

$SMFCTRL_D=1$  is provided for ultravisor debugging and also for ultravisor supervision of secure partition debugging. When  $SMFCTRL_D=1$ , exceptions due to matches that occur in hypervisor non-ultravisor state are unlikely to be desirable.

A Data Address Watchpoint match occurs for a *Load* or *Store* instruction, or for an instruction that is treated as a *Load* or *Store*, if, for any byte accessed, all of the following conditions are satisfied. For the first condition,  $chk\_DEAW$  and  $chk\_EA$  are defined as follows. If  $MSR_{HV\_DR}=0b10$  and  $HRAMMC=1$  then

$chk\_DEAW = 0b0 \parallel DEAW_{1:60}$  and  
 $chk\_EA = 0b0 \parallel EA_{1:63}$ ;

otherwise

$chk\_DEAW = DEAW$  and  
 $chk\_EA = EA$ .

- the access is located in the range  
 $chk\_DEAW_{0:60} \leq chk\_EA_{0:60} \leq$   
 $(chk\_DEAW_{0:60} + (^{55}0 \parallel MRD_{0:5}))$
- $(MSR_{DR} = DAWRX_{n_{WT}}) \mid DAWRX_{n_{WT}}$
- the thread is in
  - ultravisor state and  $SMFCTRL_D=1$ , or
  - hypervisor non-ultravisor state and  $DAWRX_{n_{HYP}} = 1$ , or
  - privileged non-hypervisor state and  $DAWRX_{n_{PNH}} = 1$ , or
  - problem state and  $DAWRX_{n_{PR}} = 1$
- the instruction is a *Store* or treated as a *Store* and  $DAWRX_{n_{DW}} = 1$ , or the instruction is a *Load* or treated as a *Load* and  $DAWRX_{n_{DR}} = 1$ .

In hypervisor and ultravisor real addressing modes, bits 1:63-m of the EA are ignored for the purpose of detecting a match, where m is the real address size supported by the implementation. In virtual real addressing mode, the high order 24 bits of the EA are ignored for the purpose of detecting a match. In 32-bit mode the high-order 32 bits of the EA are treated as zeros for the purpose of detecting a match.

A watched range must not cross any of the following boundaries in their respective circumstances. If it does, the facility will operate correctly with respect to the vari-

ous control parameters (e.g., PRIVM), but the set of EAs that cause matches is undefined.

- the 2<sup>64</sup>-byte boundary when HPT translation is being performed in other than virtual real addressing mode (i.e., a range that includes the last and first byte of the 2<sup>64</sup>-byte effective address space)
- a 2<sup>m</sup>-byte boundary when the thread is in hypervisor or ultravisor real addressing mode (i.e., a range that, if the corresponding EAs were used to address storage on a design that ignores the high-order bits of the 60-bit real address that are not supported by the implementation, would include the last and first byte of the 2<sup>m</sup>-byte real address space)
- a 2<sup>62</sup>-byte boundary when Radix Tree translation is being performed (i.e., a quadrant boundary)
- a 2<sup>40</sup>-byte boundary when HPT translation is being performed in virtual real addressing mode (i.e., a range that, if the corresponding EAs were used to address storage, would include the last and first byte of the reserved virtual segment)
- a 2<sup>32</sup>-byte boundary when the thread is in 32-bit mode (i.e., a range that, if the corresponding EAs were used to address storage, would include the last and first byte of the 2<sup>32</sup>-byte effective address space)

If the above conditions are satisfied, it is undefined whether a match occurs in the following cases.

- The instruction is *Store Conditional* but the store is not performed
- The instruction is **dcbz**. (For the purpose of determining whether a match occurs, **dcbz** is treated as a *Store*.)

The *Cache Management* instructions other than **dcbz** never cause a match.

A Data Address Watchpoint match causes a Data Storage exception or a Hypervisor Data Storage exception (see Section 7.5.3, “Data Storage Interrupt (DSI)” on page 1280 and Section 7.5.16, “Hypervisor Data Storage Interrupt (HDSI)” on page 1292). If a match occurs, some or all of the bytes of the storage operand may have been accessed; however, if a *Store* instruction causes the match, the storage operand is not modified if the instruction is one of the following:

- any *Store* instruction that causes an atomic access

**Programming Note**

The Data Address Watchpoint mechanism does not apply to instruction fetches.

**Programming Note**

The limitations of the Data Address Watchpoint mechanism may lead to uncertainties when attempting to interpret a reported match. For example, there is no explicit indication of which watchpoint matched. The watched address ranges could overlap, for example, as a result of the doubleword granularity of the address range specification, making it unclear which watchpoint matched. Even if one of the overlapping watchpoints was set to match only for stores and the other only for loads, the existence of the Atomic Memory Operations would make the reporting of a store in the DSISR inconclusive. For a given watchpoint, the doubleword granularity may make the validity of the match uncertain because only the starting address of the match is reported without a length. In such cases, it is necessary to examine the operand that caused the match to determine what actually happened.

**Programming Note**

Implementations that comply with versions of the architecture that precede Version 2.02 do not provide the DABRX (now replaced by DAWRXn). Forward compatibility for software that was written for such implementations (and uses the Data Address Breakpoint facility) can be obtained by setting DAWRXn<sub>60:63</sub> to 0b0111.

## Chapter 11. Performance Monitor Facility

### 11.1 Overview

The Performance Monitor facility provides a means of collecting information about program and system performance.

### 11.2 Performance Monitor Operation

The Performance Monitor facility includes the following features.

- an MSR bit
  - PMM (Performance Monitor Mark), which can be used to select one or more programs for monitoring
- registers
  - PMC1 - PMC6 (Performance Monitor Counters 1 - 6), which count events
  - MMCR0, MMCR1, MMCR2, MMCR3 and MMCRA (Monitor Mode Control Registers 0, 1, 2, 3 and A), which control the Performance Monitor facility
  - SIAR, SDAR, SIER, SIER2 and SIER3 (Sampled Instruction Address Register, Sampled Data Address Register, Sampled Instruction Event Register, Sampled Instruction Event Register 2 and Sampled Instruction Event Register 3), which contain the address of the “sampled instruction” and of the “sampled data,” and additional information about the “sampled instruction” (see Section 11.4.8 - Section 11.4.10).
- the Performance Monitor interrupt and Performance Monitor event-based branch, which can be caused by monitored conditions and events.
  - A “counter negative condition” exists when the value in a PMC is negative (i.e., when bit 0 of the PMC is 1). A “Time Base transition event” occurs when a selected bit of the Time Base changes from 0 to 1 (the bit is selected by a field in MMCR0). The term “condition or event” is used as an abbreviation for “counter negative condition or Time Base transition event”. A condition or event can be caused implicitly by the hardware (e.g., incrementing a PMC) or explicitly by software (*mtspr*).
  - A condition or event is enabled if the corresponding “Enable” bit (i.e., PMC1CE, PMCjCE, or TBEE) in MMCR0 is 1. The occurrence of an enabled condition or event can have side effects within the Performance Monitor, such as causing the PMCs to cease counting.
  - An enabled condition or event causes a Performance Monitor alert if Performance Monitor alerts are enabled by the corresponding “Enable” bit in MMCR0. Another cause of a Performance Monitor alert is the threshold event counter reaching its maximum value (see Section 11.4.3). A single Performance Monitor alert may reflect multiple enabled conditions and events.
  - When a Performance Monitor alert occurs, MMCR0<sub>PMAO</sub> is set to 1 and the writing of BHRB entries, if in process, is suspended.
 

When the contents of MMCR0<sub>PMAO</sub> change from 0 to 1, a Performance Monitor exception will come into existence within a reasonable period of time. When the contents of MMCR0<sub>PMAO</sub> change from 1 to 0, the existing Performance Monitor exception, if any, will cease to exist within a reasonable period of time, but not later than the completion of the next context synchronizing instruction or event.
  - A Performance Monitor exception causes one of the following.
    - If MSR<sub>EE</sub> = 1, MMCR0<sub>EBE</sub> = 0, and either HFSCR<sub>PM</sub>=1 or the thread is in hypervisor state, an interrupt occurs.
    - If MSR<sub>PR</sub> = 1, MMCR0<sub>EBE</sub> = 1, a Performance Monitor event-based exception occurs if

Many aspects of the operation of the Performance Monitor are summarized by the following hierarchy, which is described starting at the lowest level.

BESCR<sub>PME</sub>=1, provided that event-based exceptions are enabled by FSCR<sub>EBB</sub> and HFSCR<sub>EBB</sub>. When a Performance Monitor event-based exception occurs, an event-based branch is generated if BESCR<sub>GE</sub>=1.

#### Programming Note

The Performance Monitor can be effectively disabled (i.e., put into a state in which Performance Monitor SPRs are not altered and Performance Monitor exceptions do not occur) by setting MMCR0 to 0x0000\_0000\_8000\_0000.

The Performance Monitor also controls when BHRB entries are written, the instruction filters that are used when writing BHRB entries, and the availability of the BHRB in problem state. It also controls whether Performance Monitor exceptions cause Performance Monitor event-based exceptions or Performance Monitor interrupts. See Section 11.4.4.

## 11.3 No-op Instructions Reserved for the Performance Monitor

The following forms of the **and** x,x,x instruction are reserved for exclusive use by the Performance Monitor.

- **and** x,x,x, where x=0,1.

#### Programming Note

An example usage of a probe no-op by the Performance Monitor is to measure branch prediction effectiveness. In order to do this, one of probe no-ops is inserted in various sections of the code in which branch prediction efficiency is being studied. The Performance Monitor registers are then set up as follows.

##### MMCR0:

ES=010 (only probe no-ops eligible for sampling)  
SM=00 (all eligible instructions)  
SE=1 (enable random sampling).  
Other fields in MMCR0 are set as desired.

##### MMCR1:

PMC1SEL=E0 (count PMC1 on dispatch)  
PMC4SEL=E0 (count PMC4 on completion)  
Other counters initialized as desired.

**MMCR2:** Initialize as desired.

##### MMCR0:

FC is set to 0 to stop freezing the counters  
PMAE is set to 1 to enable PMU alerts.  
Other fields in MMCR0 are set as desired.

Subsequently, when a PMU alert occurs, PMCs 1 and 4 can be read. The difference between the two counter values provides an indication of branch prediction effectiveness in the areas of the code in which the probe no-op was inserted.

## 11.4 Performance Monitor Facility Registers

The Performance Monitor registers count events, control the operation of the Performance Monitor, and provide associated information.

The elapsed time between the execution of an instruction and the time at which events due to that instruction have been reflected in Performance Monitor registers is not defined. No means are provided by which software can ensure that all events due to preceding instructions have been reflected in Performance Monitor registers. Similarly, if the events being monitored may be caused by operations that are performed out-of-order, no means are provided by which software can prevent such events due to subsequent instructions from being reflected in Performance Monitor registers. Thus the contents obtained by reading a Performance Monitor register may not be precise: it may fail to reflect some events due to instructions that precede the **mfspr** and may reflect some events due to instructions that follow the **mfspr**. This lack of precision applies regardless of whether the state of the thread is such that the register is subject to change by the hardware at the time the **mfspr** is executed. Similarly, if an **mtspr** instruction is executed that changes the contents of the Time Base,

the change is not guaranteed to have taken effect with respect to causing Time Base transition events until after a subsequent context synchronizing instruction has been executed.

If an *mtspr* instruction is executed that changes the value of a Performance Monitor register other than SIAR, SDAR, and SIER, the change is not guaranteed to have taken effect until after a subsequent context synchronizing instruction has been executed (see Chapter 13. “Synchronization Requirements for Context Alterations” on page 1353).

#### Programming Note

Depending on the events being monitored, the contents of Performance Monitor registers may be affected by aspects of the runtime environment (e.g., cache contents) that are not directly attributable to the programs being monitored.

## 11.4.1 Performance Monitor SPR Numbers

The Performance Monitor registers have two sets of SPR numbers, one set that is non-privileged and another set that is privileged.

For the purpose of explanation elsewhere in the architecture, the non-privileged registers are divided into two groups as defined below.

- A: The non-privileged read/write Performance Monitor registers (i.e., the PMCs, MMCR0, MMCR2, and MMCR3 at SPR numbers 771-776, 779, 769, and 770, respectively)
- B: The non-privileged read-only Performance Monitor registers (i.e., SIER2, SIER3, MMCR3, SIER, SIAR, SDAR, and MMCR1 at SPR numbers 736, 737, 738, 768, 780, 781, and 782, respectively).

The SPRs in group B are treated as undefined registers for write (*mtspr*) operations. See the *mtspr* instruction description in Section 5.4.4 for additional information.

When the PCR makes a register in either group A or B unavailable in problem state, that SPR is not included in group A or B.

#### Programming Note

Older versions of Performance Monitor facilities used different sets of SPR numbers from those shown in Section 5.4.4. (All 32-bit PowerPC implementations used a different set.)

## 11.4.2 Performance Monitor Counters

The six Performance Monitor Counters, PMC1 through PMC6, are 32-bit registers that count events.

PMC1
PMC2
PMC3
PMC4
PMC5
PMC6

32

63

**Figure 83. Performance Monitor Counter registers**

PMC1 - PMC4 are referred to as “programmable” counters since the events that can be counted can be specified by the program. The events that are counted by each counter are specified in MMCR1.

PMC5 and PMC6 are not programmable and can be specified as being part of the Performance Monitor Facility or not part of it. PMC5 counts instructions completed, and PMC6 counts cycles. The PMCC field in MMCR0 controls whether or not PMCs 5-6 are part of the Performance Monitor Facility, and the result of accessing these counters when they are not part of the Performance Monitor Facility.

#### Programming Note

PMC5 and PMC6 are defined to facilitate calculating basic performance metrics such as cycles per instruction (CPI).

#### Programming Note

Software can use a PMC to “pace” the collection of Performance Monitor data. For example, if it is desired to collect event counts every *n* cycles, software can specify that a particular PMC count cycles, and set that PMC to 0x8000\_0000 - *n*. The events of interest would be counted in other PMCs. The counter negative condition that will occur after *n* cycles can, with the appropriate setting of MMCR bits, cause counter values to become frozen, cause a Performance Monitor exception to occur, etc.

### 11.4.2.1 Event Counting and Sampling

The PMCs are enabled to count unless they are “frozen” by one or more of the “freeze counters” fields in MMCR0 or MMCR2.

Each of PMC’s 1-4 can be configured, using MMCR1, to count “continuous” events (events that can occur at any time), or to count “randomly sampled” events (or “sampled” events) that are associated with the execution of randomly sampled instructions.

Continuous events always cause the counters to count (unless counters are frozen). These events are specified for each counter by using encodes F0-FF in the PMC<sub>n</sub> Selector fields in MMCR1.

Randomly sampled events can cause the counters to count only when random sampling has been enabled by setting MMCR<sub>ASE</sub>=1. The types of instructions that are sampled are specified in MMCR<sub>ASM</sub> and MMCR<sub>ES</sub>. Randomly sampled events are specified for each counter by using encodes E0-EF in the PMC<sub>n</sub> Selector fields in MMCR1.

#### Programming Note

A typical sequence of operations that enables use the PMCs is as follows.

- Freeze the counters by setting MMCR<sub>0FC</sub>=1.
- Set control fields in MMCR0 and MMCR2 that control counting in various privilege states and other modes, and that enable counter negative conditions.
- Initialize the events to be counted by PMCs 1-4 using the PMC<sub>n</sub> Selector fields in MMCR1.
- Specify the BHRB filtering mode, threshold event Counter events, and whether or not random sampling is enabled in the corresponding fields in MMCR1.
- Initialize the PMCs to the values desired. For example, in order to configure a counter to cause a counter negative condition after *n* counts, that counter would be initialized to  $2^{32-n}$ .
- Set MMCR<sub>0FC</sub> to 0 to disable freezing the counters, and set MMCR<sub>0PMAE</sub> to 1 if a Performance Monitor alert (and the corresponding Performance Monitor interrupt) is desired when an enabled condition or event occurs. (See Section 11.2 for the definition of enabled condition or event.)

When the Performance Monitor alert occurs, the program would typically read the values of the counters as well as the contents of SIAR, SDAR, SIER as needed in order to extract the information that was being monitored.

See Sections 11.4.4 - 11.4.10 for information regarding MMCRs, SIAR, SDAR, and SIER, and some additional usage examples.

### 11.4.3 Threshold Event Counter

The threshold event counter and associated controls are in MMCR1 (see Section 11.4.7). When Performance Monitor alerts are enabled (MMCR<sub>0PMAE</sub>=1), this counter begins incrementing from value 0 upon each occurrence of the event specified in the Threshold

Event Counter Event (TECE) field after the event specified by the Threshold Start Event (TS) field occurs. The counter stops incrementing when the event specified in the Threshold End Event (TE) field occurs. The counter subsequently freezes until the event specified in the TS field is again recognized, at which point it restarts incrementing from value 0 as explained above. If the counter reaches its maximum value or a Performance Monitor alert occurs, incrementing stops. After the Performance Monitor alert occurs, the contents of the threshold event counter are not altered by the hardware until software sets MMCR<sub>0PMAE</sub> to 1.

#### Programming Note

Because hardware can modify the contents of the threshold event counter when random sampling is enabled (MMCR<sub>ASE</sub>=1) and MMCR<sub>0PMAE</sub>=1 at any time, any value written to the threshold event counter under this condition may be immediately overwritten by hardware.

The threshold event counter value is represented as a 3-bit integral power of 4, multiplied by an 8-bit integer. The exponent is contained in MMCR<sub>TECX</sub>, and the multiplier is contained in MMCR<sub>TECM</sub>. For a given counter exponent, *e*, and multiplier, *m*, the number represented is as follows:

$$N = 4^e \times m$$

This counter format allows the counter to represent a range of 0 through approximately 4 million counts with many fewer bits than would be required by a binary counter.

To represent a given counter value, hardware uses as *e* the smallest 3-bit integer for which an 8-bit integer exists such that the given counter value can be expressed using this format.

#### Programming Note

Software can obtain the number *N* from the contents of the threshold event counter by shifting the multiplier left twice times the value contained in the exponent.

The value in the counter is the exact number of events that occur for values from 0 through the maximum multiplier value (255), within 3 events of the exact value for values from 256 - 1020 (or  $255 \times 4$ ), within 15 events of the exact value for values from 1024 - 4080 (or  $255 \times 4^2$ ), and so on. This represents a relative error in event count of less than 1.6%, which is expected to be sufficient for most situations in which a count of events between a start and end event is required.

**Programming Note**

When using the threshold event counter, software typically specifies a “threshold counter exceeded n” event in MMCR1. This enables a PMC to count the number of times the counter exceeded a specified threshold value during the time Performance Monitor alerts were enabled.

## 11.4.4 Monitor Mode Control Register 0

Monitor Mode Control Register 0 (MMCR0) is a 64-bit register as shown below.

**Figure 84. Monitor Mode Control Register 0**

MMCR0 is used to control multiple functions of the Performance Monitor. Some fields of MMCR0 are altered by the hardware when various events occur.

The following notation is used in the definitions below. “PMCs” refers to PMCs 1 - n and “PMCj” refers to PMCj, where  $2 \leq j \leq n$ .  $n=4$  when  $MMCR0_{PMCC}=0b11$  and  $n=6$  otherwise.

When  $MMCR0_{PMCC}$  is set to 0b10 or 0b11, providing problem state programs read/write access to MMCR0, only FC, PMAE, PMAO can be accessed. All other bits are not changed when *mtspr* is executed in problem state, and all other bits return 0s when *mfspr* is executed in problem state.

**Programming Note**

When  $PMCC=0b10$  or  $0b11$ , problem state programs have write access to MMCR0 in order to enable event-based branch routines to reset the FC bit after it has been set to 1 as a result of an enabled condition or event ( $FCECE=1$ ). During event processing, the event-based branch handler would write the desired initial values to the PMCs and reset the FC bit to 0. PMAO and PMAE can also be set to their appropriate values during the same write operation before returning.

The bit definitions of MMCR0 are as follows.

Bit(s)	Description
0:31	Reserved
32	<b>Freeze Counters (FC)</b>
0	The PMCs are incremented (if permitted by other MMCR bits).
1	The PMCs are not incremented.
The hardware sets this bit to 1 when an enabled condition or event occurs and $MMCR0_{FCECE}=1$ .	

33 **Freeze Counters in Privileged State (FCS)**

- 0 The PMCs are incremented (if permitted by other MMCR bits).
- 1 The PMCs are not incremented if  $MSR_{HV\_PR}=0b00$ .

34 **Conditionally Freeze Counters and BHRB in Problem State (FCP)**

If the value of bit 51 (FCPC) is 0, this field has the following meaning.

- 0 The PMCs are incremented (if permitted by other MMCR bits) and entries are written into the BHRB (if permitted by the BHRB Instruction Filtering Mode field in MMCR0).
- 1 The PMCs are not incremented, and entries are not written into the BHRB, if  $MSR_{PR}=1$ .

If the value of bit 51 (FCPC) is 1, this field has the following meaning.

- 0 The PMCs are not incremented, and entries are not written into the BHRB, if  $MSR_{HV\_PR}=0b01$ .
- 1 The PMCs are not incremented, and entries are not written into the BHRB, if  $MSR_{HV\_PR}=0b11$ .

**Programming Note**

In order to freeze counters in problem state regardless of  $MSR_{HV}$ ,  $MMCR0_{FCPC}$  must be set to 0 and  $MMCR0_{FCP}$  must be set to 1.

35 **Freeze Counters while Mark = 1 (FCM1)**

- 0 The PMCs are incremented (if permitted by other MMCR bits).
- 1 The PMCs are not incremented if  $MSR_{PMM}=1$ .

36 **Freeze Counters while Mark = 0 (FCM0)**

- 0 The PMCs are incremented (if permitted by other MMCR bits).
- 1 The PMCs are not incremented if  $MSR_{PMM}=0$ .

37 **Performance Monitor Alert Enable (PMAE)**

- 0 Performance Monitor alerts are disabled and BHRB entries are not written.
- 1 Performance Monitor alerts are enabled, and BHRB entries are written (if enabled by other bits) until a Performance Monitor alert occurs, at which time:
  - $MMCR0_{PMAE}$  is set to 0
  - $MMCR0_{PMAO}$  is set to 1

**Programming Note**

Software can set this bit and  $\text{MMCR0}_{\text{PMAO}}$  to 0 to prevent Performance Monitor exceptions.

Software can set this bit to 1 and then poll the bit to determine whether an enabled condition or event has occurred. This is especially useful for software that runs with  $\text{MSR}_{\text{EE}}=0$ .

In earlier versions of the architecture that lacked the concept of Performance Monitor alerts, this bit was called Performance Monitor Exception Enable (PMXE).

38 **Freeze Counters on Enabled Condition or Event (FCECE)**

- 0 The PMCs are incremented (if permitted by other MMCR bits).
- 1 The PMCs are incremented (if permitted by other MMCR bits) until an enabled condition or event occurs when  $\text{MMCR0}_{\text{TRIGGER}}=0$ , at which time:
  - $\text{MMCR0}_{\text{FC}}$  is set to 1

If the enabled condition or event occurs when  $\text{MMCR0}_{\text{TRIGGER}}=1$ , the FCECE bit is treated as if it were 0.

39:40 **Time Base Selector (TBSEL)**

This field selects the Time Base bit that can cause a Time Base transition event (the event occurs when the selected bit changes from 0 to 1).

- 00 Time Base bit 47 is selected.
- 01 Time Base bit 51 is selected.
- 10 Time Base bit 55 is selected.
- 11 Time Base bit 63 is selected.

**Programming Note**

Time Base transition events can be used to collect information about activity, as revealed by event counts in PMCs and by addresses in SIAR and SDAR, at periodic intervals.

In multi-threaded systems in which the Time Base registers are synchronized among the threads, Time Base transition events can be used to correlate the Performance Monitor data obtained by the several threads. For this use, software must specify the same TBSEL value for all the threads in the system.

Because the frequency of the Time Base is implementation-dependent, software should invoke a system service program to obtain the frequency before choosing a value for TBSEL.

41 **Time Base Event Enable (TBEE)**

- 0 Time Base transition events are disabled.
- 1 Time Base transition events are enabled.

**Programming Note**

When PMC3 is configured to count the occurrence of Time Base transition events, the events are counted regardless of the value of  $\text{MMCR0}_{\text{TBEE}}$ . (See Section 11.4.5.) The occurrence of a Time Base transition causes a Performance Monitor alert only if  $\text{MMCR0}_{\text{TBEE}}=1$ .

42 **BHRB Available (BHRBA)**

This field controls whether the BHRB instructions are available in problem state. If an attempt is made to execute a BHRB instruction in problem state when the BHRB instructions are not available, a Facility Unavailable interrupt will occur.

- 0 *clrbhrb* and *mfbhrbe* are not available in problem state.
- 1 *clrbhrb* and *mfbhrbe* are available in problem state unless they have been made unavailable by some other register.

43 **Performance Monitor Event-Based Branch Enable (EBE)**

This field controls whether Performance Monitor event-based branches and Performance Monitor event-based exceptions are enabled.

When Performance Monitor event-based branches and exceptions are disabled, no Performance Monitor event-based branches or exceptions occur regardless of the state of  $\text{BESCR}_{\text{PME}}$ .

- 0 Performance Monitor event-based branches and exceptions are disabled.
- 1 Performance Monitor event-based branches and exceptions are enabled.

#### Programming Note

In order to enable a problem state applications to use the event-based Branch facility for Performance Monitor events, privileged software initializes MMCR1 to specify the events to be counted, and sets MMCR2, and MMCRA to specify additional sampling controls. MMCR0 should be initialized with PMCC set to 0b10 or 0b11 (to give problem state access to various Performance Monitor registers), PMAE and PMAO set to 0s (disabling Performance Monitor alerts), and EBE set to 1 (enabling Performance Monitor event-based branches and exceptions to occur). If the Event-Based Branch facility has not been enabled in the FSCR and HFSCR, it must be enabled in these registers as well.

The above operations by the operating system enable the application to control Performance Monitor event-based branching by means of BESCR<sub>PME</sub> (to enable or disable Performance Monitor event-based branching) and MMCR0<sub>PMAE</sub> (to enable or disable Performance Monitor alerts).

#### 44:45 PMC Control (PMCC)

This field controls whether or not PMCs 5 - 6 are included in the Performance Monitor, and the accessibility of groups A and B (see Section 11.4.1) of non-privileged SPRs in problem state as described below.

#### Programming Note

The PMCC field does not affect the behavior of the privileged Performance Monitor registers (SPRs 784-792, 795-798); accesses to these SPRs in problem state result in Privileged Instruction type Program interrupts.

The PMCC field also does not affect the behavior of write operations to group B; write operations to SPRs in group B are treated as not supported regardless of privilege state. See the *mtspr* instruction description in Section 5.4.4 for additional information on accessing SPRs that are not supported.

#### Programming Note

When the PCR makes SPRs unavailable in problem state, they are treated as undefined, and they are not included in groups A or B regardless of the value of PMCC. Thus when the PCR indicates a version of the architecture prior to V. 2.07 (i.e., PCR<sub>v2.06</sub>=1), the PMCC field does not affect SPRs MMCR2 or SIER, which are newly-defined in V. 2.07; these SPRs are treated as undefined registers. Accesses to them in problem state result in Hypervisor Emulation Assistance interrupts regardless of the value of PMCC, and Facility Unavailable interrupts do not occur for them. See Section 2.5 for additional information.

- 00 PMCs 5 - 6 are included in the Performance Monitor.

Group A is read-only, and group B read access behavior is conditional on MMCR0<sub>PMCCEXT</sub> in problem state. If an attempt is made to write to an SPR in group A in problem state, a Hypervisor Emulation Assistance interrupt will occur.

- 01 PMCs 5 - 6 are included in the Performance Monitor.

Group A is not allowed to be read or written in problem state, and group B is not allowed to be read in problem state. If an attempt is made, in problem state, to read or write to an SPR in group A, or to read from an SPR in group B, a Facility Unavailable interrupt will occur.

- 10 PMCs 5 - 6 are included in the Performance Monitor.

Group A is allowed to be read and written in problem state, and group B except for MMCR1 (SPR 782) is allowed to be read in problem state. If an attempt is made to read MMCR1 in problem state, a Facility Unavailable interrupt will occur.

- 11 PMCs 5 - 6 are not included in the Performance Monitor. See Section 11.4.2 for details.

Group A except for PMCs 5-6 (SPRs 775,776) is allowed to be read and written in problem state, and group B except for MMCR1 (SPR 782) is allowed to be read in problem state.

If an attempt is made, in problem state, to read or write to PMCs 5-6 (SPRs 775,776), or to read from MMCR1, a Facility Unavailable interrupt will occur.

When an SPR is made available by the PMCC field, it is available only if it has not

been made unavailable by the HFSCR (see Section 7.2.13).

#### Programming Note

In order to give problem state programs the same level of access to the Performance Monitor registers as was specified in Power ISA V 2.06, PMCC must be set to 0b00 (restricting access to read-only) and the PCR should indicate Version 2.06 (restricting access to the set of Performance Monitor SPRs and SPR bits that were defined in V 2.06).

When PMCC=0b00 and a write operation to a Performance Monitor register in group A or B is attempted in problem state, a Hypervisor Emulation Assistance interrupt occurs in order to maintain compatibility with V 2.06. For other values of PMCC, write or read operations to group A and read operations from group B that are not allowed result in Facility Unavailable interrupts. Facility Unavailable interrupts provide the operating system with more information about the type of disallowed access that was attempted than the Hypervisor Emulation Assistance interrupt provides. See Section 7.2.12 for additional information.

#### Programming Note

In order to prevent applications from accessing Performance Monitor registers, PMCC is set to 0b01.

In order to allow applications limited control over the Performance Monitor, PMCC is set to 0b10 or 0b11. These values are also used when Performance Monitor event-based branches are enabled.

46:47 **Reserved**

48 **PMC1 Condition Enable** (PMC1CE)

This bit controls whether counter negative conditions due to a negative value in PMC1 are enabled.

- 0 Counter negative conditions for PMC1 are disabled.
- 1 Counter negative conditions for PMC1 are enabled.

49 **PMCj Condition Enable** (PMCjCE)

This bit controls whether counter negative conditions due to a negative value in any PMCj (i.e., in any PMC except PMC1) are enabled.

- 0 Counter negative conditions for all PMCjs are disabled.
- 1 Counter negative conditions for all PMCjs are enabled.

50 **Trigger** (TRIGGER)

- 0 The PMCs are incremented (if permitted by other MMCR bits).
- 1 PMC1 is incremented (if permitted by other MMCR bits). The PMCjs are not incremented until PMC1 is negative or an enabled condition or event occurs, at which time:
  - the PMCjs resume incrementing (if permitted by other MMCR bits)
  - MMCR0<sub>TRIGGER</sub> is set to 0

See the description of the FCECE bit, above, regarding the interaction between TRIGGER and FCECE.

#### Programming Note

Uses of TRIGGER include the following.

- Resume counting in the PMCjs when PMC1 becomes negative, without causing a Performance Monitor interrupt. Then freeze all PMCs (and optionally cause a Performance Monitor interrupt) when a PMCj becomes negative. The PMCjs then reflect the events that occurred between the time PMC1 became negative and the time a PMCj becomes negative. This use requires the following MMCR0 bit settings.
  - TRIGGER=1
  - PMC1CE=0
  - PMCjCE=1
  - TBEE=0
  - FCECE=1
  - PMAE=1 (if a Performance Monitor interrupt is desired)
- Resume counting in the PMCjs when PMC1 becomes negative, and cause a Performance Monitor interrupt without freezing any PMCs. The PMCjs then reflect the events that occurred between the time PMC1 became negative and the time the interrupt handler reads them. This use requires the following MMCR0 bit settings.
  - TRIGGER=1
  - PMC1CE=1
  - TBEE=0
  - FCECE=0
  - PMAE=1

51 **Freeze Counters and BHRB in Problem State Condition** (FCPC)

This bit controls the meaning of bit 34 (FCP). See the definition of bit 34 for details.

**Programming Note**

In order to enable the FCP bit to freeze counters in problem state regardless of  $MSR_{HV}$ ,  $MMCR0_{FCPC}$  must be set to 0.

52 Reserved

53 **Freeze Counters, sampling and threshold counting in Ultravisor State** (FCU)

- 0 The PMCs are incremented (if permitted by other MMCR bits).
- 1 The PMCs are not incremented, if  $MSR_S$   
 $HV_{PR}=0b110$ .

54 **PMCC Extended** (PMCCEXT)

- 0 If  $MMCR0_{PMCC} = b00$ , a SPR in group B is allowed to be read in problem state.
- 1 If  $MMCR0_{PMCC} = b00$  and an attempt is made to read from an SPR in group B, a Facility Unavailable Interrupt will occur.

55 **Control Counters 5 - 6 with Run Latch** (CC5-6RUN)

When  $MMCR0_{PMCC} = b11$ , the setting of this bit has no effect; otherwise it is defined as follows.

- 0 PMCs 5 and 6 are incremented if  $CTRL_{RUN}=1$  (if permitted by other MMCR bits).
- 1 PMCs 5 and 6 are incremented regardless of the value of  $CTRL_{RUN}$  (if permitted by other MMCR bits).

56 **Performance Monitor Alert Occurred** (PMAO)

- 0 A Performance Monitor alert has not occurred since the last time software set this bit to 0.
- 1 A Performance Monitor alert has occurred since the last time software set this bit to 0.

This bit is set to 1 by the hardware when a Performance Monitor alert occurs. This bit can be set to 0 only by the *mtspr* instruction.

**Programming Note**

Software can set this bit to 1 and set PMAE to 0 to simulate the occurrence of a Performance Monitor alert.

Software should set this bit to 0 after handling the Performance Monitor alert.

57 **Reserved**

58 **Freeze Counters 1-4** (FC1-4)

- 0 PMC1 - PMC4 are incremented (if permitted by other MMCR bits).
- 1 PMC1 - PMC4 are not incremented.

59 **Freeze Counters 5-6** (FC5-6)

- 0 PMC5 - PMC6 are incremented (if permitted by other MMCR bits).
- 1 PMC5 - PMC6 are not incremented.

60:61 Reserved

62 **Freeze Counters 1-4 in Wait State** (FC1-4WAIT)

- 0 PMCs 1-4 are incremented (if permitted by other MMCR bits).
- 1 PMCs 1-4, except for PMCs counting events that are not controlled by this bit, are not incremented if  $CTRL_{RUN}=0$ .

**Programming Note**

When PMC 1 is counting cycles, it is not controlled by this bit. See the description of the F0 event in Section 11.4.5.

63 **Freeze Counters in Hypervisor State** (FCH)

- 0 The PMCs are incremented (if permitted by other MMCR bits).
- 1 The PMCs are not incremented if  $MSR_S$   
 $HV_{PR}=0b010$ .

## 11.4.5 Monitor Mode Control Register 1

Monitor Mode Control Register 1 (MMCR1) is a 64-bit register as shown below.

**Figure 85. Monitor Mode Control Register 1**

MMCR1 enables software to specify the events that are counted by the PMCs.

In the following descriptions, events due to randomly sampled instructions occur only if random sampling is enabled ( $MMCR_{ASE}=1$ ); all other events occur whenever the event specification is met regardless of the value of  $MMCR_{ASE}$ .

Various events defined below refer to “threshold A” through “threshold H”. The table below specifies the number of threshold event counter events corresponding to each of these thresholds.

Threshold	Events
A	4096
B	32
C	64
D	128
E	256
F	512
G	1024
H	2048

Table 6: Event Counts for thresholds A-H

The bit definitions of MMCR1 are as follows. Implementation-dependent MMCR1 bits that are not supported are treated as reserved.

**Bit(s) Description**

0:31	Problem state access (SPR 782) Reserved  Privileged access (SPR 782 or 798) Implementation-dependent
32:39	<b>PMC1 Selector</b> (PMC1SEL) The value of PMC1SEL specifies the event to be counted by PMC1 as defined below. All values in the range of E0 - FF that are not specified below are reserved.
	<b>Hex Event</b>
00	Disable events. (No events occur.)
01-BF	Implementation-dependent
C0-DF	Reserved

The following events can occur only when random sampling is enabled ( $MMCR_{SE}=1$ ). The sampling modes corresponding to each event are listed in parentheses. (The sampling mode is specified in  $MMCR_{SM}$ .)

- E0 The thread has dispatched a randomly sampled instruction. (RIS)
- E2 The thread has completed a randomly sampled *Branch* instruction for which the branch was taken. (RIS, RBS)
- E4 The thread has failed to locate a randomly sampled instruction in the primary instruction cache. (RIS)
- E6 The threshold event counter has exceeded the number of events corresponding to threshold A (see Table 6). (RIS, RLS, RBS)
- E8 The threshold event counter has exceeded the number of events corresponding to threshold E (see Table 6). (RIS, RLS, RBS)

EA The thread filled a block in a data cache with data that were accessed by a randomly sampled *Load* instruction. (RIS, RLS)

EC The threshold event counter has reached its maximum value. (RIS, RLS, RBS)

The following events can occur regardless of whether random sampling is enabled.

F0 A cycle has occurred. This event is not controlled by  $MMCR_{FC1-4WAIT}$ .

F2 A cycle has occurred in which the thread completed one or more instructions.

F4 The thread has completed a *Floating-Point*, *Vector Floating-Point*, or *VSX Floating-Point* instruction other than a *Load* or *Store* instruction to the point at which it has reported all exceptions it will cause.

F6 The thread has failed to locate an ERAT entry during instruction address translation.

F8 A cycle has occurred during which all previously initiated instructions have completed and no instructions are available for initiation.

FA A cycle has occurred during which the RUN bit of the CTRL register for one or more threads of the multi-threaded processor was set to 1.

FC A load type instruction finished. If the instruction caused more than one reference, only one will be counted.

FE The thread has completed an instruction.

40:47 **PMC2 Selector** (PMC2SEL)

The value of PMC2SEL specifies the event to be counted by PMC2 as defined below. All values in the range of E0 - FF that are not specified below are reserved.

**Hex Event**

00	Disable events. (No events occur.)
01-BF	Implementation-dependent
C0-DF	Reserved

The following events can occur only when random sampling is enabled ( $MMCR_{SE}=1$ ). The sampling modes corresponding to each event are listed in parentheses. (The sampling mode is specified in  $MMCR_{SM}$ .)

E0 The thread has obtained the data for a randomly sampled *Load* instruction from storage that did not reside in any cache. (RIS, RLS)

E2 The thread has failed to locate the data for a randomly sampled *Load* instruction in the primary data cache. (RIS, RLS)

- E4 The thread filled a block in the primary data cache with data that were accessed by a randomly sampled *Load* instruction and obtained from a location other than the secondary or tertiary cache. (RIS, RLS)
- E6 The threshold event counter has exceeded the number of events corresponding to threshold B (see Table 6). (RIS, RLS, RBS)
- E6 The threshold event counter has exceeded the number of events corresponding to threshold F (see Table 6). (RIS, RLS, RBS)

The following events can occur regardless of whether random sampling is enabled.

- F0 The thread has completed a *Store* instruction to the point at which it has reported all the exceptions it will cause.
- F2 The thread has dispatched an instruction.
- F4 A cycle has occurred during which the RUN bit of the thread's CTRL register contained 1.
- F6 The thread has failed to locate an ERAT entry during data address translation, and a new ERAT entry corresponding to the data effective address has been written.
- F8 An external interrupt for the thread has occurred.
- FA The thread has completed a *Branch* instruction for which the branch was taken.
- FC The thread has failed to locate an instruction in the primary cache.
- FE The thread has filled a block in the primary data cache with data that were accessed by a *Load* instruction and obtained from a location other than the secondary cache.

#### 48:55 **PMC3Selector** (PMC3SEL)

The value of PMC3SEL specifies the event to be counted by PMC3 as defined below. All values in the range of E0 - FF that are not specified below are reserved.

Hex	Event
-----	-------

- |       |                                    |
|-------|------------------------------------|
| 00    | Disable events. (No events occur.) |
| 01-BF | Implementation-dependent           |
| C0-DF | Reserved                           |

The following events can occur only when random sampling is enabled (MMCR<sub>ASE</sub>=1). The sampling modes corresponding to each event are listed in parentheses. (The sampling mode is specified in MMCR<sub>ASM</sub>.)

- E2 The thread has completed a randomly sampled *Store* instruction to the point at which it has reported all exceptions it will cause. (RIS,RLS)

- E4 The thread has mispredicted either whether or not the branch would be taken, or if taken, the target address of a randomly sampled *Branch* instruction. (RIS, RBS)
- E6 The thread has failed to locate an ERAT entry during data address translation for a randomly sampled instruction. (RIS,RLS)
- E8 The threshold event counter has exceeded the number of events corresponding to threshold C (see Table 6). (RIS, RLS, RBS)
- EA The threshold event counter has exceeded the number of events corresponding to threshold G (see Table 6). (RIS, RLS, RBS)

The following events can occur regardless of whether random sampling is enabled.

- F0 The thread has attempted to store data in the primary data cache but no block corresponding to the real address existed.
- F2 The thread has dispatched an instruction.
- F4 The thread has completed an instruction when the RUN bit of the CTRL register for all threads on the multi-threaded processor contained 1.
- F6 The thread has filled a block in the primary data cache with data that were accessed by a *Load* instruction.
- F8 A Time Base transition event has occurred for the thread. This event is counted regardless of whether or not Time Base transition events are enabled by MMCR<sub>0TBEE</sub>.
- FA The thread has loaded an instruction from a higher level cache than the tertiary cache.
- FC The thread was unable to translate a data virtual address using the TLB.
- FE The thread has filled a block in the primary data cache with data that were accessed by a *Load* instruction and obtained from a location other than the secondary or tertiary cache.

#### 56:63 **PMC4 Selector** (PMC4SEL)

The value of PMC4SEL specifies the event to be counted by PMC4 as defined below. All values in the range of E0 - FF that are not specified below are reserved.

Hex	Event
-----	-------

- |       |                                    |
|-------|------------------------------------|
| 00    | Disable events. (No events occur.) |
| 01-BF | Implementation-dependent           |
| C0-DF | Reserved                           |

The following events can occur only when random sampling is enabled (MMCR<sub>ASE</sub>=1). The sampling modes corresponding to each event

are listed in parentheses. (The sampling mode is specified in  $MMCR_{ASM}$ .)

- E0 The thread has completed a randomly sampled instruction. (RIS, RLS, RBS)
- E4 The thread was unable to translate a data virtual address using the TLB for a randomly sampled instruction. (RIS, RLS)
- E6 The thread has loaded a randomly sampled instruction from a higher level cache than the tertiary cache. (RIS)
- E8 The thread has filled a block in the primary data cache with data that were accessed by a randomly sampled *Load* instruction and obtained from a location other than the secondary cache. (RIS, RLS)
- EA The threshold event counter has exceeded the number of events corresponding to threshold D (see Table 6). (RIS, RLS, RBS)
- EC The threshold event counter has exceeded the number of events corresponding to threshold H (see Table 6). (RIS, RLS, RBS)

The following events can occur regardless of whether random sampling is enabled.

- F0 The thread has attempted to load data from the primary data cache but no block corresponding to the real address existed.
- F2 A cycle has occurred during which the thread has dispatched one or more instructions.
- F4 A cycle has occurred during which the PURR was incremented when the RUN bit of the thread's CTRL register contained 1.
- F6 The thread has mispredicted either whether or not the branch would be taken, or if taken, the target address of a *Branch* instruction.
- F8 The thread has discarded prefetched instructions.
- FA The thread has completed an instruction when the RUN bit of the thread's CTRL register contained 1.
- FC The thread was unable to translate an instruction virtual address using the TLB, and a new TLB entry corresponding to the instruction virtual address has been written.
- FE The thread has obtained the data for a *Load* instruction from storage that did not reside in any cache.

#### Compatibility Note

In versions of the architecture that precede Version 2.02 the PMC Selector Fields were six bits long, and were split between MMCR0 and MMCR1. PMC1-8 were all programmable.

If more programmable PMCs are implemented in the future, additional MMCRs may be defined to cover the additional selectors.

## 11.4.6 Monitor Mode Control Register 2

Monitor Mode Control Register 2 (MMCR2) is a 64-bit register that contains 9-bit control fields for controlling the operation of PMC1 - PMC6 as shown below.

C1	C2	C3	C4	C5	C6	Res'd.
0 8 9	17 18	26 27	35 36	44 45	53 54	63

**Figure 86. Monitor Mode Control Register 2**

When  $MMCR0_{PMCC} = 0b11$ , fields C1 - C4 control the operation of PMC1 - PMC4, respectively and fields C5 and C6 are ignored by the hardware; otherwise, fields C1 - C6 control the operation of PMC1 - PMC6, respectively. The bit definitions of each  $C_n$  field are as follows, where  $n = 1, \dots, 6$ .

When  $MMCR0_{PMCC}$  is set to 0b10 or 0b11, providing problem state programs read/write access to MMCR2, only the  $FC_nP0$  bits can be accessed. All other bits are not changed when *mtspr* is executed in problem state, and all other bits return 0s when *mfspr* is executed in problem state.

Bit	Description
0	<b>Freeze Counter <math>n</math> in Privileged State</b> ( $FC_nS$ )
0	PM $C_n$ is incremented (if permitted by other MMCR bits).
1	PM $C_n$ is not incremented if $MSR_{HVPR} = 0b00$ .
1	<b>Freeze Counter <math>n</math> in Problem State if <math>MSR_{HV} = 0</math></b> ( $FC_nP0$ )
0	PM $C_n$ is incremented (if permitted by other MMCR bits).
1	PM $C_n$ is not incremented if $MSR_{HVPR} = 0b01$ .

**Programming Note**

Problem state programs need access to this field in order to enable them to individually enable counters when analyzing sections of code. All the other fields will typically be initialized by the operating system.

2 **Freeze Counter *n* in Problem State if  $MSR_{HV}PR=1$**  (FCnP1)

- 0 PMCn is incremented (if permitted by other MMCR bits).
- 1 PMCn is not incremented if  $MSR_{HV}PR=0b11$ .

3 **Freeze Counter *n* while Mark = 1** (FCnM1)

- 0 PMCn is incremented (if permitted by other MMCR bits).
- 1 PMCn is not incremented if  $MSR_{PMM}=1$ .

4 **Freeze Counter *n* while Mark = 0** (FCnM0)

- 0 PMCn is incremented (if permitted by other MMCR bits).
- 1 PMCn is not incremented if  $MSR_{PMM}=0$ .

5 **Freeze Counter *n* in Wait State** (FCnWAIT)

- 0 PMCn is incremented (if permitted by other MMCR bits).
- 1 PMCn is not incremented if  $CTRL_{RUN}=0$ .

**Programming Note**

The operating system is expected to set  $CTRL_{RUN}$  to 0 when the thread is in a “wait state”, i.e., when there is no process ready to run.

6 **Freeze Counter *n* in Hypervisor State** (FCnH)

- 0 PMCn is incremented (if permitted by other MMCR bits).
- 1 PMCn is not incremented if  $MSR_{HV}PR=0b10$ .

Bits 54:63 of MMCR2 are reserved.

### 11.4.7 Monitor Mode Control Register A

Monitor Mode Control Register A (MMCRA) is a 64-bit register as shown below.

**Figure 87. Monitor Mode Control Register A**

MMCRA gives privileged programs the ability to control the sampling process, BHRB filtering, and threshold events.

When  $MMCRO_{PMCC}$  is set to 0b10 or 0b11, providing problem state programs read/write access to MMCRA, the Threshold Event Counter Exponent (TECX) and Threshold Event Counter Multiplier (TECM) fields are read-only, and all other fields return 0s, when *mf spr* is executed in problem state; all fields are not changed when *mts pr* is executed in problem state.

**Programming Note**

Read/write access is provided to MMCRA in problem state (SPR 770) when  $MMCRO_{PMCC} = 0b10$  or  $0b11$  even though no fields can be modified by *mts pr* because future versions of the architecture may allow various fields of MMCRA to be modified in problem state.

The bit definitions of MMCRA are as follows.

Bit(s)	Description
0:25	Problem state access (SPR 770) Reserved
	Privileged access (SPR 770 or 786) Implementation-dependent
26	<b>BHRB Recording Disable (BHRBRD)</b> This field controls whether BHRB entries are written when BHRB recording is enabled by other bits. 0 BHRB entries are written (if enabled by other bits). 1 BHRB entries are not written.
27:31	Problem state access (SPR 770) Reserved
	Privileged access (SPR 770 or 786) Implementation-dependent
32:33	<b>BHRB Instruction Filtering Mode (IFM)</b> This field controls the filter criterion used by the hardware when recording <i>Branch</i> instructions into the BHRB. See Section 11.5. 00 All taken Branch instructions are entered into the BHRB unless prevented by other filtering fields. 01 Only taken calls are entered into the BHRB. Includes direct and indirect: <i>bl, bla, bcl, bcla, bclrl, bcctr, bctarl</i> . 10 Only taken indirect branches (excluding calls) are entered into BHRB: <i>bclr, bcctr, bctar</i> . This translates to all XL-form taken branches with LK=0. 11 Only taken conditional branches: <i>bc, bca, bcl, bcla, bclr, bclrl, bcctr, bcctr, bctar</i> .

**bctarl.** This translates to all B-form or XL-form taken branches except those with the BO field encoded to branch always (BO=0b1z1zz).

**Programming Note**

Filtering mode 10 provides additional filtering for unconditional *Branch* instructions, and for indirect *Branch* instructions only the target address is recorded.

Filtering mode 11 provides additional filtering for instructions that provide a hint or for which the outcome does not depend on the value of the Condition Register.

34:36 **Threshold Event Counter Exponent (TECX)**

This field species the exponent of the threshold event counter value. See Section 11.4.3 for additional information. The maximum exponent supported is at least 5.

37:44 **Threshold Event Counter Multiplier (TECM)**

This field species the multiplier of the threshold event counter value. See Section 11.4.3 for additional information.

**Programming Note**

When MMCR0<sub>PMCC</sub> = 0b10 or 0b11, providing problem-state programs read-write access to MMCR<sub>A</sub>, problem state programs are able to read only the TECX and TECM fields (and are not able to write any fields). The values of these fields are needed during the processing of an event-based branch that occurs due to a counter negative condition for a PMC that was counting “threshold counter exceeded n” events (e.g. MMCR1<sub>PMC1SEL</sub> = 0xE8). Reading these fields enables the application to determine the amount by which the threshold was exceeded. Applications are not given access to other fields, and these other fields must initialized by the operating system.

45:47 **Threshold Event Counter Event (TECE)**

This field specifies the event, if any, that is counted by the threshold event counter. The values and meanings are follows.

Value	Event
000	Disable counting.
001	A cycle has occurred.
010	An instruction has completed.
011	Reserved

All other values are implementation-dependent.

48:51 **Threshold Start Event (TS)**

This field specifies the event that causes the threshold event counter to start counting occurrences of the event specified in the Threshold Event Counter Event (TECE) field. The events only occur if MMCR<sub>A</sub><sub>SE</sub>=1 (random sampling enabled) and one of the sampling modes listed in parenthesis is in effect. (The sampling mode that is currently in effect is specified in MMCR<sub>A</sub><sub>SM</sub>.)

- 0000 Reserved.
- 0001 The thread has randomly sampled an instruction while it is being decoded. (RIS)
- 0010 The thread has dispatched a randomly sampled instruction. (RIS)
- 0011 A randomly sampled instruction has been sent to a facility (e.g. *Branch*, *Fixed Point*, etc.) (RIS, RLS, RBS)
- 0100 The thread has completed a randomly sampled instruction to the point at which it has reported all exceptions it will cause. (RIS, RLS, RBS)
- 0101 The thread has completed a randomly sampled instruction. (RIS, RLS, RBS)
- 0110 The thread has failed to locate data for a randomly sampled *Load* instruction in the primary data cache. (RIS, RLS)
- 0111 The thread has filled a block in the primary data cache with data that were accessed by a randomly sampled *Load* instruction. (RIS, RLS)

The definition of the following values depends on whether the access to MMCR<sub>A</sub> is in problem state or in privileged state.

- Problem state access (SPR 770)
- 1000 - 1111 - Reserved
- Privileged access (SPR 770 or 786)
- 1000 - 1111 - Implementation-dependent

52:55 **Threshold End Event (TE)**

This field specifies the event that causes the threshold event counter to stop counting occurrences of the event specified in the Threshold Event Counter Event (TECE) field. The events only occur if MMCR<sub>A</sub><sub>SE</sub>=1 (random sampling enabled) and one of the sampling modes listed in parenthesis is in effect. (The sampling mode that is currently in effect is specified in MMCR<sub>A</sub><sub>SM</sub>.)

- 0000 Reserved

--	--

63 **Random Sampling Enable (SE)**

- 0 Random sampling is disabled.
- 1 Random sampling is enabled.

See Section 11.4.2.1 for information about random sampling.

### 11.4.8 Sampled Instruction Address Register

The Sampled Instruction Address Register (SIAR) is a 64-bit register.

**Figure 88. Sampled Instruction Address Register**

When a Performance Monitor alert occurs because of an event caused by execution of a randomly sampled instruction, bits 0:61 of the SIAR contain bits 0:61 of the effective address of the instruction if  $SIER_{SIARV} = 1$  and contains an undefined value if  $SIER_{SIARV} = 0$ .

When a Performance Monitor alert occurs because of an event other than an event caused by execution of a randomly sampled instruction, the SIAR contains the effective address of an instruction that was being executed, possibly out-of-order, at or around the time that the Performance Monitor alert occurred.

The instruction located at the effective address contained in the SIAR is called the “sampled instruction”.

Except as described in the next paragraph, the contents of SIAR may be altered by the hardware if and only if  $MMCR0_{PMAE} = 1$ . Thus after the Performance Monitor alert occurs, the contents of SIAR are not altered by the hardware until software sets  $MMCR0_{PMAE}$  to 1. After software sets  $MMCR0_{PMAE}$  to 1, the contents of SIAR are undefined until the next Performance Monitor alert occurs.

If single step or branch tracing is active ( $MSR_{TE} = 0b10$  or  $0b01$ ), the contents of SIAR as used by the Performance Monitor facility are undefined and may change even when  $MMCR0_{PMAE} = 0$ .

**Programming Note**

When the Performance Monitor alert occurs,  $SIER_{AMPPR\_SAMPHV}$  indicates the value of  $MSR_{HV\_PR}$  that was in effect when the sampled instruction was being executed. (The contents of these SIER bits are visible only in privileged state.)

### 11.4.9 Sampled Data Address Register

The Sampled Data Address Register (SDAR) is a 64-bit register.

**Figure 89. Sampled Data Address Register**

When a Performance Monitor alert occurs because of an event caused by execution of a randomly sampled instruction, the SDAR contains the effective address of the storage operand of the instruction if  $SIER_{SDARV} = 1$  and contains an undefined value if  $SIER_{SDARV} = 0$ .

When a Performance Monitor alert occurs because of an event other than an event caused by execution of a randomly sampled instruction, the SDAR contains the effective address of the storage operand of an instruction that was being executed, possibly out-of-order, at or around the time that the Performance Monitor alert occurred. This storage operand may or may not be the storage operand (if any) of the sampled instruction.

The data located at the effective address contained in the SDAR are called the “sampled data.”

Except as described in the next paragraph, the contents of SDAR may be altered by the hardware if and only if  $MMCR0_{PMAE} = 1$ . Thus after the Performance Monitor alert occurs, the contents of SDAR are not altered by the hardware until software sets  $MMCR0_{PMAE}$  to 1. After software sets  $MMCR0_{PMAE}$  to 1, the contents of SDAR are undefined until the next Performance Monitor alert occurs.

If single step or branch tracing is active ( $MSR_{TE} = 0b10$  or  $0b01$ ), the contents of SDAR as used by the Performance Monitor facility are undefined and may change even when  $MMCR0_{PMAE} = 0$ .

### 11.4.10 Sampled Instruction Event Register

The Sampled Instruction Event Register (SIER) is a 64-bit register.

**Figure 90. Sampled Instruction Event Register**

When random sampling is enabled and a Performance Monitor alert occurs because of an event caused by execution of a randomly sampled instruction, the SIER contains information about the sampled instruction. The contents of all fields are valid unless otherwise indicated.

**Programming Note**

A Performance Monitor alert occurs because of an event caused by execution of a randomly sampled instruction if random sampling is enabled and a counter negative condition exists in a PMC that was counting events based on randomly sampled instructions.

When random sampling is disabled or when a Performance Monitor alert occurs because of an event that was not caused by execution of a randomly sampled instruction, the contents of the SIER are undefined.

The contents of SIER may be altered by the hardware if and only if  $MMCR0_{PMAE}=1$ . Thus after the Performance Monitor alert occurs, the contents of SIER are not altered by the hardware until software sets  $MMCR0_{PMAE}$  to 1. After software sets  $MMCR0_{PMAE}$  to 1, the contents of SIER are undefined until the next Performance Monitor alert occurs.

The bit definitions of the SIER are as follows.

0:37 The definition of these bits depends on whether the access to SIER is in problem state or in privileged state.

Problem state access (SPR 768)  
Reserved

Privileged access (SPR 768 or 784)  
Implementation-dependent

38:40 The definition of these bits depends on whether the access to SIER is in problem state or in privileged state.

Problem state access (SPR 768)  
Reserved

Privileged access (SPR 768 or 784)

38 **Sampled MSR<sub>PR</sub>** (SAMP<sub>PR</sub>)  
Value of MSR<sub>PR</sub> when the Performance Monitor alert occurred.

39 **Sampled MSR<sub>HV</sub>** (SAMP<sub>HV</sub>)  
Value of MSR<sub>HV</sub> when the Performance Monitor alert occurred.

40 Reserved

41 **SIAR Valid** (SIARV)

Set to 1 when the contents of the SIAR are valid (i.e., they contain the effective address of the sampled instruction); otherwise set to 0.

42 **SDAR Valid** (SDARV)

Set to 1 when the contents of the SDAR are valid (i.e., they contain the effective address of the sampled instruction); otherwise set to 0.

43 **Threshold Exceeded** (TE)

Set to 1 by the hardware if the contents of the threshold event counter exceeded the maximum value when the Performance Monitor

alert occurred; otherwise set to 0 by the hardware.

44 **Slew Down**

Set to 1 by the hardware if the processor clock was lower than nominal when the Performance Monitor alert occurred; otherwise set to 0 by the hardware.

45 **Slew Up**

Set to 1 by the hardware if the processor clock was higher than nominal when the Performance Monitor alert occurred; otherwise set to 0 by the hardware.

46:48 **Sampled Instruction Type** (SITYPE)

This field indicates the sampled instruction type. The values and their meanings are as follows.

000 The hardware is unable to indicate the sampled instruction type

001 *Load* Instruction

010 *Store* instruction

011 *Branch* Instruction

100 *Floating-Point* Instruction other than a *Load* or *Store* instruction

101 *Fixed-Point* Instruction other than a *Load* or *Store* instruction

110 *Condition Register* or *System Call* instruction

111 *Load And Reserve* or *Store Conditional* Instruction

49:51 **Sampled Instruction Cache Information** (SICACHE)

This field provides cache-related information about the sampled instruction.

000 The hardware is unable to provide any cache-related information for the sampled instruction.

001 The thread obtained the instruction in the primary instruction cache.

010 The thread obtained the instruction in the secondary cache.

011 The thread obtained the instruction in the tertiary cache.

100 The thread failed to obtain the instruction in the primary, secondary, or tertiary cache

101 Reserved

110 Reserved

111 Reserved

52 **Sampled Instruction Taken Branch** (SITAKBR)

Set to 1 if the SITYPE field indicates a *Branch* instruction and the branch was taken; otherwise set to 0.

53 **Sampled Instruction Mispredicted Branch** (SIMISPRED)

- Set to 1 if the SITYPE field indicates a *Branch* instruction and the thread has mispredicted either whether or not the branch would be taken, or if taken, the target address; otherwise set to 0.
- 54:55 **Sampled Branch Instruction Misprediction Information** (SIMISPREDI)
- If SIMISPRED=1, this field indicates how the thread mispredicted the outcome of a *Branch* instruction; otherwise this field is set to 0s.
- 00 The instruction was not a mispredicted *Branch* instruction.
  - 01 The thread mispredicted whether or not the branch would be taken because the contents of the Condition Register differed from the predicted contents.
  - 10 The thread mispredicted the target address of the instruction.
  - 11 Reserved
- 56 **Sampled Instruction Data ERAT Miss (SID-ERAT)**
- When the SITYPE field indicates a *Load* or *Store* instruction, this field is set to 1 if the thread has failed to locate an ERAT entry during data address translation for the sampled instruction and otherwise is set to 0.
- When the SITYPE field does not indicate a *Load* or *Store* instruction, the contents of this field are undefined.
- 57:59 **Sampled Instruction Data Address Translation Information** (SIDAXLATE)
- This field contains information about data address translation for the sampled instruction. If multiple data address translations were performed, the information pertains to the last translation. The values and their meanings are as follows.
- 000 The instruction did not require data address translation.
  - 001 The thread translated the data virtual address using the TLB.
  - 010 A PTEG required for data address translation for the instruction was obtained from the secondary cache.
  - 011 A PTEG required for data address translation for the instruction was obtained from the tertiary cache.
  - 100 A PTEG required for data address translation for the instruction was obtained from storage that did not reside in any cache.
  - 101 A PTEG required for data address translation for the instruction was obtained from a cache on a different multi-threaded processor that resides on the same chip as the thread.
- 110 A PTEG required for data address translation for the instruction was obtained from a cache on a different chip from the thread.
  - 111 Reserved
- 60:62 **Sampled Instruction Data Storage Access Information** (SIDSAI)
- This field contains information about data storage accesses made by the sampled instruction. The values and their meanings are as follows.
- 000 The instruction did not require data address translation.
  - 001 The instruction was a *Read* for which the thread obtained the referenced data from the primary data cache.
  - 010 The instruction was a *Read* for which the thread obtained the referenced data from the secondary cache.
  - 011 The instruction was a *Read* for which the thread obtained the referenced data from the tertiary cache.
  - 100 The instruction was a *Read* for which the thread obtained the referenced data from storage that did not reside in any cache.
  - 101 The instruction was a *Read* for which the thread obtained the referenced data from a cache on a different multi-threaded processor that resides on the same chip as the thread.
  - 110 The instruction was a *Read* for which the thread obtained the referenced data from a cache on a different chip from the thread.
  - 111 The instruction was a *Store* for which the data were placed into a location other than the primary data cache.
- 63 **Sampled Instruction Completed** (SICMPL)
- Set to 1 if the sampled instruction has completed; otherwise set to 0.

### 11.4.11 Other Performance Monitor Registers

SIER2, SIER3 and MMCR3 are 64-bit registers. The contents of these registers are implementation-dependent.

**Programming Note**

Applications are expected to access the contents of SIER2, SIER3 and MMCR3 by means of a privileged service program which will be typically invoked by a system call and which is capable of interpreting the contents of these registers, and returns to the application a generalized summary of the register contents in a form that is not implementation-dependent.

The recommended secure configuration of the Performance Monitor Facility is to disable access to group B Performance Monitor registers in problem state via setting MMCR0<sub>PMCC</sub> and MMCR0<sub>PMCC-CEXT</sub> appropriately, which is congruous to the programming model described above.

## 11.5 Branch History Rolling Buffer

The Branch History Rolling Buffer (BHRB) is described in Chapter 7 of Book II but only at the level required by application programmers. Additional aspects of the BHRB are described here.

In order to enable problem state programs to use the BHRB, MMCR0<sub>BHRBA</sub> must be set to 1 to enable execution of *clbrhb* and *mfbhrbe* instructions in problem state. Additionally, MMCR0<sub>PMCC</sub> must be set to 0b10 or 0b11 to allow problem state programs to read and write the necessary Performance Monitor registers. (See Section 11.4.4.)

If Performance Monitor event-based branching is desired, MMCR0<sub>EBE</sub> must also be set to 1 to enable Performance Monitor event-based branches.

**Programming Note**

Enabling Performance Monitor event-based branching eliminates the need for the problem state program to poll MMCR0<sub>PMAO</sub> in order to determine when a Performance Monitor alert occurs.

The BHRB is written by the hardware only in problem state ( $MSR_{PR}=1$ ), and if and only if  $MMCR0_{PMAE}=1$  and  $MMCR0_{BHRBRD}=0$ . After  $MMCR0_{PMAE}$  has been set to 1 and a Performance Monitor alert occurs,  $MMCR0_{PMAE}$  is set to 0 and the BHRB is not altered by hardware until software sets  $MMCR0_{PMAE}$  to 1 again.

When  $MMCR0_{PMAE}=1$ , *mfbhrbe* instructions return 0s to the target register.

**Programming Note**

*mfbhrbe* instructions return 0s when  $MMCR0_{PMAE}=1$  in order to prevent software from reading the BHRB while it is being written by hardware.

### 11.5.1 BHRB Filtering

When the BHRB is written by hardware, only those *Branch* instructions that meet the filtering criterion specified in  $MMCR0_{IFM}$  and for which the branch was taken are included.

Filtering restricts the type of Branch instructions that are entered into the BHRB. The filtering criteria are defined using the following terminology.

- **Call:** A *Branch* instruction with the LK field set to 1.
- **Return:** A *bclr* instruction with the BH field set to 0s.
- **Jump:** Any *Branch* instruction that is not a call or a return.
- **Conditional Branch:** Any *Branch* instruction other than an I-Form *Branch* instruction, or a B- or XL-Form *Branch* instruction with the BO field set to “branch always.” (See Figure 40 in Book I.)
- **Unconditional Branch:** Any *Branch* instruction other than a conditional branch instruction
- **Indirect Branch:** Any XL-Form *Branch* instruction
- **Direct Branch:** Any B- or I-Form *Branch* instruction. Software is able to prevent various combinations of each of the above types of *Branch* instructions from being entered into the BHRB using the IFM field in MMCR0. (See Section 11.4.7, “Monitor Mode Control Register A”.)

Software is able to prevent various combinations of each of the above types of Branch instructions from being entered into the BHRB using the IFM field in MMCR0. (See Section 11.4.7, “Monitor Mode Control Register A”.)

## Chapter 12. Processor Control

### 12.1 Overview

The Processor Control facility provides a mechanism for the ultravisor or hypervisor to send messages to other threads in the system. Privileged non-hypervisor programs are able to send messages to other threads on the same multi-threaded processor; however if the processor is configured into sub-processors, privileged non-hypervisor programs can only send messages to other threads on the same sub-processor.

### 12.2 Programming Model

Ultravisor-level, hypervisor-level, and privileged-level messages can be sent. Ultravisor-level messages are sent using the *msgsndu* instruction and cause ultravisor-level exceptions when received. Hypervisor-level messages are sent using the *msgsnd* instruction and cause hypervisor-level exceptions when received. Privileged-level messages are sent using the *msgsndp* instruction and cause privileged-level exceptions when received. For all three instructions, the message type and destination threads are specified in a General Purpose Register.

If a message is received by a thread, the exception corresponding to the message type is generated. When the exception is generated, the corresponding interrupt occurs when no higher priority exception exists and the interrupt is enabled ( $MSR_{EE}=1$  for the Directed Privileged Doorbell interrupt,  $MSR_{EE}=1$  or  $MSR_{HV}=0$  for the Directed Hypervisor Doorbell interrupt, and  $MSR_{EE}=1$  or  $MSR_{S_{HV}}_{PR} \neq 0b110$  for the Directed Ultravisor Doorbell interrupt).

A Directed Privileged Doorbell exception remains until the corresponding interrupt occurs, or the exception is cleared by execution of a *mtspr*(DPDES) or *msgclr* instruction.

A Directed Hypervisor Doorbell exception remains until the corresponding interrupt occurs, or the exception is cleared by execution of a *msgclr* instruction.

A Directed Ultravisor Doorbell exception remains until the corresponding interrupt occurs, or the exception is cleared by execution of a *msgclru* instruction.

If a Doorbell exception of a given privilege is present and the corresponding interrupt is pended because  $MSR_{EE}=0$ , additional Doorbell exceptions of that privilege are ignored until the exception is cleared.

### 12.3 Processor Control Registers

#### 12.3.1 Directed Privileged Doorbell Exception State

The layout of the Directed Privileged Doorbell Exception State (DPDES) register is shown in Figure 91.

**Figure 91. Directed Privileged Doorbell Exception State Register**

The DPDES register is a 64-bit register. For  $t < T$ , where  $T$  is the number of threads on the sub-processor (or on the multi-threaded processor if sub-processors are not supported), bit  $63-t$  corresponds to the thread with privileged thread number  $t$ .

The value of bit  $t$  indicates the presence of a Directed Privileged Doorbell exception on the thread with privileged thread number  $t$ . Bit  $t$  is cleared when a Directed Privileged Doorbell interrupt occurs on thread  $t$ .

When the contents of  $DPDES_{63-t}$  change from 0 to 1, a Directed Privileged Doorbell exception will come into existence on privileged thread number  $t$  within a reasonable period of time. When the contents of  $DPDES_{63-t}$  change from 1 to 0, the existing Directed Privileged Doorbell exception, if any, on privileged thread number  $t$ , will cease to exist within a reasonable period of time, but not later than the completion of the next context synchronizing instruction or event on privileged thread number  $t$ .

The preceding paragraph applies regardless of whether the change in the contents of  $DPDES_{63-t}$  is the result a *msgsndp* or *msgclr* instruction or of modification of the DPDES register caused by execution of an *mtspr* (DPDES) instruction.

Bits 0:63- $T$  of the DPDES are reserved.

**Programming Note**

The primary use of the DPDES is to provide the means for the hypervisor to save a [sub-]processor's Directed Privileged Doorbell exception state when the set of programs running on the [sub-]processor is swapped out or moved from one [sub-]processor to another. Since there is no such need for a similar function for the hypervisor or ultravisor, there is no similar register for the hypervisor or ultravisor. Privileged programs are able to read the DPDES in order to poll for Directed Privileged Doorbell exceptions when the corresponding interrupt is disabled ( $MSR_{EE}=1$ ).

## 12.4 Processor Control Instructions

*msgsndu*, *msgsnd*, *msgsndp*, *msgclru*, *msgclr*, and *msgclrp* instructions are provided for sending and clearing messages. *msgsync* is provided to enable the thread that is target of a *msgsndu* or *msgsnd* instruction to ensure that stores performed by the message-sending thread before it executed *msgsndu* or

*msgsnd* have been performed with respect to the target thread. *msgsndp* and *msgclrp* are privileged instructions; *msgsnd*, *msgclr*, and *msgsync* are hypervisor privileged instructions; *msgsndu* and *msgclru* are ultravisor privileged instructions.

### Message Send Ultravisor X-form

msgsndu RB

31	///	///	RB	78	/
0	6	11	16	21	31

```
msgtype ← GPR(RB)32:36
payload ← GPR(RB)37:63
if (msgtype = 0x05) then
    send_msg(msgtype, payload)
```

*msgsndu* sends a message to other threads in the system. The message type and destination thread(s) are specified in RB.

RB

<-Message Payload->					
///	TYPE	B	///	PROCIDTAG	/
0	32	37	39	44	63

**Figure 92. RB Contents for *msgsndu***

The contents of RB are defined below. Bits 37:63 are referred to as the message payload.

#### Field Description

0:31 Reserved

#### 32:36 Type

If Type=0x05, then a Directed Ultravisor Doorbell message is to be sent to the thread(s) specified in the Message Payload field.

All other values of the Type field are reserved; if the instruction is executed with this field set to a reserved value, the instruction is treated as a no-op.

#### 37:38 Broadcast (B)

00 The message is sent to the thread for which PIR<sub>44:63</sub> is equal to the value of the PROCIDTAG field in the message payload.

01 The message is sent to all threads on the same sub-processor as the thread for which PIR<sub>44:63</sub> is equal to the value of the PROCIDTAG field in the message payload.

10 The message is sent to all threads on the same multi-threaded processor as the thread for which PIR<sub>44:63</sub> is equal to the value of the PROCIDTAG field in the message payload.

11 Reserved

39:43 Reserved

#### 44:63 PROCIDTAG

This field indicates the recipient thread(s) as specified in the B field. If this field set to a value that is not the same as bits PIR<sub>44:63</sub> of any thread in the system, then the instruction behaves as if it were a no-op.

The actions taken on receipt of a message are defined in Section 12.2.

This instruction is ultravisor privileged.

#### Special Registers Altered:

None

#### Programming Note

If *msgsndu* is used to notify the receiver that updates have been made to storage, a *sync* should be placed between the stores and the *msgsndu*. See Section 6.9.2.

**Message Clear Ultravisor****X-form**

msgclru RB

0	31	6	///	11	///	16	RB	21	110	31	/
---	----	---	-----	----	-----	----	----	----	-----	----	---

```
t ← hypervisor thread number of executing thread
if (msgtype = 0x05) then
  clear any Directed Ultravisor Doorbell exception
  for thread t
```

**msgclru** clears a message previously accepted by the thread executing the **msgclru**.

Let msgtype be (RB)<sub>32:36</sub>, and let t be the hypervisor thread number of the thread executing the **msgclru** instruction.

If msgtype = 0x05, then clear any Directed Ultravisor Doorbell exception that exists on thread t; otherwise, this instruction is treated as a no-op.

This instruction is ultravisor privileged.

**Special Registers Altered:**

None

**Programming Note**

**msgclru** is typically issued only when MSR<sub>EE</sub>=0. If **msgclru** is executed when MSR<sub>EE</sub>=1 when a Directed Ultravisor Doorbell interrupt is about to occur, the corresponding interrupt may or may not occur.

**Message Send****X-form**

msgsnd RB

0	31	6	///	11	///	16	RB	21	206	31	/
---	----	---	-----	----	-----	----	----	----	-----	----	---

```
msgtype ← GPR(RB)32:36
payload ← GPR(RB)37:63
if (msgtype = 0x05) then
  send_msg(msgtype, payload)
```

**msgsnd** sends a message to other threads in the system. The message type and destination thread(s) are specified in RB.

RB

<-Message Payload->											
0	///					TYPE	B	///	PROCIDTAG		
						32	37	39	44	63	

**Figure 93. RB Contents for msgsnd**

The contents of RB are defined below. Bits 37:63 are referred to as the message payload.

**Field Description**

0:31 Reserved

**32:36 Type**

If Type=0x05, then a Directed Hypervisor Doorbell message is to be sent to the thread(s) specified in the Message Payload field.

All other values of the Type field are reserved; if the instruction is executed with this field set to a reserved value, the instruction is treated as a no-op.

**37:38 Broadcast (B)**

00 The message is sent to the thread for which PIR<sub>44:63</sub> is equal to the value of the PROCIDTAG field in the message payload.

01 The message is sent to all threads on the same sub-processor as the thread for which PIR<sub>44:63</sub> is equal to the value of the PROCIDTAG field in the message payload.

10 The message is sent to all threads on the same multi-threaded processor as the thread for which PIR<sub>44:63</sub> is equal to the value of the PROCIDTAG field in the message payload.

11 Reserved

39:43 Reserved

**44:63 PROCIDTAG**

This field indicates the recipient thread(s) as specified in the B field. If this field set to a

value that is not the same as bits  $PIR_{44:63}$  of any thread in the system, then the instruction behaves as if it were a no-op.

The actions taken on receipt of a message are defined in Section 12.2.

This instruction is hypervisor privileged.

**Special Registers Altered:**

None

**Programming Note**

If *msgsnd* is used to notify the receiver that updates have been made to storage, a *sync* should be placed between the stores and the *msgsnd*. See Section 6.9.2.

**Message Clear**

**X-form**

msgclr RB

31	///	///	RB	238	/
0	6	11	16	21	31

```
t ← hypervisor thread number of executing thread
if(msgtype = 0x05) then
    clear any Directed Hypervisor Doorbell exception
    for thread t
```

*msgclr* clears a message previously accepted by the thread executing the *msgclr*.

Let msgtype be  $(RB)_{32:36}$ , and let t be the hypervisor thread number of the thread executing the *msgclr* instruction.

If msgtype = 0x05, then clear any Directed Hypervisor Doorbell exception that exists on thread t; otherwise, this instruction is treated as a no-op.

This instruction is hypervisor privileged.

**Special Registers Altered:**

None

**Programming Note**

*msgclr* is typically issued only when  $MSR_{EE}=0$ . If *msgclr* is executed when  $MSR_{EE}=1$  when a Directed Hypervisor Doorbell interrupt is about to occur, the corresponding interrupt may or may not occur.

**Message Send Privileged X-form**

msgsndp RB

0	31	6	///	11	///	16	RB	21	142	31
---	----	---	-----	----	-----	----	----	----	-----	----

```

msgtype ← (RB)32:36
payload ← (RB)37:63
t ← (RB)57:63
if msgtype = 5 and
    t ≤ maximum privileged thread number
        on processor or sub-processor
    then
        DPDES63-t ← 1
        send_msg(msgtype, payload, t)
    
```

**msgsndp** sends a message to other threads that are on the same multi-threaded processor (if the processor is not in sub-processor mode) or to other threads that are on the same sub-processor (if the processor is in sub-processor mode). The message type and destination thread(s) are specified in RB.

RB

Message Payload			
0	///	TYPE	TIRTAG
		32	37 39 57 63

**Figure 94. RB Contents for msgsndp**

The contents of RB are defined below. Bits 37:63 are referred to as the message payload.

**Bits Description**

37:56 Reserved

**57:63 TIRTAG**

This message is sent to the thread for which the privileged thread number is equal to contents of the TIRTAG field of the message payload, and one of the following conditions applies.

- for processors that are not partitioned into sub-processors, the thread is sent to the thread on the same multi-threaded processor for which the privileged thread number is equal to the contents of the TIRTAG field of the message payload.
- for processors that are partitioned into sub-processors, the thread is sent to the thread on the same sub-processor for which the privileged thread number is equal to the contents of the TIRTAG field of the message payload.

If **msgsndp** is executed with TIRTAG set to a value greater than the highest privileged thread number on the sub-processor (or on the multi-threaded processor if sub-proces-

sors are not supported), then this instruction behaves as a no-op

The actions taken on receipt of a message are defined in Section 12.2.

This instruction is privileged.

**Special Registers Altered:**  
DPDES

**Programming Note**

If **msgsndp** is used to notify the receiver that updates have been made to storage, a **lwsync** or **sync** should be placed between the stores and the **msgsndp**. See Section 6.9.2.

**Message Clear Privileged****X-form**

msgclrp RB

0	31	///	///	RB	174	/
	6		11	16	21	31

```

msgtype ← (RB)32:36
t ← privileged thread number of executing thread
IF(msgtype = 0x05)
  then
    DPDES63-t ← 0

```

**msgclrp** clears a message previously accepted by the thread executing the **msgclrp**.

Let msgtype be (RB)<sub>32:36</sub>, and let t be the privileged thread number of the thread executing the **msgclrp**.

If msgtype = 0x05, then clear any Directed Privileged Doorbell exception that exists on thread t by setting DPDES<sub>63-t</sub> to 0; otherwise, this instruction is treated as a no-op.

This instruction is privileged.

**Special Registers Altered:**

DPDES

**Programming Note**

**msgclrp** is typically issued only when MSR<sub>EE</sub>=0. If **msgclrp** is executed when MSR<sub>EE</sub>=1 when a Directed Hypervisor Doorbell interrupt is about to occur, the corresponding interrupt may or may not occur.

**Message Synchronize****X-form**

msgsync

0	31	///	///	///	886	/
	6		11	16	21	31

In conjunction with the *Synchronize* and **msgsndu** or **msgsnd** instructions, the **msgsync** instruction provides an ordering function for stores that have been performed with respect to the thread executing the *Synchronize* and **msgsndu** or **msgsnd** instructions, relative to data accesses by other threads that are performed after a Directed Ultravisor Doorbell or Directed Hypervisor Doorbell interrupt has occurred, as described in the *Synchronize* instruction description on p. 1231.

This instruction is hypervisor privileged.

**Special Registers Altered:**

None

**Programming Note**

When used in conjunction with **msgsndu** or **msgsnd**, *Synchronize* with L = 0 or 2 is executed on the thread that will execute the **msgsndu** or **msgsnd**, and **msgsync** is executed on another thread -- typically the thread that is the target of the **msgsndu** or **msgsnd**, but possibly any other thread (partly because the software that services the Directed Ultravisor Doorbell or Directed Hypervisor Doorbell interrupt may ultimately run on a thread other than that which received the exception). The *Synchronize* precedes the **msgsndu** or **msgsnd**; the **msgsync** is executed after the Directed Ultravisor Doorbell or Directed Hypervisor Doorbell interrupt occurs, and precedes all instructions that need to "see" the values stored by the stores that are in set A of the memory barrier created by the *Synchronize*; see Section 6.9.2, "Synchronize Instruction".

## Chapter 13. Synchronization Requirements for Context Alterations

Changing the contents of certain System Registers, the contents of SLB entries, or the contents of other system resources that control the context in which a program executes can have the side effect of altering the context in which data addresses and instruction addresses are interpreted, and in which instructions are executed and data accesses are performed. For example, changing `MSRIR` from 0 to 1 has the side effect of enabling translation of instruction addresses. These side effects need not occur in program order, and therefore may require explicit synchronization by software. (Program order is defined in Book II.)

An instruction that alters the context in which data addresses or instruction addresses are interpreted, or in which instructions are executed or data accesses are performed, is called a *context-altering instruction*. This chapter covers all the context-altering instructions. The software synchronization required for them is shown in Table 7 (for data access) and Table 8 (for instruction fetch and execution).

The notation “CSI” in the tables means any context synchronizing instruction (e.g., *sc*, *isync*, or *rfid*). A context synchronizing interrupt (i.e., any interrupt except non-recoverable System Reset or non-recoverable Machine Check) can be used instead of a context synchronizing instruction. If it is, phrases like “the synchronizing instruction”, below, should be interpreted as meaning the instruction at which the interrupt occurs. If no software synchronization is required before (after) a context-altering instruction, “the synchronizing instruction before (after) the context-altering instruction” should be interpreted as meaning the context-altering instruction itself.

The synchronizing instruction before the context-altering instruction ensures that all instructions up to and including that synchronizing instruction are fetched and executed in the context that existed before the alteration. The synchronizing instruction after the context-altering instruction ensures that all instructions after that synchronizing instruction are fetched and executed in the context established by the alteration. Instructions after the first synchronizing instruction, up to and including the second synchronizing instruction, may be fetched or executed in either context.

If a sequence of instructions contains context-altering instructions and contains no instructions that are affected by any of the context alterations, no software synchronization is required within the sequence.

### Programming Note

Sometimes advantage can be taken of the fact that certain events, such as interrupts, and certain instructions that occur naturally in the program, such as the *rfid* that returns from an interrupt handler, provide the required synchronization.

Because the instructions between the first synchronizing instruction (exclusive) and the second synchronizing instruction (inclusive) may be fetched or executed in either context, if the context alteration affects whether the second synchronizing instruction can be fetched or executed then the context alteration will not necessarily be synchronized in the manner the programmer expected. For example, if the second synchronizing instruction is in a different virtual page from the context-altering instruction, and fetching instructions from this virtual page is prohibited by Virtual Page Class Key Storage Protection, and the context-altering instruction is an *mtiamr* that enables fetching instructions from this virtual page, it is indeterminate whether the second synchronizing instruction will be executed or a [Hypervisor] Instruction Storage interrupt will occur instead.

No software synchronization is required before or after a context-altering instruction that is also context synchronizing or when altering the MSR in most cases (see the tables). No software synchronization is required before most of the other alterations shown in Table 8, because all instructions preceding the context-altering instruction are fetched and decoded before the context-altering instruction is executed (the hardware must determine whether any of these preceding instructions are context synchronizing).

Unless otherwise stated, the material in this chapter assumes a single-threaded environment.

Table 8: Synchronization requirements for instruction fetch and/or execution

**Notes:**

1. The effect of changing the EE bit is immediate, even if the *mtmsr[d]* instruction is not context synchronizing (i.e., even if L=1).

- If an *mtmsr[d]* instruction sets the EE bit to 0, neither an External interrupt, a Decrementer interrupt nor a Performance Monitor interrupt occurs after the *mtmsr[d]* is executed.
- If an *mtmsr[d]* instruction changes the EE bit from 0 to 1 when an External, Decrementer, Performance Monitor or higher priority exception exists, the corresponding interrupt occurs immediately after the *mtmsr[d]* is executed, and before the next instruction is executed in the program that set EE to 1.
- If a hypervisor executes the *mtmsr[d]* instruction that sets the EE bit to 0, a Hypervisor Decrementer interrupt does not occur after *mtmsr[d]* is executed as long as the thread remains in hypervisor state.
- If the hypervisor executes an *mtmsr[d]* instruction that changes the EE bit from 0 to 1 when a Hypervisor Decrementer or higher priority exception exists, the corresponding interrupt occurs immediately after the *mtmsr[d]* instruction is executed, and before the next instruction is executed, provided HDICE is 1.

2. Synchronization requirements for this instruction are implementation-dependent.
3. The PTCR controls all implicit and explicit storage accesses performed by all threads on the processor when the thread is not in hypervisor or ultravisor real addressing mode. Modifying the PTCR requires that the following conditions be achieved on all threads on the processor.
  - the thread is in hypervisor or ultravisor real addressing mode
  - all previous accesses (implicit and explicit) initiated when the thread was not in hypervisor or ultravisor real addressing mode have been performed with respect to all threads
  - no subsequent accesses which require translation have been initiated

4. For data accesses, the context synchronizing instruction before the *slbie*, *slbieg*, *slbia*, *slbmte*, *tlbie*, or *tlbiel* instruction ensures that all preceding instructions that access data storage have completed to a point at which they have reported all exceptions they will cause.

The context synchronizing instruction after the *slbie*, *slbieg*, *slbia*, *tlbie* or *tlbiel* instruction ensures that storage accesses associated with instructions following the context synchronizing instruction will not use the SLB entry(s), TLB entry(s), or implementation-specific lookaside information being invalidated.

5. The notation “*{ptesync,CSI}*” denotes an instruction sequence. Other instructions may be interleaved with this sequence, but these instructions must appear in the order shown.

No software synchronization is required before the *Store* instruction because (a) stores are not performed out-of-order and (b) address translations associated with instructions preceding the *Store* instruction are not performed again after the store has been performed (see Sections 6.5 and 6.10). These properties ensure that all address translations associated with instructions preceding the *Store* instruction will be performed using the old contents of the PTE.

The *ptesync* instruction after the *Store* instruction ensures that all searches of the Page Table that are performed after the *ptesync* instruction completes will use the value stored (or a value stored subsequently). The context synchronizing instruction after the *ptesync* instruction ensures that any address translations associated with instructions following the context synchronizing instruction that were performed using the old contents of the PTE will be discarded, with the result that these address translations will be performed again and, if there is no corresponding entry in any TLB, SLB, page walk cache, cache of Partition or Process Table entries, or implementation-specific address translation lookaside information, will use the value stored (or a value stored subsequently).

6. Additional software synchronization may be required for the use of this instruction in multi-threaded environments and/or when storage management operations such as gathering Reference and Change bit values or changing EA to RA mappings are being performed. For example, it may be necessary to invalidate one or more SLB entries and/or TLB entries on all threads in the system and to be able to determine that the invalidations have completed and that all accesses that used or were associated with the invalidated translations have been performed. This requires using *slbsync* or *tlbsync* in multi-threaded environments, and using *ptesync* in all environments.

Section 6.10 describes the use of *slbie*, *slbieg*, *slbia*, *tlbiel*, *tlbie*, *Store*, and related instructions to maintain the Segment Table and Page Table, in both multi-threaded environments and environments consisting of only a single-threaded processor.

**Programming Note**

In a multi-threaded system, if software locking is used to help ensure that the requirements described in Section 6.10 are satisfied, the **isync** instruction near the end of the lock acquisition sequence (see Section B.2.1.1 of Book II) may naturally provide the context synchronization that is required before the alteration.

7. The alteration must not cause an implicit branch in effective address space. Thus, when changing  $MSR_{SF}$  from 1 to 0, the **mtmsrd** instruction must have an effective address that is less than  $2^{32} - 4$ . Furthermore, when changing  $MSR_{SF}$  from 0 to 1, the **mtmsrd** instruction must not be at effective address  $2^{32} - 4$  (see Section 6.3.2 on page 1189).
8. The alteration must not cause an implicit branch in real address space. Thus the real address of the context-altering instruction and of each subsequent instruction, up to and including the next context synchronizing instruction, must be independent of whether the alteration has taken effect.

**Programming Note**

If it is desired to set  $MSR_{IR}$  to 1 early in an operating system interrupt handler, advantage can sometimes be taken of the fact that  $EA_{0:3}$  are ignored when forming the real address when address translation is disabled and  $MSR_{HV} = 0$ . For example, if address translation resources are set such that effective address  $0xn000\_0000\_0000\_0000$  maps to real address  $0x000\_0000\_0000\_0000$  when address translation is enabled, where  $n$  is an arbitrary 4-bit value, the following code sequence, in real page 0, can be used early in the interrupt handler.

```

la      rx,target
li      ry,0xn000
sldi   ry,ry,48
or      rx,rx,ry # set high-order
                    nibble of target
                    addr to 0xn
mtctr  rx
bcctr  # branch to targ

targ:  mfmsr  rx
       orir  x,rx,0x0020
       mtmsrd rx # set  $MSR_{IR}$  to 1

```

The **mtmsrd** does not cause an implicit branch in real address space because the real address of the next sequential instruction is independent of  $MSR_{IR}$ . Using **mtmsrd**, rather than **rfd** (or similar context synchronizing instruction that alters the control flow), may yield better performance on some implementations.

(Variations on the technique are possible. For example, the target instruction of the **bcctr** can be in arbitrary real page  $P$ , where  $P$  is a 48-bit value, provided that effective address  $0xn \parallel P \parallel 0x000$  maps to real address  $P \parallel 0x000$  when address translation is enabled.)

9. The elapsed time between the contents of the Decrementer or Hypervisor Decrementer becoming negative and the signaling of the corresponding exception is not defined.
10. If an **slbmt** instruction alters the mapping, or associated attributes, of a currently mapped ESID, the **slbmt** must be preceded by an **slbie** (or **slbia**) instruction that invalidates the existing translation. This applies even if the corresponding entry is no longer in the SLB (the translation may still be in implementation-specific address translation lookaside information). No software synchronization is needed between the **slbie** and the **slbmt**, regardless of whether the index of the SLB entry (if any) containing the current translation is the same as the SLB index specified by the **slbmt**.

No *slbie* (or *slbia*) is needed if the *slbmte* instruction replaces a valid SLB entry with a mapping of a different ESID (e.g., to satisfy an SLB miss). However, the *slbie* is needed later if and when the translation that was contained in the replaced SLB entry is to be invalidated.

11. When the URMOR or the HRMOR is modified, software must invalidate all implementation-specific lookaside information used in address translation that depends on the old contents of the register (i.e., the contents immediately before the modification). The *slbia* instruction can be used to invalidate all such implementation-specific lookaside information.
12. A context synchronizing instruction or event that is executed or occurs when  $LPCR_{MER} = 1$  does not necessarily ensure that the exception effects of  $LPCR_{MER}$  are consistent with the contents of  $LPCR_{MER}$ . See Section 2.2.
13. This line applies regardless of which SPR number (13 or 29) is used for the AMR.
14. LPIDR when using HPT translation and  $LPCR_{HR}$  must not be altered when  $MSR_{DR}=1$  or  $MSR_{IR}=1$ ; if they are, the results are undefined.

#### Programming Note

For instruction fetch, the prohibitions above are because of the difficulty of avoiding an implicit branch relative to the value of enabling software to avoid using hypervisor real addressing mode for the operation. For data access, the prohibitions above are to avoid errant (wrongly timed and/or for an incorrect context) speculative translation in support of hardware data prefetching. (The tables used for translation are determined by the partition ID and  $LPCR_{HR}$  is used as a shortcut. See Section 6.7.6 for details.)

15. This line applies to the following Performance Monitor SPRs: PMC1-6, MMCR0, MMCR1, MMCR2, and MMCR3.
16. This line applies to all SPR numbers that access the BESCR (800-803, 806).
17. There are additional software synchronization requirements when an *mtspr* instruction modifies this SPR in a multi-threaded environment. See Section 2.7.
18. As an alternative to a CSI, the execution of an *rfebb* instruction or the occurrence of an event-based branch is sufficient to provide the necessary synchronization.
19. When  $LPCR_{ISL}$  or  $PATE_{PS}$  is modified, software must invalidate all implementation-specific lookaside information used in address translation that depends on the old contents of the field (i.e., the contents immediately before the modification). The *slbia* instruction can be used to invalidate all such implementation-specific lookaside information.
20. If the current contents of LPIDR correspond to a partition that uses Radix Tree translation, there must be an *hwsync* between the last instruction for which the address of an associated storage access was translated using the current contents of LPIDR and a subsequent *mtpidr*, and similarly for PIDR and *mpidr*. For the similar situation when the current contents of LPIDR correspond to a partition that uses HPT translation, no additional synchronization is required preceding *mpidr*, but *ptesync* must be used instead of *hwsync* prior to *mtpidr*, and the thread must be in hypervisor state with address translation disabled when the *ptesync* is executed and must remain in that condition until after the *mtpidr* is executed.

### Programming Note

The preceding requirement permits designs to optimize *tlbie* processing when the LPID and/or PID values specified by the *tlbie* differ from those in the corresponding register on the receiving thread, by ensuring, in software, that all storage accesses, by the receiving thread, for which the address was translated using the current contents of LPIDR and/or PIDR, and all Reference, Change, and Tag Set bit updates associated with address translations, by the receiving thread, that used the current contents of LPIDR and/or PIDR, have been performed with respect to all threads before the contents of these registers are changed.

The more stringent requirements for partitions that use HPT translation are needed in order to prevent a Reference, Change, or Tag Set bit update, that was performed out-of-order, from corrupting a new PTE that was created, by the thread executing the *tlbie*, at the same real address as the PTE that was used for the address translation (performed out-of-order) with which the Reference, Change, or Tag Set bit update was associated, or from being performed entirely in the new PTE. (*hwsync* does not order these updates; *ptesync* does.) The more stringent requirements are not needed for partitions that use Radix Tree translation because for Radix Tree translation Reference and Change bit updates are performed atomically. (If an attempt by hardware to update a Reference or Change bit atomically and out-of-order fails, an [H]DSI or [H]ISI will not occur, because such interrupts do not occur out-of-order.)

If changing the contents of LPIDR and/or PIDR is part of dispatching a new program on the thread, the *hwsync* or *ptesync* just described can, if placed properly, also serve as the *[p]hwsync* or *ptesync* that is required when a new program is dispatched, as described in the first Programming Note in Section 7.4.3. If advantage is taken of this commonality, the stronger of the two required sync variants must be used. E.g., if the current note requires *hwsync* and the Programming Note requires *ptesync*, *ptesync* must be used.

Because for Radix Tree translation addresses can be translated using LPID (PID) value 0 without that value being in LPIDR (PIDR), the optimization described above is not possible for a *tlbie* instruction for which *effR*=1 and either (a) the specified LPID value is 0, or (b) the specified LPID value is equal to the contents of LPIDR and the specified PID value is 0. As a consequence, no *hwsync* is needed before changing the contents of LPIDR or PIDR from 0 to a non-zero value when Radix Tree translation is in use.

21. Changes to values of ENF bits in the HDEXCR and PRO bits in the DEXCR can only affect instruction fetch / execution behavior in a lower privilege state than the privilege state in which the *mtspr* is executed. The requisite *Return From* instruction is sufficient synchronization for such changes.
22. The notation “*{isync, exser}*” denotes an instruction sequence. Other instructions may be interleaved within this sequence, but the specified instructions must appear in the order shown. In contrast to the changes described in the note immediately above, changes to values of HNU and PNH may take effect immediately, making additional software synchronization useful in those cases.

# Power ISA Book I-III Appendices

## Appendix A. Notes on the Removal of Transactional Memory from the Architecture

Facilities that are available in problem state are generally not removed from the architecture because of the potential impact to the code base. Transactional Memory is a special case in that the major operating environments require software to check the availability of the facility prior to using it. In addition, the requirement that every transaction have a failure handler means that any application that uses TM will continue to function on a degenerate TM implementation that simply fails each transaction on the instruction that follows *tbegin*. These two facts enable a minimally-disruptive ecosystem transition to remove TM, even while continuing to provide product features such as live partition migration.

The anticipated system support for the removal of TM uses a *synthetic TM* implementation when the thread is running in “Version 3.0 mode” ( $PCR_{v3.0\ v2.07} = 0b10$ ) or in “Version 2.07 mode” ( $PCR_{v3.0\ v2.07} = 0b11$ ). (See Section 2.5 of Book III.) For partitions running in “Version 3.1 mode” ( $PCR_{v3.0\ v2.07} = 0b00$ ), hypervisor software disables TM by setting  $HFSCR_{58}$  (formerly the Transactional Memory Facility bit) to zero, and then ensures that the thread will always be in Non-transactional state by setting  $MSR_{29:30}$  (formerly the Transaction State field) to  $0b00$  before dispatching the partition. (The latter requirement will be satisfied naturally provided that the hypervisor executes *treclaim* as part of context switch, as required in Versions 2.07B and 3.0C of the architecture.)

Synthetic TM is required in order to provide unrestricted live migration of partitions running in PCR modes that supported TM ( $PCR_{v3.0}=1$ ). The TM architecture allowed for access to TM SPRs and execution of TM instructions even in Non-transactional state, making pure, interrupt-driven emulation too great a performance risk. Instead, processor implementations provide default behaviors for TM-related operations. Each new transaction fails on the instruction after *tbegin*, going immediately to the failure handler. (Failure recording for this special case sets the Failure Persistent bit in TEXASR to reduce the likelihood that software will pointlessly retry the transaction, and also sets the Implementation-specific cause bit in TEXASR. The *tbegin* is not traced, regardless of the contents of  $MSR_{TE}$  and CIABR.) *mtspr* and *mfspr* for TM SPRs have their normal behavior. Most of the other TM

instructions behave as they would have behaved in Non-transactional state -- i.e., just changing CR0 and FXCC. (See Book II Section 5.5 and Book III Section 5.4.4 in Version 3.0C for background on the TM instructions.) These are the behaviors that will be seen by most software. Thus, under synthetic TM, a thread is never productively in Transactional state, and is in Suspended state (actually, synthetic Suspended state) only if the program was migrated, while in Suspended state, from a processor that implements Version 3.0C or Version 2.07B. The handling for applications migrated while in Suspended state is beyond the scope of this explanation. See the implementation’s user manual for details.

The architecture proper portrays TM to be fully removed. The HFSCR is used to disable TM in Version 3.1 mode because it is impractical to give the appearance that TM has been entirely removed. When the thread is in problem state or privileged non-hypervisor state, the deviations from the behavior for complete removal will be what one would expect if TM was implemented but disabled by the HFSCR. The following sections describe deviations in Version 3.1 mode with  $HFSCR_{58}$  set to zero from the behavior if TM was completely removed. The description is somewhat redundant in describing deviations both from the cause and effect points of view. It does not discuss deviations that can happen only in hypervisor state. The hypervisor and ultravisor must not use any resource formerly allocated to TM other than  $HFSCR_{58}$ .

### A.1 Attempted Execution of TM Instructions

Non-privileged TM instructions were encoded using primary opcode 31 with extended opcodes 654, 686, 718, 750, 782, 814, 846, 878, and 910. Privileged TM instructions were encoded using primary opcode 31 with extended opcodes 942 and 1006.

An attempt in privileged non-hypervisor state to execute a TM instruction, or an attempt in problem state to execute a non-privileged TM instruction, will cause a Hypervisor Facility Unavailable interrupt with  $HFSCR_{IC} = 0x05$  indicating that the cause was an attempt to use a TM resource. Since the architecture portrays the

instructions as reserved, a Hypervisor Emulation Assistance interrupt would be expected. The hypervisor's Hypervisor Facility Unavailable interrupt handler must pass the interrupt to the operating system as if the instruction had caused an "Illegal Instruction type Program Interrupt" just as the hypervisor's HEAL handler would.

An attempt in problem state to execute a privileged TM instruction will cause a Privileged Instruction type Program interrupt (because a Privileged Instruction type Program interrupt has higher priority than a Hypervisor Facility Unavailable interrupt). Since the architecture portrays the instructions as reserved, an HEAL would be expected. There is no way for the hypervisor to intercept this interrupt to pass it to the operating system as if the instruction had caused an "Illegal Instruction type Program interrupt". Moreover, there is no easy way for the OS's Program interrupt handler to determine that the instruction that caused the Privileged Instruction type Program interrupt is a TM instruction and then to handle that case as if the instruction were illegal. In the major operating environments the two kinds of error are reported to the application program in a manner that differs only slightly between the two, so this deviation is deemed acceptable.

## A.2 Attempted Access of a TM SPR

The TM SPRs were SPRs 128, 129, and 130, with 131 as a partial alias to 130 for 32-bit software. (They were all non-privileged.)

An attempt in problem state, or in privileged non-hypervisor state when  $LPCR_{EVRT}=1$ , to access a TM SPR will cause a Hypervisor Facility Unavailable interrupt with  $HFSCR_{IC} = 0x05$ . Since the architecture portrays the SPRs as "undefined for the implementation" (see the instruction descriptions for *mtspr* and *mfspr* in Section 5.4.4 of Book III), an HEAL would be expected. The hypervisor's Hypervisor Facility Unavailable interrupt handler must pass the interrupt to the operating system as if the instruction had caused an "Illegal Instruction type Program interrupt" just as the hypervisor's HEAL handler would.

An attempt in privileged non-hypervisor state when  $LPCR_{EVRT}=0$  to access a TM SPR will cause a Hypervisor Facility Unavailable interrupt (with  $HFSCR_{IC} = 0x05$ ). Since the architecture portrays the SPR numbers as undefined, the implementation would be expected to treat the instruction as a no-op. There is no easy way for the hypervisor to determine the interrupt's cause in this case. (The interrupt does not set the HEIR.) The hypervisor's Hypervisor Facility Unavailable interrupt handler should pass the interrupt to the operating system as if the instruction had caused an "Illegal Instruction type Program interrupt" to avoid the complexity of determining its cause.

## A.3 Occurrence of the Hypervisor Facility Unavailable Interrupt with $HFSCR_{IC}=0x05$

A Hypervisor Facility Unavailable interrupt that set  $HFSCR_{IC}$  to  $0x05$  indicated an attempt to execute a TM instruction or to access a TM SPR when  $HFSCR_{58}$  is set to zero. Despite that the architecture no longer includes Transactional Memory, this variant of the Hypervisor Facility Unavailable interrupt will occur in the circumstances described in the previous two sections and should be handled as described there.

## A.4 Occurrence of the TM Bad Thing Type Program Interrupt

A Program interrupt that set  $SRR_{142}$  to 1 indicated a TM Bad Thing type Program interrupt. Despite that the architecture no longer includes Transactional Memory, this variant of Program interrupt will occur as the result of an attempt to set  $MSR_{29:30}$  to a value other than  $0b00$  via an *mtmsrd* or a "return from"-type instruction, including *rfebb*. These bits had indicated the Transaction State. As they are now reserved, the Program interrupt would be unanticipated. Because the connection between the BESC and the MSR bits is especially hard to make without referencing previous versions of the architecture, the forms of *rfebb* that set  $MSR_{29:30}$  to a value other than  $0b00$  are specified to be treated as though the instruction form is invalid. If a Program interrupt occurs from problem state with  $SRR_{142} = 1$ , the Program interrupt handler should treat the offending instruction as an illegal instruction.

## A.5 Failure of Performance Monitor Counters to Count

$MMCR_{047}$  was formerly the Freeze Counters in Non-Transactional State bit. Despite the architecture's portrayal of this bit as reserved, a 1 value in this bit will prevent Performance Monitor Counters from counting their assigned events. Software should set  $MMCR_{047}$  to zero.

## A.6 Behavior of SPR Bits Formerly Related to TM

Aside from handling the bits formerly related to TM as described above, a good general rule is to practice read-modify-write on the containing SPRs for TM-related bits, leaving their values unchanged. Software is generally permitted to write reserved bits with the expectation, in privileged state, of reading back the written value if the bit is implemented in hardware and

with the expectation that the bit will be ignored by hardware. Capriciously setting the relevant bits in SRR1, the CTR, or directly in the MSR may have the result discussed in Section A.4. Beyond this, the deviations take the form of hardware occasionally setting bits, such as the bits that were formerly MSR<sub>TM</sub> and BES-CR<sub>TS</sub>, to zero.

## Appendix B. Illegal Instructions

With the exception of the instruction consisting entirely of binary 0s, the instructions in this class are available for future extensions of the Power ISA; that is, some future version of the Power ISA may define any of these instructions to perform new functions.

The following primary opcodes are illegal.

5

The following primary opcode is used for an instruction prefix.

1

The following primary opcodes have unused extended opcodes. Their unused extended opcodes can be determined from the opcode maps in Appendix D of Book Appendices. All unused extended opcodes are illegal.

4, 6, 19, 30, 3156, , 58, 59, 60, 62, 63

The following primary+extended opcodes have unused expanded opcodes. Their unused expanded opcodes can be determined from the opcode maps in Appendix C of Book Appendices. All unused expanded opcodes are illegal.

### primary / extended opcode

4 / 0b10110\_000001  
 4 / 0b11110\_000001  
 4 / 0b11000\_000010  
 60 / 0b01011\_01000.  
 60 / 0b10101\_1011..  
 60 / 0b11101\_1011..  
 63 / 0b11001\_00100.  
 63 / 0b11010\_00100.  
 63 / 0b10010\_00111.

An instruction consisting entirely of binary 0s is illegal, and is guaranteed to be illegal in all future versions of this architecture.

## Appendix C. Reserved Instructions

The instructions in this class are allocated to specific purposes that are outside the scope of the Power ISA.

The following types of instruction are included in this class.

1. The instruction having primary opcode 0, except the instruction consisting entirely of binary 0s (which is an illegal instruction; see Section 1.7.2, “Illegal Instruction Class” on page 25) and the extended opcode shown below.

**256** Service Processor “Attention”

2. Instructions from the POWER Architecture that have not been included in the Power ISA.
3. Instructions defined in a previous version of the Power ISA that have been removed.
4. Implementation-specific instructions used to conform to the Power ISA specification.
5. Any other implementation-dependent instructions that are not defined in the Power ISA.

## Appendix D. Opcode Maps

This appendix contains opcode maps showing the primary opcodes, extended opcodes, and expanded opcodes.

Table 9 describes the conventions used in the opcode maps.

**Table 9: Opcode Maps Legend**

	<b>po</b> primary opcode (decimal format)
	<b>xop</b> extended or expanded opcode image (binary format) 0 instruction bit corresponding to an extended/expanded opcode bit having value of 0 1 instruction bit corresponding to an extended/expanded opcode bit having value of 1 / reserved instruction bit, must have value of 0, otherwise invalid form . instruction bit corresponding to an operand or control bit, can have a value of either 0 or 1
	<b>book</b> Book instruction defined
	<b>version</b> ISA version instruction introduced
	<b>privilege</b> P privileged instruction HV hypervisor-privileged instruction UV ultravisor-privileged instruction
	<b>format</b> instruction format
	<b>Illegal opcode</b> Opcode having no previous or current assignment, available for future use
	<b>Defined opcode (primary, extended, or expanded)</b> Opcode assigned to a defined instruction
	<b>Primary opcode having an extended opcode field</b> Opcode having extended opcode field used to identify multiple instructions
	<b>Extended opcode having an expanded opcode field</b> Opcode having expanded opcode field used to identify multiple instructions
	<b>Reserved opcode (primary, extended, or expanded)</b> Opcode is not available for future use without careful consideration 1. Opcode corresponds to an instruction defined in a previous version of the architecture that has been subsequently removed from the architecture. The opcode is treated as an illegal opcode. 2. Or, opcode is reserved for implementation-dependent use.  These opcodes will not be assigned a meaning in the Power ISA except after careful consideration of the effect of such assignment on existing implementations.
	<b>Invalid form opcode</b> Opcode corresponding to a defined instruction encoding with one or more reserved opcode bits having a value of 1

**Table 10: Primary Opcode Map for Opcode Space 0 (32-bit instruction encoding) (bits 0-5)**

## Appendix E. Power ISA Instruction Set Sorted by Opcode

This appendix lists all the instructions in the Power ISA, sorted by primary opcode (bits 0-5), then by extended opcode column (bits 26:31, if any), then by extended

opcode row (bits 21:25, if any), then by expanded opcode (bits 11:15, if any).

Figure 95. Power ISA AS Instruction Set Sorted by Opcode (Sheet 30 of 30)

#### 1. Instruction

- / Instruction bit that corresponds to a reserved field, must have a value of 0, otherwise invalid form.
- Instruction bit that corresponds to an operand bit, may have a value of either 0 or 1.
- 0 Instruction bit that corresponds to an opcode bit having a value 0.
- 1 Instruction bit that corresponds to an opcode bit having a value 1.

#### 2. OpenPOWER Compliance Subsets

- X... Instruction included in the Scalar Fixed-Point Compliance subset
- .X.. Instruction included in the Scalar Fixed-Point + Floating-Point Compliance subset.
- ..X. Instruction included in the Linux Compliance subset.
- ...X Instruction included in the AIX Compliance subset.

#### 3. Linux Optional Category

- AMO Instruction part of Atomic Memory Operations category.
- BFP128 Instruction part of Quad-Precision Floating-Point category.
- BHRB Instruction part of Branch History Rolling Buffer category.
- DFP Instruction part of Decimal Floating-Point category.
- EBB Instruction part of Event-Based Branch category.
- MMA Instruction part of Matrix-Multiplication Assist category.

#### 4. Always Optional Category

- MMA Instruction part of Matrix-Multiplication Assist category.

#### 5. Version

- P1 Instruction introduced in POWER Architecture.
- P2 Instruction introduced in POWER2 Architecture.
- PPC Instruction introduced in PowerPC Architecture prior to v2.00.
- v2.00 Instruction introduced in PowerPC Architecture Version 2.00.
- v2.01 Instruction introduced in PowerPC Architecture Version 2.01.
- v2.02 Instruction introduced in PowerPC Architecture Version 2.02.
- v2.03 Instruction introduced in Power ISA Version 2.03.
- v2.04 Instruction introduced in Power ISA Version 2.04.
- v2.05 Instruction introduced in Power ISA Version 2.05.
- v2.06 Instruction introduced in Power ISA Version 2.06.
- v2.07 Instruction introduced in Power ISA Version 2.07.
- v3.0 Instruction introduced in Power ISA Version 3.0.
- v3.0B Instruction introduced in Power ISA Version 3.0B.
- v3.0C Instruction introduced in Power ISA Version 3.0C.
- v3.1 Instruction introduced in Power ISA Version 3.1.

**6. Privilege**

- P Denotes an instruction that is treated as privileged.
- O Denotes an instruction that is treated as privileged or nonprivileged (or hypervisor-privileged for mtspr), depending on the SPR or PMR number.
- PI Denotes an instruction that is illegal in privileged state.
- HV Denotes an instruction that can be executed only in hypervisor state.
- UV Denotes an instruction that can be executed only in ultravisor state.

**7. Mode Dependency.**

Except as described below and in Section 1.10.3, "Effective Address Calculation", in Book I, all instructions are independent of whether the processor is in 32-bit or 64-bit mode.

- CT If the instruction tests the Count Register, it tests the low-order 32 bits in 32-bit mode and all 64 bits in 64-bit mode.
- SR The setting of status registers (such as XER and CR0) is mode-dependent.
- SF=1 The instruction can be executed only in 64-bit mode.

# Appendix F. Power ISA Instruction Set Sorted by Version

This appendix lists all the instructions in the Power ISA, sorted in reverse order by ISA version, then by mnemonic.

Instruction <sup>1</sup>	Book	Compliance Subsets <sup>2</sup>	Linux Optional Category <sup>3</sup>	Always Optional Category <sup>4</sup>	Mnemonic	Version <sup>5</sup>	Privilege <sup>6</sup>	Mode Dep <sup>7</sup>	Page	Name

Figure 96. Power ISA AS Instruction Set Sorted by Version (Sheet 30 of 30)

1. Instruction

- / Instruction bit that corresponds to a reserved field, must have a value of 0, otherwise invalid form.
- Instruction bit that corresponds to an operand bit, may have a value of either 0 or 1.
- 0 Instruction bit that corresponds to an opcode bit having a value 0.
- 1 Instruction bit that corresponds to an opcode bit having a value 1.

2. OpenPOWER Compliance Subsets

- X... Instruction included in the Scalar Fixed-Point Compliance subset
- ..X.. Instruction included in the Scalar Fixed-Point + Floating-Point Compliance subset.
- ..X. Instruction included in the Linux Compliance subset.
- ...X Instruction included in the AIX Compliance subset.

3. Linux Optional Category

- AMO Instruction part of Atomic Memory Operations category.
- BFP128 Instruction part of Quad-Precision Floating-Point category.
- BHRB Instruction part of Branch History Rolling Buffer category.
- DFP Instruction part of Decimal Floating-Point category.
- EBB Instruction part of Event-Based Branch category.
- MMA Instruction part of Matrix-Multiplication Assist category.

4. Always Optional Category

- MMA Instruction part of Matrix-Multiplication Assist category.

5. Version

- P1 Instruction introduced in POWER Architecture.
- P2 Instruction introduced in POWER2 Architecture.
- PPC Instruction introduced in PowerPC Architecture prior to v2.00.
- v2.00 Instruction introduced in PowerPC Architecture Version 2.00.
- v2.01 Instruction introduced in PowerPC Architecture Version 2.01.
- v2.02 Instruction introduced in PowerPC Architecture Version 2.02.
- v2.03 Instruction introduced in Power ISA Version 2.03.
- v2.04 Instruction introduced in Power ISA Version 2.04.
- v2.05 Instruction introduced in Power ISA Version 2.05.
- v2.06 Instruction introduced in Power ISA Version 2.06.
- v2.07 Instruction introduced in Power ISA Version 2.07.
- v3.0 Instruction introduced in Power ISA Version 3.0.
- v3.0B Instruction introduced in Power ISA Version 3.0B.
- v3.0C Instruction introduced in Power ISA Version 3.0C.
- v3.1 Instruction introduced in Power ISA Version 3.1.

**6. Privilege**

- P Denotes an instruction that is treated as privileged.
- O Denotes an instruction that is treated as privileged or nonprivileged (or hypervisor-privileged for mtspr), depending on the SPR or PMR number.
- PI Denotes an instruction that is illegal in privileged state.
- HV Denotes an instruction that can be executed only in hypervisor state.
- UV Denotes an instruction that can be executed only in ultravisor state.

**7. Mode Dependency.**

Except as described below and in Section 1.10.3, "Effective Address Calculation", in Book I, all instructions are independent of whether the processor is in 32-bit or 64-bit mode.

- CT If the instruction tests the Count Register, it tests the low-order 32 bits in 32-bit mode and all 64 bits in 64-bit mode.
- SR The setting of status registers (such as XER and CR0) is mode-dependent.
- SF=1 The instruction can be executed only in 64-bit mode.

## Appendix G. Power ISA Instruction Set Sorted by OpenPOWER Compliance Subset

This appendix lists all the instructions in the Power ISA, sorted by the instruction's OpenPOWER compliancy subset membership, then by mnemonic.

Instruction <sup>1</sup>	Book	Compliance Subsets <sup>2</sup>	Linux Optional Category <sup>3</sup>	Always Optional Category <sup>4</sup>	Mnemonic	Version <sup>5</sup>	Privilege <sup>6</sup>	Mode Dep <sup>7</sup>	Page	Name

Figure 97. Power ISA AS Instruction Set Sorted by Compliance Subset (Sheet 30 of 30)

**1. Instruction**

- / Instruction bit that corresponds to a reserved field, must have a value of 0, otherwise invalid form.
- Instruction bit that corresponds to an operand bit, may have a value of either 0 or 1.
- 0 Instruction bit that corresponds to an opcode bit having a value 0.
- 1 Instruction bit that corresponds to an opcode bit having a value 1.

**2. OpenPOWER Compliance Subsets**

- X... Instruction included in the Scalar Fixed-Point Compliance subset
- .X.. Instruction included in the Scalar Fixed-Point + Floating-Point Compliance subset.
- ..X. Instruction included in the Linux Compliance subset.
- ...X Instruction included in the AIX Compliance subset.

**3. Linux Optional Category**

- AMO Instruction part of Atomic Memory Operations category.
- BFP128 Instruction part of Quad-Precision Floating-Point category.
- BHRB Instruction part of Branch History Rolling Buffer category.
- DFP Instruction part of Decimal Floating-Point category.
- EBB Instruction part of Event-Based Branch category.
- MMA Instruction part of Matrix-Multiplication Assist category.

**4. Always Optional Category**

- MMA Instruction part of Matrix-Multiplication Assist category.

**5. Version**

P1	Instruction introduced in POWER Architecture.
P2	Instruction introduced in POWER2 Architecture.
PPC	Instruction introduced in PowerPC Architecture prior to v2.00.
v2.00	Instruction introduced in PowerPC Architecture Version 2.00.
v2.01	Instruction introduced in PowerPC Architecture Version 2.01.
v2.02	Instruction introduced in PowerPC Architecture Version 2.02.
v2.03	Instruction introduced in Power ISA Version 2.03.
v2.04	Instruction introduced in Power ISA Version 2.04.
v2.05	Instruction introduced in Power ISA Version 2.05.
v2.06	Instruction introduced in Power ISA Version 2.06.
v2.07	Instruction introduced in Power ISA Version 2.07.
v3.0	Instruction introduced in Power ISA Version 3.0.
v3.0B	Instruction introduced in Power ISA Version 3.0B.
v3.0C	Instruction introduced in Power ISA Version 3.0C.
v3.1	Instruction introduced in Power ISA Version 3.1.

**6. Privilege**

P	Denotes an instruction that is treated as privileged.
O	Denotes an instruction that is treated as privileged or nonprivileged (or hypervisor-privileged for mtspr), depending on the SPR or PMR number.
PI	Denotes an instruction that is illegal in privileged state.
HV	Denotes an instruction that can be executed only in hypervisor state.
UV	Denotes an instruction that can be executed only in ultravisor state.

**7. Mode Dependency.**

Except as described below and in Section 1.10.3, "Effective Address Calculation", in Book I, all instructions are independent of whether the processor is in 32-bit or 64-bit mode.

CT	If the instruction tests the Count Register, it tests the low-order 32 bits in 32-bit mode and all 64 bits in 64-bit mode.
SR	The setting of status registers (such as XER and CR0) is mode-dependent.
SF=1	The instruction can be executed only in 64-bit mode.

## Appendix H. Power ISA Instruction Set Sorted by Mnemonic

This appendix lists all the instructions in the Power ISA, sorted by mnemonic.

Instruction <sup>1</sup>	Book	Compliance Subsets <sup>2</sup>	Linux Optional Category <sup>3</sup>	Always Optional Category <sup>4</sup>	Mnemonic	Version <sup>5</sup>	Privilege <sup>6</sup>	Mode Dep <sup>7</sup>	Page	Name

Figure 98. Power ISA AS Instruction Set Sorted by Mnemonic (Sheet 30 of 30)

**1. Instruction**

/	Instruction bit that corresponds to a reserved field, must have a value of 0, otherwise invalid form.
-	Instruction bit that corresponds to an operand bit, may have a value of either 0 or 1.
0	Instruction bit that corresponds to an opcode bit having a value 0.
1	Instruction bit that corresponds to an opcode bit having a value 1.

**2. OpenPOWER Compliance Subsets**

X...	Instruction included in the Scalar Fixed-Point Compliance subset
.X..	Instruction included in the Scalar Fixed-Point + Floating-Point Compliance subset.
..X.	Instruction included in the Linux Compliance subset.
...X	Instruction included in the AIX Compliance subset.

**3. Linux Optional Category**

AMO	Instruction part of Atomic Memory Operations category.
BFP128	Instruction part of Quad-Precision Floating-Point category.
BHRB	Instruction part of Branch History Rolling Buffer category.
DFP	Instruction part of Decimal Floating-Point category.
EBB	Instruction part of Event-Based Branch category.
MMA	Instruction part of Matrix-Multiplication Assist category.

**4. Always Optional Category**

MMA	Instruction part of Matrix-Multiplication Assist category.
-----	--

**5. Version**

P1	Instruction introduced in POWER Architecture.
P2	Instruction introduced in POWER2 Architecture.
PPC	Instruction introduced in PowerPC Architecture prior to v2.00.
v2.00	Instruction introduced in PowerPC Architecture Version 2.00.
v2.01	Instruction introduced in PowerPC Architecture Version 2.01.
v2.02	Instruction introduced in PowerPC Architecture Version 2.02.
v2.03	Instruction introduced in Power ISA Version 2.03.
v2.04	Instruction introduced in Power ISA Version 2.04.
v2.05	Instruction introduced in Power ISA Version 2.05.
v2.06	Instruction introduced in Power ISA Version 2.06.
v2.07	Instruction introduced in Power ISA Version 2.07.
v3.0	Instruction introduced in Power ISA Version 3.0.
v3.0B	Instruction introduced in Power ISA Version 3.0B.
v3.0C	Instruction introduced in Power ISA Version 3.0C.
v3.1	Instruction introduced in Power ISA Version 3.1.

**6. Privilege**

- P Denotes an instruction that is treated as privileged.
- O Denotes an instruction that is treated as privileged or nonprivileged (or hypervisor-privileged for mtspr), depending on the SPR or PMR number.
- PI Denotes an instruction that is illegal in privileged state.
- HV Denotes an instruction that can be executed only in hypervisor state.
- UV Denotes an instruction that can be executed only in ultravisor state.

**7. Mode Dependency.**

Except as described below and in Section 1.10.3, "Effective Address Calculation", in Book I, all instructions are independent of whether the processor is in 32-bit or 64-bit mode.

- CT If the instruction tests the Count Register, it tests the low-order 32 bits in 32-bit mode and all 64 bits in 64-bit mode.
- SR The setting of status registers (such as XER and CR0) is mode-dependent.
- SF=1 The instruction can be executed only in 64-bit mode.
